$dA/dT = 3.679$, which gives $I = 1.50$, and $U_0 = 14800$. This, however, is believed to be less reliable than the results with the more dilute solution. It should be noticed that the more dilute solution, in which the activity of the ions is more nearly proportional to the concentration, shows the higher value of I .

A quite different procedure is sometimes adopted in papers from Nernst's laboratory to prove that $I = 0$. Equation 8 is used (with the term IT missing, which, of course, involves the assumption that $I = 0$), to calculate a numerical value of U_0 from the experimentally determined value of A at one temperature. Then, using this value of U_0 , the numerical value of U is computed by means of Equation 2, and this value is compared with the experimentally determined value of U . But since the exact value of U is often in doubt by many hundred calories a rigid test of the fundamental assumption is not secured. Or the procedure may be reversed by calculating U_0 from U by Equation 2 and then calculating A from Equation 8 (with the term IT missing). In either case the uncertainty in U makes a rigid test impossible.

An examination of Equation 9 shows that U_0 has been eliminated and that, therefore, what is really needed to secure a more direct determination of the value of I is a determination of the temperature coefficient of the free energy. Since electromotive force measurements are, in general, more precise than calorimetric measurements, and since in a comparison of very similar measurements made at slightly different temperatures, systematic errors are largely eliminated, unless these errors have an appreciable temperature coefficient, we conclude that the value of I can best be determined by means of data on the temperature coefficient of the electromotive force of galvanic cells. It is obvious from Equation 9 that an accurate determination of the temperature coefficient is of primary importance in testing the Nernst Heat Theorem.

There still remains the possibility that I might be made equal to zero by a slight change in $\beta\nu$ and a , which would still give calculated values for the specific heats which were within the limit of accuracy of the experimental determinations of specific heats.

In order to test this possibility we assume the $\beta\nu$ and a values for silver and silver iodide to be correct, because these agree with the formula best, and find by trial that, if we assume for iodine $\beta\nu = 143$ and $a = 0.00007$, then the computed value of dA/dT becomes $+4.5$, which makes $I = 0$. Then we compute the atomic heat capacity of iodine from these values, which shows that the computed results differ from the observed by an amount which is many times the experimental error. For example, at 28.3°A , the computed value is 2.31 calories per degree, whereas the observed value is 3.78, at 36.5° , the computed value is 3.14, and the observed

4.17; at 77°, the computed value is 5.07, and the observed value 5.38; at 298° the computed value is 6.21 and the observed 6.64.

We, therefore, conclude that in the present state of our knowledge the variation of heat capacity with the temperature and with the available data on the heat capacities of the substances concerned, the evidence of the case is against the general theorem that $I = 0$ in the case of all reactions between solids.

While the experimental work described in this paper was in progress, there appeared a paper by Ulrich Fischer,¹ describing an experimental study of the same problem, as it was carried out in Nernst's laboratory. Fischer interprets his results as supporting the Nernst Heat Theorem. He found $dA/dT = 2.419$ calories per degree from his cells containing 0.5 *N* KI, $dA/dT = 1.267$ from cells containing $1/3$ *N* KI, and $dA/dT = 1.66$ from cells containing 0.1 *N* KI.

Fischer reports measurements on seven cells containing 0.1 *N* KI at temperatures ranging from 14.2 to 40.2°, the results being best expressed by the equation, $E = 0.6916 + 0.000305 t$.

Fischer's cells were, however, less satisfactory than ours in constancy and reproducibility, the average difference of his 35 measurements from the mean expressed by the above equation being 0.9 millivolts, with a maximum difference of 2.8 millivolts, and 6 out of the 35 readings showing a difference of 2 millivolts or more. Our cells showed variations not more than 0.1 of this, and were about 1 millivolt higher. His cells containing 0.5 *N* KI are even less reproducible, the average deviation from the mean being 1.15 millivolts, and the maximum 5.7 millivolts. Our experience leads us to infer that the cause of this irregularity in Fischer's cells was in the liquid junction. We constructed some cells like Fischer's, and found them not to be reproducible with an accuracy better than 1 millivolt.

Fischer makes no reference to the potential at the boundary of the two solutions, which has a value of about +3.0 millivolts at 0°, and +3.2 millivolts at 25°, thus raising the value of dA/dT .

In applying a correction for osmotic work, Fischer makes an error which makes his value of dA/dT less than it ought to be. He assumes that all the iodine dissolved in potassium iodide solution is present as KI_3 . But, in the stronger solutions ($N/3$ and $N/2$) the existence of higher complexes and the deviations of these solutions from the laws of dilute solutions cannot be safely ignored. Furthermore, an appreciable part of the free iodine is present as I_2 , especially in the 0.1 *N* solution, and, moreover, the amount present as I_2 increases greatly with the tempera-

¹ *Z. anorg. Chem.*, 78, 41 (1912).

ture,¹ so that their neglect of this fact results in an error in their value for the temperature coefficient, dA/dT .

In order to apply this correction accurately, and to make the application of the liquid junction correction possible, a careful study of the conditions in solution of KI saturated with iodine at 13.1°, 23.9° and 35.4° should have been made by Fischer, similar to the work of Bray and Mackay at 25°, and Jones and Hartmann at 0°. An estimate based on these two investigations indicates very clearly that Fischer's rough method of applying the correction has made his temperature coefficient less than one-half of what it should be. In the discussion of Equations 8 and 9, it was pointed out that accuracy in the determination of the temperature coefficient is essential to make a test of the Nernst Heat Theorem of any value.

Summary.

The electromotive force of silver-silver iodide-iodine cells was measured at 0° and 25°.

An improved method of preparing silver-silver iodide electrodes was devised.

An improvement in the constancy and reproducibility of the results was secured when the junction between the solutions around the electrodes was made to occur within a ground-glass joint.

The free energy of formation of silver iodide from silver and iodine is 65.1 kilojoules at 0°, and 66.1 kilojoules at 25°.

These measurements show that the affinity of silver and iodine for each other increases with rising temperature, which makes possible a plausible explanation of the negative coefficient of expansion of silver iodide, and thus supports the analysis of coefficients of expansion based on the Richards' hypothesis of compressible atoms.

The heat of formation of silver iodide is 61.0 kilojoules.

It is shown that the relationships between the properties and thermodynamic constants of silver iodide support many conclusions which Richards drew from his hypothesis of compressible atoms, but that they do not support the second of the assumptions which Nernst applied to these conclusions, commonly known as the Nernst Heat Theorem.

It is shown that the best way to test the Nernst assumptions is by means of accurate determinations of the temperature coefficient of free energy, interpreted by Equation 9.

REV.

RADIOMETRIC MEASUREMENTS OF THE IONIZATION CONSTANTS OF INDICATORS.¹

By E. J. SHAEFFER, M. G. PAULUS AND HARRY C. JONES.

Received February 22, 1915.

The radiometric measurements recorded in this paper were made with a very sensitive radiomicrometer and a grating spectroscope. The spectroscope is well known to the chemist, but its use in connection with the radiomicrometer, has not, as yet, found an extensive application to the study of chemical problems. This is perhaps due in part to the difficulty in constructing a sensitive and easily controlled radiomicrometer. By means of the grating spectroscope and radiomicrometer, it is possible to study quantitatively chemical reactions involving color changes, and even those not involving such changes, if there are absorption bands in the invisible regions of the spectrum. It will be seen that accurate determinations of very small concentrations of colored components in solutions, can be made very rapidly even when two or more such components are present. The structure of the solvent bands, and time reactions, are a few of the many other important chemical problems which may be investigated by means of this radiometric apparatus.

Purpose of this Investigation.—In connection with some problems now under investigation in this laboratory, it was desired to secure accurate measurements of the hydrolysis constants of certain salts. The spectroscope and radiomicrometer suggested the indicator method, which is based on the changes in the transmission of light by solutions of indicators when varying amounts of hydrogen or hydroxyl ion are present. It will be shown that by means of these changes the concentrations of very small amounts of hydrogen and hydroxyl ions can be determined. The method obviously involves a knowledge of the ionization constant of the indicator as an acid or as a base. A comparison of the ionization constants of the indicators obtained by several investigators, showed that the recorded values varied widely, not only with different methods, but with the same method. The results for phenolphthalein in particular, show how inaccurate is our knowledge concerning the ionization constant of that important indicator. Salm² gives the value 8×10^{-10} ; McCoy,³ 0.8×10^{-10} . In many cases the results of an individual investigation vary as much as 300 to 400 per cent. A. A. Noyes⁴ has applied the theory of indicators to volumetric analysis, making use of the ionization constants of the various indicators. He expresses the opinion that our knowledge of the ionization constants of the indicators is for the most part inexact,

¹ This investigation was carried out with the aid of a Grant from the Carnegie Institution of Washington generously awarded to H. C. Jones.

and needs to be supplemented by further careful investigation. Stieglitz,¹ McCoy,² and Salm² have also recognized the importance of such a study. McCoy, Salm, and in particular Noyes and Bjerrum,³ have already applied the indicator constants to some of the more important problems which the chemist must face in titrating weak acids and bases; and they have shown in certain cases the extent of the error involved in such titrations. It will then be readily seen, that it is important to know the ionization constants of the more important indicators, especially of methyl orange and phenolphthalein. In view of these facts, and the value of such ionization constants in many other lines of work involving the use of indicators, it was decided to make a radiometric investigation of this problem. Methyl orange was first studied, and a method was developed through the application of Beer's law, which readily gave the concentration of the yellow azo-base and that of the red quinoid ion. Knowing these values and the hydrogen ion concentration, the hydrolysis constant of methyl orange can be readily calculated. The method employed is different from, and was worked out independently of any other method thus far used in investigating this problem.

Historical.—The results of a number of preliminary investigations on the ionization constants of various indicators were published in 1904. McCoy,⁴ like most of the other investigators who studied this problem, worked colorimetrically, the intensity of the color being judged by the eye. McCoy employed Nessler tubes for this purpose, while others made use of special colorimeters to determine the amount of indicator transformed into its salt by varying amounts of hydrogen or hydroxyl ions. Tables showing roughly the hydrogen ion concentration at which a large number of indicators undergo change in color, have been published by Friedenthal,⁵ Salessky,⁶ Fels,⁷ and Salm.⁸ Nearly all of the early investigators utilized the principle that the ionization constant of an indicator is equal to the hydrogen ion concentration at which it is one-half transformed into its salt. (See Salm² and A. A. Noyes.²) Salessky, and later Salm, determined the concentration of the hydrogen ions at this point by means of the hydrogen electrode. Criticisms showing how inexact most of these methods are will be found in the separate articles. Salm,⁹ referring to the work previous to 1907, says that the investigations have been for the most

part qualitative, and that with few exceptions, the dissociation constants of the indicators are still unknown. Salm made a more careful investigation, employing a satisfactory colorimeter to determine when the indicator was one-half transformed into its salt, and like Salessky obtained the hydrogen ion concentration at this point by means of the hydrogen electrode. The results which he obtained with phenolphthalein illustrate the uncertainty of the values found by his method. Wegscheider¹ proceeded in much the same manner as the others who have used the colorimetric method, and obtained constants for the ionization of phenolphthalein which seem to be in fair agreement with those found by Hildebrand.² Hildebrand's method, involving the use of the spectro-photometer for the estimation of color intensities, is the most exact of all the methods previously employed. His photometric method somewhat resembles the radiometric method which we employed. Rosenstein,³ following essentially the procedure of McCoy, has carried out very carefully a colorimetric investigation of the ionization constant of phenolphthalein, and the effect upon it of neutral salts. He employed the Duboscq type of colorimeter to determine the fraction of the indicator transformed by a known hydrogen ion concentration. As he shows, the ionization constant is equal to the hydrogen ion concentration, times the fraction of the indicator transformed into its salt. When the indicator is a fairly strong electrolyte, *e. g.*, *p*-nitrophenol, its dissociation constant was determined by the conductivity method.

Before we can judge of the absolute value of the results obtained in any radiometric investigation, it is necessary that the radiometric instrument, and the other parts of the apparatus used in connection with it, fulfill several requirements. What these requirements are will be taken up in the discussion of the apparatus which follows. In view of the fact that radiometric apparatus has not been extensively used by chemists, it seems desirable that this be discussed in some detail.

The Radiomicrometer.—The methods employed in the construction of the radiomicrometer and especially of the thermo-junctions, we owe to Prof. A. H. Pfund.⁴ By means of these methods we were able to build a very satisfactory instrument.

The radiomicrometer previously constructed by Guy⁵ was found to be unsatisfactory for use with the grating spectroscope. Its sensibility, according to a recent test, was 2 per sq. mm. of exposed vane, candle and scale being at a meter's distance. The full period of this instrument was,

⁵ Publication of the Carnegie Institution of Washington, No. 190, 30 (1913).

however, very short, it being 8 seconds. His radiomicrometer could have been made about as sensitive as the one constructed for this work, by using a longer and finer quartz fiber, and making the full period about 20 seconds. However, due to the fact that this instrument was not equipped with a compensating junction, and that its drift, due to this cause, had proved so troublesome in the work of the previous year, it was decided to construct a new radiomicrometer.

Briefly, the radiomicrometer consists of a thermo-electric junction attached to a loop of nonmagnetic wire. The whole system is suspended by a quartz fiber in a glass tube. A strong magnetic field surrounds that portion of the tube inclosing the loop of wire. Radiant energy falling upon the blackened junction is converted into electrical energy. In proportion to the amount of energy received by the junction, the suspended system turns through a definite angle in the magnetic field, the loop tending to set itself at right angles to the lines of force. The deflection or turn is given by means of a mirror attached to the suspended system.

The essential parts of the radiomicrometer are shown in the following sketch. Fig. I represents the type of compensating junction which was constructed and used. It is fastened to the loop of copper wire w at c and c' , as shown in Fig. II. To support the loop of wire small glass rods are placed at h and h' . A light mirror is attached to h at m . A quartz fiber, f , is fastened to the end of the glass rod h , and to the brass stopper S . The whole system is then set in the glass tube T , having two windows l and p . The lens l focuses the reflected light from the mirror m , on a glass scale. At p is inserted a plane glass window 1 mm. thick. The beam of light which is to be measured passes through this window before falling on the junction. The magnetic field is placed between l and p .

The wire loop was made of a very fine specimen of No. 36 copper wire, furnished by Leeds and Northrup. Pure nitric acid was used to dissolve the exterior surface of the wire, which was very likely to be contaminated with various magnetic materials. That this wire must have been very pure is shown by the behavior of the completed instrument. As regards purity,

a still better specimen of silver wire was obtained from Weston; but unfortunately none of the junctions attached to this silver wire were sufficiently sensitive for our purpose.

The alloys used for the construction of the thermo-junction were of the composition recommended by Hutchins.¹ Fig. I of the sketch gives an enlarged view of the junction. It will be noticed that it consists of two thermo-electric junctions A and B, which compensate each other. When the same beam of light falls on both junctions, each sends equal amounts of electrical energy through the loop of nonmagnetic wire w , but in opposite directions. Hence, it follows that for exact compensation there should be no turn of the suspended system. In actual operation the beam of light energy which is to be measured is focused on one of the junctions. This arrangement of junctions is quite essential in any sensitive radiomicrometer where a constant zero point is required; and it is only in this way that the effects of temperature changes and stray sources of light can be eliminated.

The two arms represented by a and a' in Fig. I, have the composition 97 parts bismuth and 3 parts antimony. The composition of b is 95 parts bismuth and 5 parts tin. These metals are quite pure and the strips used are very thin. Junction A is formed by sealing strip a to strip b , and junction B is formed by sealing strip b to strip a' . R. and R' are the receiving surfaces, or so-called vanes, cut from very thin tin foil, and soldered to junctions A and B, respectively. These vanes each have an area of four square millimeters, and are coated with lamp black to prevent radiation of light energy. It was found that the action of an acidified solution of antimony chloride on the tin foil produces a black receiving surface. Theoretically, it appears that such a metallic receiving surface should be more effective than lamp black. However, none of the junctions having the antimony receiving surface were sufficiently sensitive to determine whether or not its use is to be preferred to that of lamp black. Greater sensibility can be obtained with a single junction than with a compensating one, since in the former we have but one seal and two metal strips. This follows from the fact that the sensibility of the radiomicrometer is materially increased when the resistance of the junction is made more nearly equal to that of the wire loop. However, the advantages to be derived from the compensating type of junction are well worth the sacrifice in sensibility.

It is very important that the weight of the junction be kept as small as possible, not only to lessen the weight of the suspended system, but especially to reduce the heat capacity of the junction to a minimum. A small heat capacity insures a quick acting suspension, and one which will more rapidly return to the zero point. That the mass of material

¹ *Sill. Journ.*, 48, 226 (1894).

in the junction is very small, can be seen from the fact that the actual weight of one of the completed compensating junctions was 2.9 milligrams.

The quartz fiber¹ was obtained from molten quartz by means of a bow and arrow arrangement. The total length of this fiber is nearly 30 cm. A long fiber materially aids in eliminating vibrations. This is most essential, especially when the work necessitates small deflections. The period and sensibility of the radiomicrometer depend in a large measure on the proper selection of the quartz fiber.

The plane mirror m (Fig. II) is very thin and has an area of about 20 sq. mm. Directly in front of it is the lens l , having a focal length of twelve feet. By means of this arrangement the image of a lamp filament could be sharply focused on a glass scale about twelve feet distant from the mirror; and it is on this scale that the deflections as given by the radiomicrometer are noted.

The torsion-head stopper s , made of brass and tightly ground into the glass tube T , serves the purpose of making adjustment. By means of it, the suspended system can be made to occupy any position in the magnetic field, and the whole system can be raised or lowered without danger of breaking the very fragile suspension. The torsion-head stopper contains a brass rod r and the two screws s_1 and s_2 for making the above adjustments.

The glass tube T in which the whole system is suspended is about 45 cm. in length. To it is attached the lens l previously referred to, and the glass window p , through which the beam of light is directed either to junction A or to junction B.

The glass tube surrounding that portion of the suspended system to which the thermo-junction is attached was insulated from temperature changes and air drafts by a layer of fine lead shot and wool fiber. To prevent stray sources of light and air drafts from reaching the radiomicrometer, it was inclosed in a wooden box covered with painted canvas.

That the image on the scale should remain steady at a focal distance of twelve feet, it is necessary to shield the radiomicrometer very carefully from the usual vibrations of the building. The long quartz fiber aided materially in this respect. Between the leveling stand of the radiomicrometer and the base on which it rested, various insulating materials were introduced at six points to absorb vibrations.

The completed radiomicrometer, candle and scale being at a meter's distance, gave a deflection of 20 cm., the half-period being nearly 10 seconds. In making this determination of the sensibility of the instrument the radiation was passed through a glass window 1 mm. thick, and the tube containing the suspension was not evacuated. Evacuating the tube and passing the radiation through a rock salt window would increase the sensibility about six times, and the period would become somewhat shorter.

¹ Dr. C. W. Hewlett has very kindly supplied us with several satisfactory fibers.

Since the receiving vane has an area of four square millimeters, the sensibility per square millimeter of exposed vane is 5, and the full period 20 seconds. When making this determination, owing to the difficulty of properly shielding the junction not in use but serving as compensator, it is thought that the value of 5 for the sensibility is somewhat low. Practically every junction that was tested showed that the sensibility was approximately one-fourth of the whole period in seconds. The sensibility value as given by the candle has but little meaning, owing to the varying intensity of the light emitted. The light from the Nernst glower burning at 0.8 ampere and 120 volts, dispersed into the visible first order spectrum six inches long at slit s_1 of the spectroscope, gave at $\lambda = 0.95\mu$, a deflection of 250 mm. when focused on the junction of the radiomicrometer. Both slits are 1 mm. in width, and the scale twelve feet from the mirror. Considering the high resolving power of the grating, it will be seen that our radiomicrometer is very satisfactory both as regards sensibility and period. It enabled us to make quantitative measurements of radiant energy from $\lambda = 0.4\mu$ to $\lambda = 2.0\mu$.

For the same source of light energy, the radiomicrometer always gave the same deflection and returned quickly to zero; showing that our efforts to eliminate magnetic materials from the wire loop had been very successful. The conduct of the completed instrument has demonstrated that the suspended system is very free from paramagnetic disturbances. The diamagnetic materials composing the junction were all arranged at right angles to the lines of force of the magnetic field, and in this way diamagnetic disturbances were reduced to a minimum. The use of the radiomicrometer has shown that the heat capacity of the junction is sufficiently low to be within the desired limit. The compensating junction and its insulation from temperature changes practically removed any drift of the zero point. The zero point for weeks at a time would not drift more than 10 cm. on either side of the zero. In case there was any drift during the measurements, it was always very slight and the proper correction could easily be applied. The insulation from vibrations made the reflected beam upon the scale fairly steady, even when there were rather violent disturbances in the building. There is every reason to suppose that the scale could be read to about one-quarter of a millimeter when the building was quiet. Duplicate readings under ordinary conditions nearly always agreed to within 0.5 mm.

The Spectroscope.—The grating spectroscope was designed and built in the Physical Laboratory under the direction of Prof. John A. Anderson. The use of such a spectroscope presents two especially desirable advantages. First, the position of regions of absorption can be very accurately determined; second, due to its high resolving power, the structure of even the very narrow absorption bands and some absorption lines can be

studied in detail. The spectroscope is so constructed that either the photographic plate or any of the radiometric instruments can be used with it. The use of the radiomicrometer enables us to determine not only the actual positions of regions of absorption, but also to make quantitative measurements of the light transmitted by a solution, for a wide range of wave lengths. The deflections of the radiomicrometer give an accurate measure of the relative intensities of the different absorption bands, and of the different parts of the same bands. It will thus be seen that the radiometric method has distinct advantages over the photographic method, which is chiefly useful in determining the positions of regions of absorption and the general characteristics of the visible spectrum as transmitted by the solutions. Moreover, the photographic plate is only sensitive from $\lambda = 0.2\mu$ to $\lambda = 0.76\mu$, whereas, with the radiomicrometer and the apparatus used in this work, quantitative measurements of absorption could be made from $\lambda = 0.4\mu$ to $\lambda = 2.0\mu$, using slits only 1 mm. in width. Considering the high dispersion that could be obtained with the four inch grating, this width of slit gives a very pure spectrum.

The plane four inch grating with which the spectroscope is equipped, was ruled by Anderson; and the ruling is of such a character that a very bright first order spectrum is produced. This is quite essential for radiometric measurements in the visible region of the spectrum. Energy measurements were made in both first order spectra, one being on each side of the central image. The spectrum on one side was found to be somewhat more intense, and therefore this brighter side was used.

If either the intensity of the light source, or the sensitiveness of the radiomicrometer exceeds certain limits, it is possible that light energy from the second order spectrum will vitiate the energy measurements made in the first order spectrum. This will be readily seen if we consider that wave length of light $\lambda = 0.35\mu$ of the second order overlaps wave length of light $\lambda = 0.7\mu$ of the first order, etc. Therefore, it was desired to know if, with a Nernst glower burning at 0.8 amperes and 120 volts, the second order spectrum had sufficient energy to be detected by the radiomicrometer. If such proved to be the case, it would be found necessary to introduce color screens to eliminate the light energy from the second order spectrum. That the first order spectrum can be regarded as pure is shown by the following considerations.

Glass cuts off all wave lengths of light beyond $\lambda = 0.35\mu$. Since the glass in the path of the light is of considerable thickness, the first order spectrum is not contaminated with any light from the second order spectrum as far out as $\lambda = 0.7\mu$ of the first order. A solution of copper sulfate is entirely transparent to all wave lengths of light shorter than $\lambda = 0.6\mu$. A 10 mm. depth of a saturated solution of copper sulfate shows complete absorption beyond $\lambda = 0.6\mu$. Using the above solution

of copper sulfate, radiometric measurements were made from $\lambda = 0.4\mu$ to $\lambda = 1.3\mu$. Beyond $\lambda = 0.6\mu$ the solution of copper sulfate is entirely opaque, and therefore no evidence of light energy from the second order was obtained as far out as $\lambda = 1.3\mu$. It has already been shown that the first order spectrum is pure up to $\lambda = 0.7\mu$, and the above shows that the light from the overlapping second order spectrum does not contain a sufficient amount of energy to be detected by the radiomicrometer as far out in the infra-red as $\lambda = 1.2\mu$ of the first order spectrum. The radiometric measurements of the dissociation constants of the indicators were all made between $\lambda = 0.5\mu$ and $\lambda = 0.6\mu$, and in this region the first order spectrum is absolutely pure.

The drum head which rotated the grating through definite angles is a large one, its diameter being four inches. It is attached to a very carefully constructed screw, so designed that each complete revolution changes the wave length of light falling on the slit by approximately 500 Ångstrom units. The drum contains five hundred divisions, and, all things considered, it is quite probable that the wave length settings are accurate to within one or two Ångstrom units.

The spectroscope is of the Littrow mounting, the same lens serving both as telescope and collimator. It is provided with two four inch lenses made by Brashear. One lens has a focal length of 72 inches and is intended for photographic work. The other, and the one which was used in this work, has a focal length of 30 inches. With this lens, the visible first order spectrum at slit s_2 , has a length of over six inches. Provision has also been made for the mounting of a large glass prism on the grating table, and it is purposed to use this prism when an intense first order spectrum is desired, rather than a spectrum which is widely dispersed. Had we not been successful in constructing a very sensitive radiomicrometer, it would have been necessary to make frequent use of the glass prism.

The spectroscope was placed in a brass box, blackened on the inside, which prevented stray sources of light from reaching the grating. The slits were of the bilateral type.

The calibration curve for the grating and drum head was calculated from the known grating space, by means of the equation:

$$\lambda = 33,866.7 \sin \frac{3000T + 6R}{3500}$$

where T is the number of complete turns of the screw which rotates the grating, and R is the reading on the drum. The calibration was also effected by observing the positions of various mercury, sodium and lithium lines. It was decided that the calculated values are more accurate than the observed; and, accordingly, the dispersion curve based on the calculated values was used.

Source of Light.—A Nernst glower served as the source of light, the electrical energy being supplied by a series of storage batteries. By means of a rheostat, the light intensity could be kept quite uniform. The glower was protected from air drafts by means of a box of asbestos wood. Provision was also made for the mounting of a nitrogen lamp,¹ when it was desired to secure large deflections of the radiomicrometer for wave lengths of light shorter than $\lambda = 0.5\mu$.

The Cells.—A very important part of the equipment is the cells which contain the solutions to be investigated. There are two cells both made as nearly alike as possible. The cell consists of two brass cylinders which closely telescope into one another. One end of each cylinder is closed by a glass plate held in position by Wood's fusible metal. The four glass ends used in the cells are all of the same thickness, *i. e.*, 2 mm. Their surfaces are plane, and are parallel to within five wave lengths of light. It is a difficult problem to set these plates in the brass cylinder with Wood's fusible metal, without warping them and destroying their plane-parallelism. The character of the interference fringes which the plates gave with the mercury arc determined when they were correctly adjusted. A fine thread was "chased" on the outer cylinder. This thread carried a nut which, when turned, raised or lowered the inner cylinder a definite amount. Each complete revolution of this nut changed the distance between the plates by 1 mm. The nut contained 100 divisions, and by means of this arrangement we could readily adjust the depth of the solutions to within less than 0.01 mm. Each cell was then filled with a layer of water 5 mm. in depth, and the deflections given by the radiomicrometer were noted for a light source of uniform intensity throughout the whole region of the spectrum under investigation, namely, from $\lambda = 0.4\mu$ to $\lambda = 2.0\mu$. The deflections should agree with each other very closely for all wave lengths of light, if the cells are optically identical. Having made sure that the cells are optically identical, they were heavily plated with gold to remove any possibility of the solutions attacking the metals of the cell. It is very important to keep the solutions perfectly clear when measurements are being made, and the glass ends must be maintained absolutely clean. The following table shows the optical identity of the two cells. Under Cell A and Cell B are given the actual radiomicrometer deflections for various wave lengths of light (Table I).

Having discussed the principal parts of the apparatus, *viz.*, the radiomicrometer, spectroscope, source of light, and the cells; and having shown how they meet the requirements demanded by work of this character, it is desirable to consider next the general arrangement of the various parts.

¹ Dr. W. R. Whitney of the General Electric Co. very kindly supplied us with two lamps of special design to be used for this purpose.

Arrangement of Apparatus.—The Nernst glower, lenses, prisms and carriage for the cells were mounted on an upright steel standard placed by the side and near the end of the spectroscope next to the radiomicrometer. Parallel light from the Nernst glower was made to pass, by means of a carefully adjusted sliding carriage, first through one cell and then through the other. The two cells could thus be made to occupy the same position in the path of the light. The light transmitted by the solutions contained in the cells was then deflected by means of a right angle prism and focused on the slit of the spectroscope s_1 . Inside of the box inclosing the spectroscope and directly in the rear of slit s_1 , was placed another right angle prism which reflected the light through a four inch lens to the grating. The dispersed light was reflected back through this same lens and focused on the slit of the spectroscope s_2 . The light which emerged through slit s_2 was again brought to a focus on the junction of the radiomicrometer. By turning the drum head of the spectroscope to the proper points, we could then determine quantitatively the light transmitted by any solution for all wave lengths of light between $\lambda = 0.4\mu$ and $\lambda = 2.0\mu$.

The Differential Method.—It was desired to measure the absolute percentage transmission of 20 mm. of solution. This was done by a differential method which eliminated corrections for reflection from the glass ends, and differences in the refractive index of the glass and the solutions. The method of procedure is as follows: Cell A is filled with 21 mm. of solution; cell B with 1 mm. of solution. Light of unvarying intensity I_0 , was then passed through cell A, and the intensity of the transmitted light I_I measured by means of the radiomicrometer. As soon as possible cell B was made to occupy the same position formerly occupied by cell A, and the intensity of its transmitted light I_{II} determined. The deflection produced when cell A was in the path of light, divided by that given when cell B occupied the same position, determines the ab-

solute percentage transmission for 20 mm. of solution; or, in other words, I_I/I_{II} is the value desired. The justification for this procedure is seen from what follows.

If the depth of solution under investigation is l , the intensity of the incident light I_0 , and that of the transmitted light I , we have the following relations for depths of solution l' and l'' .

$$I_I = I_0 e^{-kl'} \quad (a)$$

$$I_{II} = I_0 e^{-kl''} \quad (b)$$

Dividing a by b we get

$$I_I/I_{II} = e^{k(l''-l')} \quad (c)$$

But the actual percentage transmission of the same solution of depth $l' - l'' = l$ is given by

$$I/I_0 = e^{-k(l'-l'')} = e^{-k(l''-l')}, \text{ or } I_I/I_{II} = I/I_0 \quad (d)$$

Theoretical Discussion.—The Ostwald¹ theory of indicators, explaining first the cause of color, and second, the difference in sensitiveness of various indicators towards different acids and bases, has been found to be inadequate. Concerning the latter, which is by far the most important side of the indicator question, the Ostwald interpretation is substantially correct. But in consideration of well known relations between the color and structure of organic compounds, and of the researches of Bernthsen,² Nietzi and Burckhart,³ Hantzsch⁴ and others, it has been found necessary to modify the Ostwald view as to the cause of color. The facts and relations brought out by these investigations have been correlated and interpreted by Stieglitz⁵ in the so-called chromophoric theory of color. A. A. Noyes,⁶ in a quantitative application of the theory of indicators to volumetric analysis, has also fully explained the significance of the chromophoric theory. According to this theory it is necessary to consider an indicator solution as containing a mixture of two tautomeric substances of different structural types. The ionization constants of the two forms and the equilibrium relations between them are such that when the indicator exists as a slightly ionized acid or base, one form is present in greatly predominating quantity. The other form largely predominates when the indicator exists as a highly ionized salt.

Considering phenolphthalein, the ionization constant K_i , according to the Ostwald conception is expressed by the simple equilibrium equation:

¹ *Lehrbuch der all. Chem.*, 1, 799 (1891).

² *Chem. Zeit.*, 1956 (1892); also Friedländer, *Ber.*, 26, 172, 2258 (1893).

³ *Ber.*, 30, 175 (1897).

⁴ *Ibid.*, 32, 583, 3085 (1899).

⁵ *THIS JOURNAL*, 25, 1112 (1903).

⁶ *Ibid.*, 32, 815 (1910).

The chromophoric theory, as Stieglitz¹ has shown, requires two such equations, (a) and (b).

where k is the stability constant expressing the equilibrium relation between the two tautomeric acids. The acid represented by LH is assumed to be a pseudo- or an extremely weak acid; and that by QH is the true acid. Its ionization constant K' is of such a magnitude that the quinoid salt is formed in greatly predominating quantity in the presence of alkalis, the stability constant k acting so as to maintain the equilibrium relation between the two tautomeric acids. The ionization constant for phenolphthalein is the product of the stability constant k , and the ionization constant K' of the acid QH; or combining a and b and incorporating k and K' into K_i we have:

The above equations illustrate the fundamental differences between the two color theories; and accepting the Stieglitz interpretation of K_i according to Equation 2, the theory underlying the calculation of the dissociation constant of methyl orange from radiometric measurements will be discussed.

Methyl orange is in reality a weak base. Noyes² has deduced a general expression for the equilibrium relations of any pair of tautomeric bases and their ions. This deduction involves three fundamental equations. Expressing the equilibrium relation k , between the quinoid and azo-base, it being understood that the symbols represent gram-molecular or gram-ionic concentrations, we have:

The quinoid base and the azo-base are also in equilibrium with their ions according to 4 and 5 —

Multiplying 3 by 4 and adding 5 to the product, we obtain:

¹ *Loc. cit.*

² *THIS JOURNAL*, 32, 818 (1910).

and substituting in the denominator for AzOH its value $\frac{AzOH + QOH}{1 + k}$, it follows that—

$$\frac{Q \times OH + Az \times OH}{AzOH + QOH} = \frac{k \times K_{QOH} + K_{AzOH}}{1 + k} \quad (7)$$

Letting the above equal K_i , we have:

$$\frac{OH(Az + Q)}{AzOH + QOH} = K_i \quad (8)$$

Noyes has called attention to the fact that for a satisfactory two-color indicator such as methyl orange, the sum of the two tautomeric bases ($AzOH + QOH$), must be substantially equal to $AzOH$; and that the sum of the two ions ($Q + Az$) must be substantially identical with Q . It therefore follows:

$$\frac{OH \times Q}{AzOH} = K_i \quad (9)$$

where K_i expresses the equilibrium relations of the two tautomeric bases and their ions, and is substantially the equation derived by Stieglitz.¹

Combining Equation 9 with that of the ion product of water $H \times OH = K_w$, we get:

$$\frac{H \times AzOH}{Q^+} = \frac{K_w}{K_i} = K_{(\text{hydrolysis})} \quad (10)$$

which is in reality the familiar equation of Walker² ($\frac{\text{acid} \times \text{base}}{\text{salt}} = k$).

Having determined the hydrolysis constant according to Equation 10, the ionization constant K_i of methyl orange as a base can readily be obtained. The procedure, then, is to determine by radiometric measurements, the concentrations of Q , H and $AzOH$ in solutions of methyl orange containing varying amounts of these constituents. A method was developed whereby the concentration of the quinoid ions Q in Equation 10 could be determined from the light transmitted by the indicator solutions. The percentage transmissions for these solutions were given by the radiomicrometer deflections. The method will be made clear by the following theoretical considerations applied to methyl orange.

If we consider light to pass through an absorbing solution of depth l , the solvent itself having no absorption, the rate of change of intensity dI is given by

$$dI = -kI dl \quad (11)$$

¹ THIS JOURNAL, 25, 1112 (1903).

² Z. physik. Chem., 4, 324 (1889).

The constant k depends only on the wave length of light and the nature of the absorbing medium. If I_0 denotes the intensity of the incident light, then, when $l = 0$, $I_0 = I = \text{constant}$. Integrating, the intensity of the transmitted light I given by an absorbing solution of depth l and concentration c is—

$$I = I_0 e^{-klc}. \quad (12)$$

If the solution has a second absorbing component, the light transmitted by it will be:

$$I_1 = I_0 e^{-k'l'c'}. \quad (13)$$

Since the total transmission is the product of the separate transmissions, we have for the actual percentage transmission of a solution containing two absorbing components such as methyl orange:

$$I/I_0 = e^{-klc - k'l'c'}; \text{ or } \ln(I/I_0) = -klc - k'l'c'. \quad (14)$$

Since the depth of solution was maintained constant (20 mm.), the above equation becomes—

$$\ln(I/I_0) = -Kc - K'c'. \quad (15)$$

Applying this equation to methyl orange, let c represent the concentration of the quinoid salt or Q in Equation 10, and c' that of the azo-base. If T is the total quantity of methyl orange in solution, then $c' = (T - c)$; or since a dibasic acid was used, *viz.*, sulfuric acid, $c' = (T - 2c)$. When a pure solution of methyl orange is slightly acidified with sulfuric acid, and not all of the azo-base converted into the quinoid salt, both c and c' are present. The light transmitted by such a solution will be:

$$\ln(I/I_0) = -Kc - K'(T - 2c). \quad (16)$$

In a pure aqueous solution of methyl orange, or one containing an excess of alkali, $c = 0$, therefore, Equation 15 reduces to:

$$\ln(I/I_0)' = -K'c' = -K'T. \quad (17)$$

If to a solution of methyl orange sufficient sulfuric acid is added to convert all of the azo-base into the quinoid salt and completely suppress hydrolysis, $c' = 0$, and Equation 15 becomes:

$$\ln(I/I_0)'' = -Kc = -KT/2. \quad (18)$$

From Equations 16, 17 and 18, K and K' can be eliminated, and solving for c we obtain:

$$c = \frac{T[\ln(I/I_0) - \ln(I/I_0)']}{2[\ln(I/I_0)'' - \ln(I/I_0)']}. \quad (19)$$

In the above equation $(I/I_0)'$ is the percentage transmission for the solution of pure methyl orange for some given wave length of light; $(I/I_0)''$ the percentage transmission of the solution containing an excess of acid for the same wave length, and (I/I_0) the percentage transmission for the same wave length of the solution whose quinoid salt concentration c , is to be determined.

Returning now to the fundamental hydrolysis equation for methyl orange previously derived:

$$\frac{H \times AzOH}{Q^+} = \frac{K_w}{K_i},$$

we can readily insert the proper values knowing the total concentration of methyl orange T , and having determined by radiometric means the quinoid salt concentration c . Q is equal to $2c$. $AzOH = c' = T - 2c$.

H is given by $2(T' - c)$, where T' represents the total quantity of acid added. It is assumed that the dissociation of these extremely dilute solutions is practically complete. The sulfonic acid group can have but little effect upon the hydrogen ion concentration, since benzenesulfonic acid¹ is as strong as sulfuric acid, being dissociated at 25° to the extent of 90% for a dilution $v = 32$. As Stieglitz² has pointed out the whole behavior of methyl orange is that of a very weak base, and the elimination of the sodium sulfonate group from it leaves dimethylaniline azobenzene, which shows all the characteristics of methyl orange as an indicator.

It will be noticed from Equation 10 that it is necessary to know the ionization constant for water, before the constant for the indicator can be calculated from its hydrolysis constant. The generally accepted value of K_w at 25° is 1.2×10^{-14} . It was desired to know the value of the constant at 20° , since, unless otherwise stated, it was at this temperature that all measurements were made. Owing to the large value of the heat of ionization of water, the value of its ionization constant is much less at 20° than at 25° . Just what this change is may be calculated from the well known Van't Hoff formula:

$$\ln \frac{K_1}{K_2} = \frac{q}{R} \left(\frac{T_2 - T_1}{T_2 \times T_1} \right) \quad (20)$$

where K_1 and K_2 represent the ionization constants for water at temperatures T_1 and T_2 . R is the gas constant which equals 1.986 calories per degree, and q is the heat of ionization of water or 13,700 calories. Inserting these values in Equation 20, $K_w = 0.81 \times 10^{-14}$ at 20° . This value was used for the calculation of the ionization constants of both methyl orange and phenolphthalein.

Experimental Work on Methyl Orange.—Before discussing the tables showing the results of the calculations based on the above deductions, it will perhaps be of interest to consider a few of the more important results of the preliminary work on methyl orange. Two mother solutions of known concentrations were prepared, the one being methyl orange and the other sulfuric acid. All solutions were made up at 20° , and carefully

¹ Publication of the Carnegie Institution of Washington, No. 170, 128 (1912).

² THIS JOURNAL, 25, 1117 (1903).

purified substances dissolved in conductivity water, were employed in all cases. A number of test solutions were prepared from the mother solutions, all of which contain equal amounts of methyl orange but different amounts of sulfuric acid. The volume of each solution was 100 cc. The solutions thus presented a series of color shades, ranging from yellow to deep red. The percentage transmissions I/I_0 , were taken with a 20 mm. depth of each solution for the same four or five wave lengths of light. The region of the spectrum to be studied is given by the ascending arm of the transmission curve for methyl orange. This region for the above named indicator is between $\lambda = 0.56\mu$ and $\lambda = 0.59\mu$. The radiomicrometer deflections in this region are necessarily small, and certain variations which appear in the data can be explained in a large measure as due to the vibrations of the building, which often prevented accurate readings.

Special attention is called to a solution of methyl orange containing an excess of alkali, and another solution containing an excess of acid. Equation 19 shows that the calculation of c depends not only on the percentage transmission of the solution in question, but also on the percentage transmission for a solution in which all of the methyl orange exists as the azo-base, and one in which all of the indicator has been converted into the quinoid salt. It is thus necessary to know if any alkali must be added to convert all of the methyl orange into the azo-base and to prevent hydrolysis; and also how much acid is required to form the quinoid salt and to completely suppress hydrolysis. Furthermore, the stability of these solutions must be considered.

Table II shows that in a pure aqueous solution of methyl orange, there is no appreciable hydrolysis, and that practically all of the indicator exists as the azo-base. It is, therefore, not necessary to add alkali in determining the value of $(I/I_0)'$ in Equation 19. The volume of all solutions used in Table II was 100 cc. and each solution contained the same amount of methyl orange.

- I Methyl orange in pure water.
- II Methyl orange plus 1 cc. *N* sodium hydroxide.
- III Methyl orange plus 2.5 cc. *N* sodium hydroxide.

TABLE II.
 I/I_0 for depth of solution = 20 mm.

$\lambda = \text{\AA. U.}$	I.	II.	III.
5648	70.3	71.2	70.5
5698	79.3	78.8	79.0
5748	84.6	86.0	84.8
5797	90.0	90.0	88.5
5847	91.4	92.2	90.0

Table III gives results for three solutions of methyl orange, each containing an excess of acid and the same amount of indicator diluted to 100 cc.

- I Methyl orange plus 0.2 cc. concentrated sulfuric acid.
 II Methyl orange plus 0.5 cc. concentrated sulfuric acid.
 III Methyl orange plus 1.0 cc. concentrated sulfuric acid.

TABLE III.
 I/I₀ for depth of solution = 20 mm.

$\lambda = \text{\AA. U.}$	I.	II.	III.
5698	15.2	15.2	16.6
5723	20.2	20.1	20.1
5748	30.7	31.2	31.9
5773	39.5	39.2	38.8
5797	48.7	49.2	48.1
5823	55.0	53.8	55.3
5847	61.4	62.6	63.2

It is obvious from Table III, that 0.2 cc. of the acid is sufficient to convert all of the azo-base into the quinoid salt and to suppress hydrolysis completely.

Stable solutions of methyl orange are given only when the concentration is less than 2×10^{-4} gram molecules per liter. Considerable difficulty was encountered during the preliminary work, owing to the fact that the indicator solutions were more concentrated than the above named limit. Such solutions of methyl orange, especially those containing a large excess of acid and also those with enough acid to give an intense red color, gradually become more transparent on standing. The action of light very greatly accelerates this bleaching process. The solutions most susceptible to the action of light and of time are those containing the greatest amounts of acid. It was found that these solutions could be kept in the dark for four or five hours unchanged, and that as soon as they were exposed to the light, bleaching again took place. Experiments were made which showed that light of the shorter wave lengths was more actinic in increasing the transparency of the solutions than light of longer wave lengths. The addition of ten per cent of ethyl alcohol rendered these solutions fairly stable against the action of light and time. After standing for a day or two, solutions containing an excess of acid often showed the presence of fine crystals. Large amounts of these crystals could be obtained by strongly acidifying a saturated solution of methyl orange. It is thought that the formation of these crystals, very probably helianthine itself, causes the instability of the solutions in question. The obvious procedure to follow was to use more dilute solutions, which were found to be quite stable, and even the solution containing the excess of acid would remain practically unchanged when exposed to the action of light for a short time. However, when the concentration of methyl orange approximated 2×10^{-4} gram-molecules per liter, as is the case for the solutions given in Table IV, the solution containing an excess of acid was prepared last and its percentage transmission measured immediately. The remaining solutions were

kept in the dark until used. It is certain that when such precautions are taken, no appreciable change in transparency could occur before the radiometric measurements were completed. Table III, the concentration of the methyl orange being 1.98×10^{-4} gram-molecules per liter, shows that even the solutions containing an excess of acid can be safely used in this way.

The following shows how accurately small concentrations of hydrogen and hydroxyl ions can be estimated by radiometric measurements. If the percentage transmission for the various solutions be plotted as curves, the abscissas being wave lengths and the ordinates percentage transmissions, it will be noted that with increasing amounts of acid the transmission curve for pure methyl orange is widely displaced towards the red end of the spectrum. The solution curve corresponding to the excess of acid is displaced about 400 Ångstrom units from the curve corresponding to a pure aqueous solution of methyl orange. From the displacements produced by solutions containing known amounts of acid, and the displacement given by a solution containing an unknown amount, the concentration of the unknown amount of acid can be quite accurately and quickly determined. In one case a solution was prepared containing an amount of sulfuric acid unknown to us. The concentration of the acid was determined by the above method, and the value found was 0.00000216 gram per cc. The amount actually present was 0.00000210 gram per cc. Several similar attempts were made and they were quite as successful.

Results with Methyl Orange.—The hydrolysis and ionization constants for methyl orange, recorded in Tables V and VII, are to be regarded as part of the preliminary work. Table IV contains the percentage transmissions for nine solutions of methyl orange prepared in accordance with the scheme given below. The concentration of the mother solutions of methyl orange was 3.973×10^{-4} ; that of the mother solution of sulfuric acid 3.0885×10^{-4} gram-molecules per liter.

SOLUTIONS.

- I 50 cc. methyl orange, diluted to 100 cc.
- II 50 cc. methyl orange, 5 cc. sulfuric acid, diluted to 100 cc.
- III 50 cc. methyl orange, 10 cc. sulfuric acid, diluted to 100 cc.
- IV 50 cc. methyl orange, 15 cc. sulfuric acid, diluted to 100 cc.
- V 50 cc. methyl orange, 20 cc. sulfuric acid, diluted to 100 cc.
- VI 50 cc. methyl orange, 30.9 cc. sulfuric acid, diluted to 100 cc.
- VII 50 cc. methyl orange, 35 cc. sulfuric acid, diluted to 100 cc.
- VIII 50 cc. methyl orange, 1.0 cc. conc. sulfuric acid, diluted to 100 cc.
- IX 50 cc. methyl orange, 2.0 cc. conc. sulfuric acid, diluted to 100 cc.

TABLE IV.

I/I_0 for depth of solution = 20 mm.

λ —Å. U.	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	Average of VIII and IX.
5748	84.6	..	71.9	65.1	57.7	49.1	46.7	9.5	8.4	8.95

5847	91.4	..	84.6	81.4	77.9	70.3	..	35.7	35.7	35.7

Attention is called to the blank spaces appearing in some of the tables. For some solutions and certain wave lengths of light no transmission values were obtained. It was known at the time the measurements were made that certain transmission values were erroneous, due either to variations in the current intensity or to vibrational disturbances. The action of light, as has been previously explained, renders these solutions of methyl orange more transparent, and for this reason it was necessary to complete the reading as soon as possible. This excluded the possibility of remeasuring the percentage transmissions made when conditions were unfavorable for accurate readings.

Table V gives the quinoid salt and azo-base concentrations of each of the above solutions, the hydrolysis constant (K_w/K_i), and the ionization constant K_i of methyl orange as a base.

TABLE V.

Av., 4.5×10^{-4} Av., 1.8×10^{-11}

The calculations of the hydrolysis and ionization constants are based on logarithmic functions; and where the transmission of the solution is nearly complete, a slight variation from the actual percentage transmission will cause a great change in the calculated hydrolysis and ionization constants. If we consider an experimental case where the amount of absorption to be measured is slight, the above can be made quite clear. Solution II in Table IV for wave length of light $\lambda = 5798 \text{ \AA. U.}$ actually gave a percentage transmission of 85.6. Changing the percentage transmission by small amounts, and calculating the value of the hydrolysis and ionization constants from these values, we obtain:

I/I_0	K_w/K_i	K_i	
85.6	6.46×10^{-4}	1.25×10^{-11}	found experimentally
86.0	7.21×10^{-4}	1.12×10^{-11}	
86.6	8.59×10^{-4}	0.94×10^{-11}	

It will thus be seen that changing the percentage transmission by about 1% will cause a variation in the ionization constant of about 25%. When conditions are not satisfactory, it is quite possible that the error in some of the percentage transmissions may be greater than one per cent. Considering these facts, the constants show that the efforts which were made to eliminate errors arising from variations of the current intensity and vibrational disturbances, were fairly successful.

The transmission values given in Table VI are for a much more dilute solution of methyl orange. The concentration of the mother solution of methyl orange was 1.9865×10^{-4} gram-molecules per liter; that of the mother solution of sulfuric acid being 3.0885×10^{-4} gram-molecules per liter.

SOLUTIONS.

- I 50 cc. methyl orange, diluted to 100 cc.
- II 50 cc. methyl orange, 10 cc. sulfuric acid, diluted to 100 cc.
- III 50 cc. methyl orange, 15 cc. sulfuric acid, diluted to 100 cc.
- IV 50 cc. methyl orange, 20 cc. sulfuric acid, diluted to 100 cc.
- V 50 cc. methyl orange, 1 cc. conc. sulfuric acid, diluted to 100 cc.
- VI 50 cc. methyl orange, 0.5 cc. conc. sulfuric acid, diluted to 100 cc.
- VII 50 cc. methyl orange, 0.2 cc. conc. sulfuric acid, diluted to 100 cc.
- VIII 50 cc. methyl orange, 0.5 cc. conc. sulfuric acid, diluted to 100 cc.

5847	95.6	91.7	..	88.2	63.2	62.6	61.4	61.7	62.2

The constants given in Table VII are calculated from the values in Table VI.

The ionization constants for methyl orange, recorded in Tables V and VII, do not by any means represent the most accurate values that can be obtained by this radiometric method. It is necessary that the measurements be made in a region of the spectrum where the light energy is not intense, and, consequently, the deflections of the radiomicrometer are small. The largest deflection that could be obtained for wave lengths of light $\lambda = 0.58\mu$ was 60 mm. It is for this reason that vibrations, and variations in the intensity of the Nernst glower, seriously interfere with the accuracy of the percentage transmissions. The temperature which prevailed at the time these measurements were made was not accurately known. However,

it is certain that it was between 20° and 23° . The constants were calculated for 20° ; therefore, there is good reason to suppose that the real constants are somewhat higher (See Table IX).

Av., 5.8×10^{-4} Av., 1.5×10^{-11}

The transmission values given in Table VIII, were obtained when the temperature at the time of measurement was known to be 20° . The measurements were made at night when the building was fairly free from vibrations. Under these conditions, the scale could be read accurately to 0.25 mm. Except for Solutions II and VI, the current intensity remained very constant. A different mother solution of methyl orange was used, its concentration being 3.054×10^{-4} gram-molecules per liter. The concentration of the mother solution of sulfuric acid was 3.089×10^{-4} gram molecules per liter.

SOLUTIONS.

- I 50 cc. methyl orange, diluted to 100 cc.
- II 50 cc. methyl orange, 10 cc. sulfuric acid, diluted to 100 cc.
- III 50 cc. methyl orange, 15 cc. sulfuric acid, diluted to 100 cc.
- IV 50 cc. methyl orange, 20 cc. sulfuric acid, diluted to 100 cc.
- V 50 cc. methyl orange, 25 cc. sulfuric acid, diluted to 100 cc.
- VI 50 cc. methyl orange, 40 cc. sulfuric acid, diluted to 100 cc.
- VII 50 cc. methyl orange, 0.7 cc. conc. sulfuric acid, diluted to 100 cc.
- VIII 50 cc. methyl orange, 0.8 cc. conc. sulfuric acid, diluted to 100 cc.

The greatest variation from the mean is less than 20%. It has already been shown in one experimental case, that an error of 1 per cent. in the percentage transmission would cause a variation of 25 per cent. in the ionization constant. The determination of the percentage transmissions from which the constants recorded in Table IX are calculated was made under the most favorable conditions. These constants, therefore, more likely represent the true constants of the indicator.

Phenolphthalein.—Regarding phenolphthalein as a monobasic acid, we have from Equation 2:

$$\frac{Q \times H}{LH} = K_i.$$

Dividing this by the ion product of water, it follows that:

$$\frac{\text{LH} \times \text{OH}^-}{\text{Q}^+} = \frac{K_w}{K_i} \quad (21)$$

Phenolphthalein has but one component of absorption, and the application of Beer's Law is much simpler than for methyl orange where there are two components of absorption. A solution of phenolphthalein in pure water is perfectly transparent. The addition of an excess of sodium hydroxide converts all the colorless lactoid molecules into the red quinoid salt, the concentration of which we will represent by c' . Let c be the concentration of the quinoid salt in the phenolphthalein solutions containing ammonium hydroxide and ammonium chloride. Since the depth of solution was maintained constant, we have the two fundamental equations given below:

$$\ln (I/I_0) = -Kc \quad (22)$$

$$\ln (I/I_0)' = -Kc' \quad (23)$$

The constant K is the same in both cases. Dividing 22 by 23 we obtain:

$$\frac{\ln (I/I_0)}{\ln (I/I_0)'} = c/c' \text{ or } c = \frac{c' \times \ln (I/I_0)}{\ln (I/I_0)'} \quad (24)$$

Where $(I/I_0)'$ is the percentage transmission of a solution of phenolphthalein containing an excess of alkali, for some given wave length of light; (I/I_0) that for the solution in which the concentration of the quinoid salt c , is to be determined for the same wave length of light. Knowing then, the amount of phenolphthalein converted into the quinoid salt, LH in Equation 21 is given by $T - c$, where T represents the total amount of phenolphthalein. The hydroxyl ion concentration was varied by the addition of ammonium chloride to ammonium hydroxide.

The value of OH^- to be substituted in the hydrolysis equation for phenolphthalein was obtained from the following equation:

If ammonium chloride and ammonium hydroxide are present in the same solution, the concentration of the NH_4^+ ions is furnished almost entirely by the ammonium chloride. Let S equal the concentration of the salt and B the concentration of the base. We then have for dilute solutions:

$$\frac{S \times \text{OH}^-}{B} = K_b \quad (25)$$

or

$$\text{OH}^- = \frac{K_b \times B}{S} \quad (26)$$

The ionization constant for ammonium hydroxide¹ at 25° is given as 18×10^{-6} . All of the work on phenolphthalein was done at 20°, and reducing the above value to 20°, we obtain from Equation 20, q being equal to 1400 calories, $K_b = 17.4 \times 10^{-6}$.

A pure sample of phenolphthalein was recrystallized from absolute methyl alcohol. A weighed amount of purified phenolphthalein was dissolved in 50 cc. of absolute ethyl alcohol. By means of a small pipet, carefully calibrated, a small volume of this alcoholic solution, say 1.25 cc., could be quite accurately measured. This volume was diluted with conductivity water to 2000 cc. Experiments were made which showed that the effect of this small trace of alcohol was negligible. (See McCoy.²) The ammonia employed for the solution of ammonium hydroxide, was distilled from barium hydroxide to eliminate carbon dioxide. All solutions were prepared with conductivity water at 20°. Special care was taken to prevent carbon dioxide from coming in contact with any of the solutions.

It is well known that an excess of alkali causes a rather rapid fading of solutions of phenolphthalein. Experiments were made which showed that a very slight error would be introduced, if the solutions of phenolphthalein containing an excess of alkali were used directly after being prepared. Filling the cells with the solution, and taking radiometric measurements for five wave lengths of light, required about eight minutes, and during this short space of time, the change in transparency was found to be very slight.

A few of the experiments made with solutions of phenolphthalein containing an excess of alkali are recorded in Table X. All solutions were diluted to 100 cc., and each contained equal amounts of phenolphthalein. A normal solution of sodium hydroxide was used for these experiments. The percentage transmissions given by Solutions I and II are for 0.8 cc. and 1 cc., respectively, of the alkali. The interval which elapsed between the time the solutions were prepared and the last measurement made, was between seven and eight minutes. Measurements were again made with Solution II, fifteen minutes later. The results are recorded under III. By comparing the transmission values, the effect of the bleaching for an interval of fifteen minutes can be noted. Solution IV contained 0.5 cc. alkali, and was kept in the dark nearly a half-hour before being used. Solution V containing 1 cc. of alkali, was used about four hours after being prepared.

Similar experiments were made with solutions of phenolphthalein, partially converted into the quinoid salt, and it was found that such solutions are fairly stable. Very little change in transparency could be detected during the first four or five hours after the solutions were prepared.

The percentage transmissions for these solutions are given in Table XI. The concentrations of the two tautomeric forms, and the hydrolysis and ionization constants calculated from Table XI, are recorded in Table XII.

The series of solutions, the results of which are recorded in Table XIII, were prepared from another solution of phenolphthalein. Its concentration was 4.603×10^{-5} gram-molecules per liter. The concentrations of the ammonium hydroxide and ammonium chloride solutions were the same as for the previous series. It will be noticed that 1 cc. of a solution of ammonium hydroxide was used instead of 2 cc. as in the former case.

SOLUTIONS.

- I 75 cc. phenolphthalein, 1 cc. NH_4OH , 0.5 cc. NH_4Cl , diluted to 100 cc.
- II 75 cc. phenolphthalein, 1 cc. NH_4OH , 1 cc. NH_4Cl , diluted to 100 cc.
- III 75 cc. phenolphthalein, 1 cc. NH_4OH , 2 cc. NH_4Cl , diluted to 100 cc.
- IV 75 cc. phenolphthalein, 1 cc. NH_4OH , 2.5 cc. NH_4Cl , diluted to 100 cc.
- V 75 cc. phenolphthalein, 0.8 cc. $N \text{ NaOH}$, diluted to 100 cc.

The concentration of phenolphthalein is not a factor in the variations of the constants in the different tables. The following shows that it is possible to determine K_i without knowing the concentration of the indicator.

If we consider Equation 21—

$$\frac{\text{LH} \times \text{OH}}{Q^+} = \frac{K_w}{K_i}$$

and, represent the total concentration of phenolphthalein by T , and that of the quinoid salt by Q , we have from Equation 24:

$$\frac{\ln(I/I_0) \times T}{\ln(I/I_0)'} = Q.$$

LH is then equal to $(T - Q)$ or,

$$LH = (T - Q) = T - \frac{\ln (I/I_o) \times T}{\ln (I/I_o)'} \quad (27)$$

Substituting these values in the hydrolysis equation, we have:

$$\frac{\left[T - \frac{\ln (I/I_o) \times T}{\ln (I/I_o)'} \right] \times \overline{OH}}{\frac{\ln (I/I_o) \times T}{\ln (I/I_o)'}} = \frac{K_w}{K_i} \quad (28)$$

Simplifying, T , the concentration of the phenolphthalein disappears, and we have:

$$\frac{\overline{OH} [\ln (I/I_o)' - \ln (I/I_o)]}{\ln (I/I_o)} = \frac{K_w}{K_i} \quad (29)$$

K_i , calculated from Equation 29, gives the same value as when calculated from the equations previously derived.

Since it is not necessary to know the concentration of the indicator to determine its ionization constant, the variation of K_i , shown by the different tables, must be due to other causes. It will be noticed from the separate tables that K_i decreases with the hydroxyl ion concentration. This is in accordance with the results of previous investigators. When the hydroxyl ion concentration, or the ratio of ammonium chloride to ammonium hydroxide remains the same, K_i shows a marked decrease with decreasing amounts of neutral salts. If we consider Solutions III and I in Tables XII and XVI, respectively, it will be seen that decreasing the concentration of the neutral salt four times, changes K_i from 1.6×10^{-10} to 0.9×10^{-10} . This is in accord with the results of Rosenstein,¹ who has made a very careful study of the effect of neutral salts on the ionization constant of phenolphthalein. It will, therefore, be seen that the discrepancies in the value of K_i are due in part at least to the effect of the neutral salt. From this it might be concluded that K_i would be largest for those solutions containing the greatest amount of neutral salt. A study of the separate Tables, Table XII for instance, shows that just the reverse is true. The solution which contains the largest amount of neutral salt always gives the smallest concentration of hydroxyl ions, and the K_i value for such a solution is much lower than for a solution containing less neutral salt but a greater concentration of hydroxyl ions. It is thus evident that K_i varies not only with the concentration of the neutral salt, but also with the concentration of the hydroxyl ions. From the above, it will be seen that if the neutral salt had no effect, the variation of K_i in the separate tables would be much greater than it actually is. It is therefore obvious that the equilibrium equations, based on the assumption that phenolphthalein acts as a monobasic acid, do not hold.

¹ *Loc. cit.*

Wegscheider¹ concludes that these variations may be accounted for by regarding phenolphthalein as a dibasic acid. The results of Rosenstein¹ make it appear very probable that this indicator does act as a dibasic acid. The limitations of his method and the presence of neutral salts made it impossible for him to determine satisfactorily the ionization constant for phenolphthalein and the question must therefore be regarded as still open.

The radiometric method has thus far been applied for determining the hydrolysis and ionization constants of indicators. Knowing these values, it is possible, by radiometric means, to determine from them the hydrolysis constants of many salts. The calculation of the ionization constants of weak acids and bases formed by the hydrolysis of these salts is then a simple matter.

This method has been applied in a preliminary way to aluminum sulfate, using methyl orange as the indicator. It is assumed that the secondary and tertiary hydrolysis of this salt can be neglected, and, on this assumption, the ionization constant of the base formed by the primary hydrolysis has been calculated.

The calculations of the constants are based on two fundamental equilibrium equations, the symbols representing gram-ions per liter. Expressing the equilibrium relation for the primary hydrolysis of aluminum sulfate, we have:

$$\frac{\overset{++}{\text{AlOH}} \times \overset{+}{\text{H}}}{\overset{+++}{\text{Al}}} = \frac{K_w}{K_b} \quad (30)$$

In the hydrolysis equation for methyl orange,—

$$\frac{\text{AzOH} \times \overset{+}{\text{H}}}{\overset{+}{\text{Q}}} = \frac{K_w}{K_i}$$

K_i has been determined and K_w is known. The concentration of the quinoid ions $\overset{+}{\text{Q}}$ is given by:

$$\overset{+}{\text{Q}} = \frac{\overset{+}{\text{T}} [\ln (\overset{+}{\text{I}}/\overset{+}{\text{I}_0}) - \ln (\overset{+}{\text{I}}/\overset{+}{\text{I}_0})']}{\ln (\overset{+}{\text{I}}/\overset{+}{\text{I}_0})'' - \ln (\overset{+}{\text{I}}/\overset{+}{\text{I}_0})'} \quad (31)$$

as explained in Equation 19. If the total amount of indicator is $\overset{+}{\text{T}}$, $\text{AzOH} = \overset{+}{\text{T}} - \overset{+}{\text{Q}}$. We then have all the data necessary for the calculation of the hydrogen ion concentration in Equation 30. The concentration of the ion $\overset{++}{\text{AlOH}}$ in the same equation is given by $\overset{+}{\text{H}} + \overset{+}{\text{Q}}$, both of which have been determined. If $\overset{+++}{\text{T'}}$ represents the total salt added and α its dissociation, $\overset{+++}{\text{Al}}$ is $(\overset{+++}{\text{T'}} - \overset{++}{\text{AlOH}}) \alpha$.

¹ *Loc. cit.*

The following solutions were prepared from mother solutions of methyl orange and aluminium sulfate, the concentrations being 1.9865×10^{-4} and 0.391 gram-molecules per liter, respectively.

SOLUTIONS.

- I 50 cc. methyl orange, diluted to 100 cc.
- II 50 cc. methyl orange, 5 cc. $\text{Al}_2(\text{SO}_4)_3$, diluted to 100 cc.
- III 50 cc. methyl orange, 7 cc. $\text{Al}_2(\text{SO}_4)_3$, diluted to 100 cc.
- IV 50 cc. methyl orange, 10 cc. $\text{Al}_2(\text{SO}_4)_3$, diluted to 100 cc.
- V 50 cc. methyl orange, 0.5 cc. conc. H_2SO_4 , diluted to 100 cc.

The percentage transmissions given by these solutions are recorded in Table XVII.

TABLE XVII.

I/I ₀ for depth of solution = 20 mm.

¹ Publication of the Carnegie Institution of Washington, No. 170, 60 (1912).

Summary.

A satisfactory radiomicrometer, having a half-period of 10 seconds and a sensibility of 5 per square millimeter of exposed vane (candle and scale being at a meter's distance) was constructed.

Making use of the radiomicrometer and the grating spectroscope, a radiometric method was worked out for the determination of the ionization constants of indicators. This method is freer from objections and limitations than any method previously used. It serves as well for a two-colored indicator as for a one-colored indicator.

Very small concentrations of colored components were determined, and it has been shown that minute concentrations of hydrogen and hydroxyl ions can be quickly and accurately estimated by means of radiometric measurements.

Satisfactory constants were obtained for the ionization of methyl orange as a base. The value found is 2.1×10^{-11} .

The ionization and hydrolysis constants for phenolphthalein considered as a monobasic acid are far from being satisfactory.

From the known ionization constant of methyl orange and from radiometric measurements, the ionization constant of a very weak base and the hydrolysis constant of one of its salts have been roughly determined. The method can likewise be applied for the determination of the ionization constants of very weak acids, and the hydrolysis constants of the salts formed by these acids. Work is now in progress in this laboratory on other indicators, from this same standpoint, and the results will soon be published in THIS JOURNAL.

THE FRACTIONAL CRYSTALLIZATION OF THE PICRATES OF THE RARE EARTHS OF THE DIDYMIUM GROUP.

By L. M. DENNIS AND F. H. RHODES.

Received February 13, 1913.

The salts of the rare earths with picric acid form well-defined crystals, are much more soluble in hot water than in cold, and crystallize very well from solution. For these reasons, the fractional crystallization of the picrates naturally suggests itself as a method for the separation of the rare earths. Holmberg¹ made a brief examination of this method in the attempt to separate the earths of the terbium group. By the fractional crystallization of the picrates of gadolinium and terbium containing 25 g. of the earths he obtained a rapid concentration of terbium in the first mother liquors and an accumulation of gadolinium in the crystals which

¹ *Z. anorg. Chem.*, 53, 80 (1907).

separated first from the solution. James¹ tried to purify thulium by the fractional crystallization of the picrates, but found that the method is not satisfactory for this purpose.

The work of Holmberg and of James on the fractional crystallization of the picrates was done with small amounts of material and with rare earth mixtures that contained unusual components, and was more or less incidental to other researches. The applicability of the method to the general problem of the separation of the rare earths was investigated systematically for the first time by Dennis and Bennett,² who fractionated a mixture of the picrates of the didymium, erbium, and yttrium groups containing about 1500 g. of the oxides. Fractional crystallization of the neutral solution of the picrates of this material yielded a series of twenty-five final fractions. They determined the atomic weights of the earths in these final fractions and made a comparative study of the absorption spectra of solutions of the chlorides of the earths. They summarized their results as follows:

"... with an original material of an atomic weight of 116, containing earths of the didymium, erbium, and yttrium groups, fractional crystallization of the picrates from aqueous solution yields the following results:

"(1) A concentration of praseodymium and neodymium in the first fractions followed by a rapid decrease of these two elements after the sixth fraction.

"(2) A peculiar increase in the amounts of praseodymium and neodymium in the tenth and nineteenth fractions.

"(3) A sudden concentration of erbium and holmium in the eighth fraction and an entire absence of these two elements in the first six fractions of the series.

"The fractional crystallization of the picrates of the rare earths appears to furnish excellent means of effecting a rapid concentration of praseodymium and neodymium practically free from erbium and holmium, and concentration of erbium and holmium with but relatively small amounts of the members of the didymium group. The peculiar rise in the concentration of praseodymium and neodymium in the tenth and nineteenth fractions is under further investigation."

The work here to be described was undertaken with the object of making careful investigation of the apparently abnormal behavior of the earths of the didymium group upon the fractional crystallization of their picrates.

The original material used in this work consisted of about 25 kg. of the double sodium sulfates of the rare earths obtained as a byproduct in the extraction of thorium from monazite sand and which was kindly presented to us by Dr. H. S. Miner. This material was particularly suited to our purpose because of the relatively large amounts of the earths of the didymium group that it contained. A qualitative analysis of the crude double sulfates revealed the presence of sodium, cerium, and the rare earths, with small amounts of iron, calcium, and silica. No thorium was present. An examination of the absorption spectrum of a concentrated solution of

¹ THIS JOURNAL, 33, 133e (1911).

² *Ibid.*, 34, 7 (1912).

the chlorides of the rare earths from the double sulfates showed that the material contained large amounts of neodymium and praseodymium. None of the absorption bands of samarium, erbium, or holmium could be detected, even on examining a syrupy solution of the chlorides that was 15 cm. thick.

The difficultly soluble double sulfates of the rare earths were decomposed and converted into the chlorides by the method suggested by Browning and Blumenthal.¹ The material was mixed with about five times its weight of coke dust, and the mixture was placed in large graphite crucibles which were then heated to bright redness for about one hour in crucible assay-furnaces. The reduction of the sulfates took place readily at this temperature, and large volumes of carbon monoxide were evolved. When the reduction was complete, the crucibles were withdrawn and allowed to cool. The mixture of coke dust and sulfides was treated with an excess of commercial concentrated hydrochloric acid. The sulfides of the rare earths dissolved readily with the copious evolution of hydrogen sulfide. As soon as the first vigorous reaction had ceased, the mixture was heated rapidly to boiling to drive off the hydrogen sulfide. The resulting solution of the chlorides of the rare earths was diluted with about six times its own volume of water, allowed to stand until most of the undissolved material had settled out, and then filtered through a Büchner filter. The mass of carbon at the bottom of the cylinder was transferred to the filter, washed thoroughly with hot water, and drained as completely as possible. The finely divided carbon remaining on the filter paper was dried and used for the reduction of further amounts of the crude double sulfates. The oxalates of the rare earths were precipitated by the addition of a solution of oxalic acid to the filtrate after the removal of the carbon. These oxalates were washed, filtered, dried, and ignited to the oxides in bowls of fused quartz heated in a muffle furnace. About 10 kg. of the crude oxides of the rare earths and cerium was obtained. Cerium was next removed by the chlorination method of Mosander. After the material had been subjected to four chlorinations, a solution of the chlorides of the earths from the final filtrate was tested for cerium by making the solution *very faintly* alkaline with ammonium hydroxide and adding hydrogen peroxide. Since no yellow color was produced, cerium was present in no more than minute traces.

From the final solution, after the removal of the cerium, the rare earths were precipitated as the oxalates, which were converted to the oxides by ignition. About 6 kg. of the purified oxides was obtained. The oxides were then dissolved in hydrochloric acid, and the solution was filtered, transferred to large precipitating cylinders, and treated with a slight excess of ammonium hydroxide. The precipitated hydroxides were washed

¹ *Z. anorg. Chem.*, 72, 358 (1911).

by decantation with water until the supernatant liquid was free from chlorides. A qualitative analysis of the washed hydroxides showed the absence of salts of iron, calcium, and ammonium. The average atomic weight of the mixture of rare earths in the purified material was determined by the oxalate method and was found to be 141.48.

There was thus obtained a mixture of the hydroxides of the rare earths of the didymium group, containing small amounts of the earths of the erbium and yttrium groups, but free from cerium, thorium, and the common elements. To convert the hydroxides into the picrates, the suspension of the hydroxides was heated almost to boiling in large pans of enameled ware and a hot solution of picric acid was added in small amounts at a time. In order to insure the formation of a neutral solution of the picrates, the hydroxides were kept always in excess, and the addition of the picric acid was discontinued while a small amount of the hydroxides remained yet undissolved.

The solution of the picrates of the rare earths was diluted with water until it was just saturated at room temperature. The saturated solution was then subjected to fractional crystallization. The first few series of fractionations, involving the concentration of large volumes of solutions, were made in enameled pans holding about forty liters each and heated by means of small gas stoves. As soon as the fractions became sufficiently reduced in size, the crystallization was continued in smaller pans of a capacity of from fifteen to twenty liters. Subsequent fractions of smaller size were concentrated in porcelain evaporators.

The plan of the fractionation is shown in Fig. 1. When an end fraction became too small for further separation it was set aside, and the adjacent fraction became the end fraction in the next series of recrystallizations. Fractions 58, 136, 278, 428, 610, 768, 944, 1008, 1140, 1352, 1504, and 1584 from the soluble end, and fractions 183, 461, 809, 925, 1115, 1323, and 1629 from the insoluble end, were thus removed from further fractionation. When forty-two series of crystallizations had been made, the fractionation was stopped and the fractions of the final series, together with the end fractions set aside during the progress of the fractionation, were examined to determine the nature and the relative amount of the rare earths contained in each.

A considerable difference in the appearance of the crystals and of the mother liquors from the various fractions was observed. The picrates from the less soluble portions of the material crystallized in large plates and columns of an orange-yellow color, while the crystals from the more soluble fractions separated as small bundles of yellow needles. The mother liquors from the less soluble fractions were yellow, while those at the soluble end were of a yellowish brown color. From the first mother liquor set aside from the fractionation at the soluble end, a gelatinous substance

separated on standing. This jelly-like material was analyzed and was found to consist of silica, which had probably been introduced into the original mixture of rare earths from the quartz bowls in which the oxalates had been ignited.

In the examination of the fractions of the final series and of the end fractions set aside during the fractionation, the average atomic weight of

Fig. 1.

the earths in each fraction was determined, and an examination of the absorption spectrum of a solution of the chlorides from each fraction was made.

In the determination of the average atomic weights of the mixtures of rare earths from the various fractions the usual oxalate method was employed. The results of the determination of the average atomic weights of the rare earths from the various fractions were as follows:

Fraction number soluble end.	Atomic weight.	Color of oxides.	Fraction number soluble end.	Atomic weight.	Color of oxides.
58	128.06	Orange-yellow	1684-85	142.12	Grey

1680-81	143.47	Grey	183	141.12	Grey
1682-83	142.87	Grey			

Fig. 2 shows the curve obtained by plotting the average atomic weights of the fractions against the positions of the fractions in the plan of fractionation.

It appears from these results that the average atomic weights remained almost constant at a value between 141 and 142 in all of the fractions removed from fractionation at the insoluble end, and throughout the less soluble fractions in the final series up to fraction 1684-85. From this point the atomic weights rose to a maximum value of 154.59 in fraction 1666-67, fell rapidly to a minimum value of 114.67 in fraction 278, and rose again slightly in fractions 136 and 58. By far the greater portion of the material was contained in the portions with an almost constant atomic weight of about 141.

In the examination of the absorption spectra of the earths from the various fractions, neutral solutions of the chlorides of equal concentrations were used. Weighed amounts of the oxides from the various fractions were dissolved in hydrochloric acid, the acid being added very gradually

until the oxides just dissolved on boiling. The approximately neutral solutions of the chlorides of the rare earths thus obtained were diluted with water until each cubic centimeter contained 0.2 g. of the oxides and were then transferred to glass boxes 55 mm. in width. The absorption spectra were examined by means of a Krüss spectroscope previously cali-

Fig. 2.

brated by the use of the Fraunhofer lines, the spectrum of the mercury arc, and the emission spectra of potassium, lithium, and thallium. A disc of zirconium oxide heated to incandescence in the oxyhydrogen flame was used as the source of light. In comparing the intensities of the absorption bands of the solutions of the rare earths from the various fractions, the apparatus devised by Dennis and Bennett was used.¹

In Fig. 3 are shown the curves obtained by plotting the relative intensities of the characteristic lines of the absorption spectra of neodymium, praseodymium, erbium, and holmium in the various fractions against the positions of the fractions in the plan of fractionation.

The general course of the separation may be traced by the examination of the results of the comparison of the absorption spectra and the determination of the average atomic weights of the earths from the end fractions and from the fractions of the final series. The high and constant concentration of praseodymium and neodymium in the less soluble fractions and the fact that these fractions have an average atomic weight of between 141 and 142 proves that the less soluble portions of the material consisted of a mixture of the elements of the didymium group and that little or no

¹ *Loc. cit.*

separation of the elements of this group had been effected. The increase of the concentrations of erbium and holmium beyond fraction 1678-79 explains the increase of the atomic weights to fraction 1584. That the atomic weights reached a maximum in fraction 1584 while the concentration of the erbium and holmium continued to increase until fraction 1008 was reached was probably due to the effect of the increasing concentration

Fig. 3.

of yttrium in the more soluble fractions. The slight increase in the concentration of the neodymium and praseodymium in fractions 136 and 58 was in agreement with the rise in the atomic weight in these fractions and was due to the fact that they were removed from fractionation after comparatively few series of recrystallizations and therefore resembled more closely in composition the initial mixture of rare earths.

Dennis and Bennett, in their investigation of the fractional crystallization of the picrates of the rare earths, had observed a sudden and isolated concentration of neodymium and praseodymium in certain of the fractions of intermediate solubility. This observation was not confirmed in this present work. The earths of the didymium group were found to concentrate in the fractions at the insoluble end and in these fractions only. A portion of the material from one of the fractions of intermediate solubility from the final series of fractions obtained by Dennis and Bennett was analyzed and was found to contain considerable amounts of ammonium salts. Therefore it is probable that the results obtained by them in their work on the fractional crystallization of the picrates of the rare earths

were due to the fact that they were fractionating a complex mixture of the simple and the double ammonium picrates of the various earths. It is evident that the results of the fractional crystallization of such a mixture would be the results of two simultaneous, superimposed fractionations, and that each earth present would tend to concentrate in two or more separate regions of the final series of fractions.

The fractional crystallization of the picrates does not give an efficient separation of the individual elements of the didymium group. The ratio of the intensity of the neodymium spectrum to the intensity of the praseodymium spectrum remains approximately constant throughout all of the fractions. As a method for the separation of the didymium group from the yttrium and erbium groups, however, the fractionation of the picrates promises very good results. About 200 g. of the oxides of the yttrium and erbium groups was obtained from the more soluble fractions, although no trace of erbium or holmium bands could be detected in the absorption spectrum of the original material. Even after a comparatively short series of recrystallizations, the mother liquor at the soluble end showed a marked increase in the concentration of erbium and holmium and a very great decrease in the concentration of neodymium and praseodymium. Therefore the picrate method should be especially useful for the separation of the elements of the didymium group from the other rare earths and for the isolation of the earths of the erbium or yttrium groups from material containing large amounts of the didymium elements. The fractional crystallization of the picrates also appears to afford a rapid method for the separation of the yttrium earths of the erbium group.

Summary.

A mixture of the picrates of the rare earths of the didymium group, containing small amounts of the elements of the yttrium and erbium groups, was subjected to 42 series of fractional crystallizations. The earths of the didymium group concentrated in the less soluble fractions, while the most soluble fractions showed a concentration of yttrium, and the elements of the erbium group accumulated in the fractions of intermediate solubility. No indications of a concentration of neodymium or praseodymium in any fraction of intermediate solubility were observed.

The fractional crystallization of the picrates does not effect a separation of the individual elements of the didymium group, but is an efficient method for removing small amounts of the elements of the erbium and yttrium groups from the earths of the didymium group and for separating yttrium from erbium and holmium.

ANHYDROUS HYDRAZINE. III. ANHYDROUS HYDRAZINE AS A SOLVENT.¹

BY T. W. B. WELSH AND H. J. BRODERSON.

Received January 18, 1915.

In 1873, Gore² determined the approximate solubilities of a large number of substances in liquid ammonia. That liquid ammonia is an ionizing solvent has been shown by Cady.³ Franklin and Kraus⁴ studied the solubility in liquid ammonia of a large number of elements, and of various organic and inorganic compounds.

Other inorganic substances⁵ which act as ionizing solvents include such compounds as water, liquid hydrogen cyanide, liquid sulfur dioxide, concentrated nitric acid, arsenic trichloride, arsenic tribromide, phosphorus oxychloride, antimony trichloride, thionyl chloride, sulfuryl chloride, dimethyl sulfate, chlorosulfonic acid, concentrated sulfuric acid, and sulfur dichloride.

Nonaqueous ionizing solvents have also been investigated by McIntosh,⁶ Archibald,⁷ Calvert,⁸ Walden,⁹ Garner,¹⁰ and Schlesinger.¹¹

That anhydrous hydrazine is a poor conductor of the electric current has been shown by Cohen and Lobry de Bruyn.¹² The solubilities of sodium chloride, sodium nitrate, potassium chloride, potassium bromide, potassium iodide, potassium nitrate, and barium nitrate in anhydrous hydrazine have been determined by de Bruyn.¹³ Welsh¹⁴ has shown that sodium hydrazide is soluble in anhydrous hydrazine. In the present paper, the solubilities of a large number of substances in anhydrous hydrazine have been approximately determined as a preliminary investigation to the study of chemical reactions in this solvent. The results of the present investigation are described under the following headings: (1) Materials

Used; (2) Apparatus Employed; (3) General Procedure; (4) Table of Results; (5) Summary.

Materials Used.

The anhydrous hydrazine employed as solvent in the experimental work described in the following pages was prepared by first partially dehydrating commercial hydrazine hydrate with sodium hydroxide according to the method of Raschig.¹ Further removal of water was effected by treatment with barium oxide after the method of de Bruyn.² The form of distillation apparatus employed and the procedure followed in the respective distillations were those described by Welsh.³ The product was found on analysis to contain 99.7% hydrazine. The hydrazine was stored in 50 cc. sealed tubes. That no decomposition of hydrazine preserved in this way had taken place after a period of two years was shown by the fact that no appreciable increase in pressure could be noted when the containers were opened.

The solutes employed, with the exception of those noted below, were the ordinary pure chemicals of standard manufacture. Water of crystallization was removed wherever it was possible to accomplish this without decomposition. The salts of lanthanum, samarium, praseo- and neodymium which were employed were such as had been prepared during the course of certain investigations in this laboratory.

Apparatus Employed.

The solubility determinations were made in the form of apparatus shown in Fig. 1. The glass tube *A*, approximately 7 cm. in length and 1 cm. in diameter, was connected to a supply of pure, dry nitrogen through the capillary tube *B* and the stopcock *C*. During the course of an experiment, *A* was closed by means of the loosely fitting cork *D*, covered with tin foil. The action of the electric current upon the solutions was studied by means of the small platinum electrodes shown in Fig. 2. These electrodes, fused into the ends of glass tubes of small

diameter, had an area of 32 sq. mm., were 4 mm. apart, and were mounted in a cork covered with tin foil and fitted to the tube A. The electrodes were connected to the source of current through a reversing switch, a voltmeter and a milliammeter, both of which could be temporarily cut out of the circuit. A number of solubility vessels were mounted on a wooden support and one pair of electrodes used interchangeably.

General Procedure.

The solubility vessels were thoroughly cleaned and dried, one cc. of anhydrous hydrazine introduced, and the vessel tightly corked. The finely powdered solute was then introduced in successive small portions taken from a weighed amount contained in a small glass bottle. Nitrogen was allowed to bubble slowly through the apparatus in order to provide thorough stirring, care being taken that the cork did not fit tightly enough to prevent the escape of gas. This procedure was continued until no more of the solute would dissolve. In the course of the experiments the solutions were closely observed for evolution of gas and other accompanying phenomena. The action of the electric current was then studied by removing the cork *D*, and substituting for it the cork supporting the electrodes, as previously described. In those cases where a noticeable deposit was formed on an electrode, the direction of the current was reversed and the effect upon the deposit was noted under these conditions. No great accuracy is claimed for the solubility determinations, as weighings were made only to the second place and the temperature was not kept constant, and furthermore, it was very difficult to prevent slight oxidation of the hydrazine taking place, and the introduction of slight amounts of moisture with the apparatus at hand. The chief object of the research has been to obtain qualitative and approximate quantitative data concerning the behavior of various substances toward hydrazine. In Table I the third column contains the results of observations upon the behavior of the substances when introduced into hydrazine. In the fourth and fifth columns are recorded chiefly the facts noted during electrolysis. The abbreviations "G. C.," "M. C.," and "P. C.," signify, respectively, that the solutions under consideration are good, medium, or poor conductors of the electric current. A four volt circuit was used and where the current was less than 15 m. amp. it was designated as "P. C.," between 15 and 50 m. amp. as "M. C.," and above 50 m. amp. as "G. C."

Summary.

The principal results of this investigation, the details of which have been recorded in the foregoing table, may conveniently be summed up under the following headings:

Elements.—Of the metallic elements employed, the alkali metals are the only ones that are appreciably acted upon and dissolved. The solubility increases with rise of atomic weight. Sulfur and iodine are both

very soluble and chemical decomposition of the solvent takes place with rapidity, especially in the latter case.

Halogen Compounds.—The solubility of these compounds appears to increase with the increase of atomic weight of the halogen. In the case of the alkaline earth metals, crystals separate out from the solutions on standing, which are probably hydrazinated salts.¹ This was especially noticeable in the case of calcium chloride. The iodides are much more readily soluble than the corresponding bromides.

Carbonates.—The carbonates are insoluble or at most only very slightly soluble.

Oxides.—The oxides are apparently all insoluble.

Nitrates.—The nitrates, with the exception of those which react with the solvent, are in the majority of cases soluble.

Sulfates and Sulfides.—Both of these classes of compounds are only slightly soluble.

Ammonium Compounds.—These are all soluble with the exception of tertiary ammonium phosphate. Solution is accompanied by the evolution of large amounts of ammonia gas. Liberation of ammonia from ammonium salts by the action of free hydrazine has already been noted by de Bruyn.² This process, which is essentially one of *hydrazinolysis*, is the reverse of the decomposition of hydrazine salts in liquid ammonia already studied in this laboratory.³

Bismuth Compounds.—Bismuth chloride dissolves and reacts with the solvent, giving a quantitative precipitation of metallic bismuth.

Cadmium Compounds.—The carbonate and sulfide are insoluble. The halogen compounds are very soluble without visible chemical action.

Miscellaneous Compounds.—The mercury compounds, with the exception of mercuric sulfide which is insoluble, react chemically with the solvent immediately on being introduced, with formation of metallic mercury.

It is very probable that nickel and cobalt compounds are dissolved and react chemically with the solvent giving hydrazine addition products. In the case of cobalt chloride, a slow continuous decomposition was noticed with formation of a cobalt mirror on the tube.

The copper and lead compounds are all soluble with more or less decomposition. With the silver salts, the formation of a silver mirror was noted in each case.

This investigation was undertaken at the suggestion of Professor A. W. Browne and was carried out in coöperation with him.

ANHYDROUS HYDRAZINE. IV. CHEMICAL REACTIONS IN ANHYDROUS HYDRAZINE.¹

By T. W. B. WELSH AND H. J. BRODERSON.

Received January 18, 1915.

Considerable attention has been given to the study of chemical reactions in nonaqueous inorganic solvents by a number of investigators. The most important work as related to the present investigation was that carried out by Franklin and his associates upon liquid ammonia.² The behavior of hydrazine sulfate in liquid ammonia has been studied by Browne, Welsh, and Houlehan,³ and by Friedrichs⁴ who showed that ammonolysis took place with formation of free hydrazine and ammonium sulfate.

That sulfur dioxide will act as a solvent and also as a medium in which chemical action may take place has been shown by Walden⁵ and his associates, and also by Franklin.⁶ Investigations of reactions in organic solvents have been carried on by Naumann,⁷ Kahlenberg,⁸ Kahlenberg and Schmidt,⁹ Matthews,¹⁰ Gates,¹¹ and Barneby.¹²

Franklin has shown that the acids of the ammonia system are the acid amides and imides, including the amides and imides of the nonmetallic elements. The bases are the metallic amides and imides and the salts the metallic derivatives of the amides and imides. In an analogous man-

ner, the acid hydrazides, the metallic hydrazides and the metallic derivatives of the acid hydrazides may be considered, respectively, as acids, bases, and salts in the hydrazine system. The nitrides and tetrahydrazides may be considered as bearing the same relation to the ammonia and the hydrazine system, respectively, that the oxides bear to the aquo system of Lavoisier. Furthermore that the hydrazine salts of aquo acids, soluble in anhydrous hydrazine, will act as acids is indicated by the fact that they will discharge the color of phenolphthalein, and will dissolve certain metals that are insoluble in anhydrous hydrazine itself, with liberation of hydrogen. This is similar to the action of analogous ammonium salts in liquid ammonia.

The present paper is a preliminary report on the hydrazine system of acids, bases and salts, and contains a study of the action in anhydrous hydrazine solutions of: (a) hydrazine sulfide upon cadmium iodide; (b) hydrazine sulfide upon zinc chloride; (c) sodium hydrazide upon zinc chloride; (d) metallic sodium upon certain salts; (e) certain metals upon hydrazine sulfate; (f) metallic sodium and sodium hydrazide upon hydrazine chloride.

Action of Hydrazine Sulfide upon Cadmium Iodide in Anhydrous Hydrazine.—Since cadmium iodide is appreciably soluble and cadmium sulfide insoluble in anhydrous hydrazine, it could be reasonably supposed that hydrazine sulfide would precipitate cadmium sulfide from a solution of cadmium iodide in anhydrous hydrazine in accordance with either of the following equations:

or

Ephraim and Peiotrowski¹ state that either $(\text{N}_2\text{H}_4)_2\text{H}_2\text{S}$ or $\text{N}_2\text{H}_4\text{H}_2\text{S}$ is formed when sulfur is dissolved in anhydrous hydrazine. The solution of hydrazine sulfide used in this experiment was prepared, therefore, by dissolving sufficient sulfur in anhydrous hydrazine to form a deep reddish yellow solution. A solution of cadmium iodide was prepared in the form of apparatus used in studying solubilities in anhydrous hydrazine.² The hydrazine sulfide solution was added to this, and a yellow precipitate of cadmium sulfide was formed, which on analysis was found to contain cadmium 74.6%, sulfur 22.8%. Theory for CdS, cadmium, 77.79%; sulphur, 22.21%.

In view of the fact that solutions of hydrazine sulfide are highly colored it was considered possible to titrate unknown solutions of such salts as zinc chloride and cadmium iodide, with standard solutions of the sulfide, using the disappearance of the color to indicate the end point of the

¹ *Ber.*, 44, 386 (1911); see also de Bruyn, *Rec. trav. chim.*, 13, 433 (1894).

² See the preceding article.

reaction. In order to test the method in a preliminary way, the apparatus shown in Fig. 1 was devised. It consists of the two ten cubic centimeter burets *A* and *A'* with long curved tips reaching into the vessel *B*. The joints *C* and *C'* are made tight by means of mercury seals. The vessel *B* is connected with a source of pure, dry nitrogen which could be bubbled through the liquid contained in *B* at any desired speed by regulating the stopcock *D*, and then be allowed to escape into the atmosphere through stopcock, *E*. Oxidation of the solutions contained in the burets *A* and *A'* was prevented by keeping them in an atmosphere of nitrogen introduced through the tubes *F* and *F'*, held in place by the corks *G* and *G'*, which were completely encased in tin foil.

Solutions of hydrazine sulfide and cadmium iodide were prepared by dissolving weighed amounts of sulfur and cadmium iodide, respectively, in a known volume of anhydrous hydrazine. The hydrazine sulfide contained 0.039 g. of sulfur per cc. and the cadmium iodide solution 0.27 g. cadmium iodide per cc. A measured amount of the hydrazine sulfide solution was introduced into *B*, nitrogen was slowly bubbled through this in order to provide stirring, and cadmium iodide solution was slowly run in until the yellow color of the sulfur solution disappeared. It was found that 3.3 cc. of cadmium iodide solution completely discharged the yellow color from 2 cc. of the hydrazine sulfide solution. The calculated amount of cadmium iodide solution for 2 cc. of hydrazine solution was 3.2 cc.

Action of Hydrazine Sulfide upon Zinc Chloride in Anhydrous Hydrazine.—The apparatus employed and the procedure were the same as were described in the preceding experiments. When a solution of zinc chloride was added to a solution of hydrazine sulfide a white precipitate of ZnS was obtained, probably in accordance with either of the following equations:

The precipitate was analyzed and was found to contain zinc 60.7%, and sulphur 28.3%. Theory for ZnS, zinc 67.1%, sulphur 32.9%.

A solution of hydrazine sulfide containing 0.039 g. sulfur per cc. was titrated against a solution of zinc chloride containing 0.098 g. per cc. It was found that 3.3 cc. of the zinc chloride solution would discharge the color from 1.9 cc. of the sulfide solution. The calculated amount of zinc chloride solution for 1.9 cc. sulfide solution is 3.26 cc.

Action of Sodium Hydrazide on Zinc Chloride in Anhydrous Hydrazine.—Föbller and Krause¹ prepared zinc hydrazide by the action of zinc ethyl or zinc diamide on a suspension of hydrazine in anhydrous ether, and suggest these methods as generally applicable for the preparation of metallic hydrazides. It was thought that zinc hydrazide might be precipitated in hydrazine by the action of sodium hydrazide on zinc chloride in accordance with the following equation:

which would be analogous to the precipitation of zinc hydroxide by sodium hydroxide in aqueous solution. A preliminary study of this reaction was made in the apparatus described in Fig. 1. Approximately equivalent solutions of sodium hydrazide and zinc chloride were employed. The yellow color of sodium hydrazide solution was immediately destroyed on coming into contact with zinc chloride solution and a white flocculent precipitate, probably zinc hydrazide, was immediately formed. This precipitate seemed to be insoluble in an excess of sodium hydrazide but was dissolved in an excess of zinc chloride solution. Satisfactory analyses of the product could not be obtained both because of the small amount of the product and because of the difficulty in removing the last trace of hydrazine without decomposition. This solubility of zinc hydrazide in a hydrazine solution of zinc chloride is analogous to the solubility of zinc hydroxide in a water solution of zinc chloride.

Action of Metallic Sodium on Solutions of Certain Salts in Anhydrous Hydrazine.—A preliminary study was made of the action of metallic sodium upon solutions of cadmium iodide, zinc chloride, magnesium chloride, calcium chloride, barium chloride, and ferric sulfate in anhydrous hydrazine.

About 10 cc. of a saturated solution of cadmium iodide in a solubility tube was treated successively with small amounts of metallic sodium. The action proceeded fairly rapidly with the formation of a finely divided black precipitate, undoubtedly metallic cadmium. In contact with water the precipitate became superficially coated with a white material, probably cadmium hydroxide, which, when treated with a small amount of dilute hydrochloric acid, was dissolved, leaving at first the black finely divided cadmium which finally reacted with the acid with evolution of gas. The black precipitate oxidized very readily in the air, and even during the process of drying the moist product at 150° in an atmosphere of hydrogen,

¹ *Ber.*, 43, 1690-5 (1910).

oxidation took place with formation of small amounts of yellow and green oxides.

When a solution of zinc chloride was treated with metallic sodium a finely divided black precipitate was produced which was very easily oxidized in the presence of air or moisture. The material, after being dried in hydrogen at 200° , was decidedly metallic and showed traces of zinc oxide. No satisfactory analyses could be made because of the small amount of precipitate obtained, but the substance was undoubtedly metallic zinc in finely divided form.

When a solution of ferric sulfate was treated with metallic sodium, a black precipitate was formed which, after being washed with alcohol and water, was found to be soluble in hydrochloric acid with evolution of gas. Qualitative tests of this solution showed the presence of iron and the absence of hydrazine and sulfuric acid, showing that the precipitate was in all probability metallic iron.

When saturated solutions of the chlorides of magnesium, calcium or barium were treated with metallic sodium, chemical action took place and ceased when the sodium became coated with a white material. When this was removed by scraping with a glass rod, the action again commenced and continued until the metal was again coated. Since metallic magnesium calcium and barium in the finely divided state react with anhydrous hydrazine in the presence of hydrazine salts, these metals would not be expected to precipitate as do cadmium, zinc and iron. The white coating on the sodium was probably sodium chloride.

Action of Certain Metals upon a Solution of Hydrazine Sulfate in Anhydrous Hydrazine.—The behavior of zinc, copper, tin, aluminum, magnesium, calcium, and lithium toward anhydrous hydrazine and toward solutions of hydrazine sulfate in anhydrous hydrazine was studied with the apparatus shown in Fig. 2. This consisted of the tube *A* of about 10 cc. capacity with the side arm *B*, which was formed with a bulb of slightly greater capacity than tube *A*. The glass stopper *C* could be removed for the purpose of introducing solid material or of connecting the tube *B* with the tube *D*, which was connected with a mercury trap, not shown in the sketch. Communication could be established between *A* and either a Hempel buret or a suction apparatus by means of a two-way stopcock *E*. The stopcock *F* served for the introduction of hydrazine by means of suction or for the withdrawal of a sample during the course of the experiments.

The behavior of zinc upon anhydrous hydrazine was

studied in the following manner: the apparatus was evacuated, tube *A* was filled with anhydrous hydrazine drawn in through the stopcock *F*, stopcock *C* was then withdrawn and about 0.02 g. of zinc was introduced through the side arm *B*. Stopcock *C* was then turned to make connection with *D*. No measurable amount of gas was evolved. About 0.06 g. of hydrazine sulfate was introduced through *C* but no action was observed to take place. Even in contact with small pieces of platinum foil the zinc showed no tendency to dissolve. Metallic copper, tin, and aluminum, respectively, were similarly introduced, but were found to be without action upon either the hydrazine or the solution of hydrazine sulfate in hydrazine. Magnesium and calcium showed no tendency to dissolve in hydrazine or to react with it, while lithium slowly went into solution with evolution of gas. On the addition of hydrazine sulfate, however, gas was rapidly evolved in each case until the metal became coated with a white deposit which in all probability consisted of the sulfate. This coating could be partially removed by shaking, whereupon gas was again evolved until the metal became recoated. Shaking was continued from time to time until no further evolution of gas could be induced. The gases were analyzed in each case and were found to consist solely of hydrogen and nitrogen, the former in rather larger amounts than the latter. The presence of nitrogen in the gases evolved from hydrazine, when acted upon by certain metals, recalls the work of Turrentine and Moore¹ who have found that by the action of metallic copper upon hydronitric acid in aqueous solution nitrogen and ammonia were formed. Hydrazine under these conditions may therefore be considered to act virtually as an oxidizing or more strictly a nitridizing² agent. The reduction of hydrazine (hydrogen dinitride) with formation of ammonia and nitrogen would obviously be analogous to the reduction of hydrogen dioxide with the formation of water and oxygen. Magnesium was used both in the form of ribbon and powder. The action of the powder was much more rapid and complete than that of the ribbon. From the above results hydrazine sulfate can be regarded as acting as an acid in anhydrous hydrazine solution. This action is analogous to that of an ammonium salt in liquid ammonia.³

Action of Metallic Sodium and a Solution of Sodium Hydrazide upon Solutions of Hydrazine Chloride in Anhydrous Hydrazine.—Hydrazine monochloride was prepared according to the method described by Curtius and Schulz.⁴

The action of sodium upon a solution of hydrazine chloride was studied in one of the solubility tubes described in the preceding article. A strong

¹ THIS JOURNAL, 33, 382-4 (1912).

² See Browne and Welsh, THIS JOURNAL, 33, 1728 (1911).

³ Franklin, *loc. cit.*; see also Browne and Houlehan, THIS JOURNAL, 33, 1734 (1911).

⁴ J. prakt. Chem., [2] 42, 520 (1890).

solution of hydrazine chloride was placed in the tube and metallic sodium was added in successive small quantities. The sodium floated on the surface of the solution and reacted slowly. A white crystalline precipitate was formed which, after it had accumulated in sufficient quantity, was filtered in a Gooch crucible, washed with 95% alcohol, dried, and heated to dull redness on platinum foil to remove any hydrazine chloride. This material was dissolved in a measured volume of water and aliquot portions were analyzed for sodium and chlorine. The sodium was determined as sodium sulfate and the chlorine was titrated with ammonium thiocyanate. The results of the analyses of the two samples were: Na (1) 39.12%, (2) 39.03%; Cl (1) 60.41%, (2) 60.03%. Theory for NaCl: Na 39.34%, Cl 60.66%.

The action of sodium hydrazide upon hydrazine chloride was next studied. In order to prepare and keep a sufficient amount of sodium hydrazide solution, the apparatus shown in Fig. 3 was devised. It consisted of a mixing tube, *A*, closed by the glass stopper *B*, and connected with a supply of pure dry nitrogen through the capillary tube and stopcock *C*. The glass wool shown at *D* served to filter out any solid material when the solution was passed into the storage tube *E* which was connected with *A* through the stopcock *F* and the ground joint *G*. *H* is a two-way stopcock connecting either with *G* or with the capillary tube and bulb *I*. Stopcock *K* served for the withdrawal of portions of sodium hydrazide solution.

Sodium hydrazide was prepared in the following manner: a quantity of hydrazine was introduced into *A*, after air had been displaced from the entire apparatus by means of nitrogen introduced through *C*. While nitrogen was allowed to bubble through the liquid in *A*, successive portions of metallic sodium were introduced by removing stopper *B* which was prevented from fitting tightly by means of a piece of fine platinum wire hung over the lip. After the sodium had completely dissolved, the storage tube *E* was evacuated and the sodium hydrazide solution was introduced by proper manipulation of stopcocks *F* and *H*. The storage tube was then separated from the rest of the apparatus, the end of tube *I* was allowed to dip below the surface of mercury contained in a vessel not shown in the sketch, and the stopcock *H* adjusted so as to permit the escape of any gas that might be formed in *E* through *I* without danger of introduction of air.

When solutions of sodium hydrazide and hydrazine chloride are mixed

the yellow color of the sodium hydrazide is immediately discharged, provided that the hydrazine chloride is in excess. In order to obtain the sodium chloride, which did not precipitate from the rather dilute solutions employed, the resulting liquid was evaporated to dryness, and the residue was heated to drive off the excess of hydrazine chloride. Analysis of two samples of the solid residue gave the following results: Na (1) 39.53%, (2) 39.59%; Cl (1) 59.61%, (2) 60.15%. Theory for NaCl:Na 39.34%, Cl 60.66%.

The action of sodium and of sodium hydrazide upon hydrazine chloride in hydrazine solution may be expressed by means of the following equations:

and

Summary.

In the present investigation it has been shown :

1. That cadmium and zinc may be precipitated as sulfides (or hydrazinated sulfides) by the action of hydrazine sulfide on salts of these metals soluble in anhydrous hydrazine. It was also shown that the yellow color of the hydrazine sulfide could be made to serve as indicator in the titration of cadmium and zinc salts.
2. That a hydrazide of zinc is probably precipitated when sodium hydrazide acts upon zinc chloride in anhydrous hydrazine.
3. That metallic sodium will precipitate the metals cadmium, zinc, and iron from solutions of these salts in anhydrous hydrazine and that magnesium, calcium, and barium are not precipitated.
4. That zinc, copper, tin, and aluminum do not react with anhydrous hydrazine; but that magnesium, calcium, and lithium show a slight action.
5. That sodium chloride is formed by the action of either metallic sodium or a solution of sodium hydrazide on a solution of hydrazine chloride in anhydrous hydrazine.
6. That reactions may take place in anhydrous hydrazine similar to those that occur in water, in liquid ammonia and in certain other dissociating solvents.

A further study of reactions in anhydrous hydrazine solution with the special object in view of gaining information regarding the hydrazine system of acids, bases, and salts is now in progress in this laboratory and will be made the subject of a future communication.

This investigation was undertaken at the suggestion of Professor A. W. Browne and was carried out in coöperation with him.

THE ATOMIC WEIGHT OF TANTALUM.

[SECOND PAPER.]¹

BY GEORGE W. SEARS AND CLARENCE W. BALKE.

Received February 18, 1915.

No very satisfactory agreement or concordance has been obtained in the investigations which have been carried out for the determination of the atomic weight of tantalum. In 1906 Hinrichsen and Sahlborn² published five determinations of the ratio $2Ta : Ta_2O_5$, but with a variation amounting to more than a unit in the atomic weight. Yet, these determinations, without doubt, were the most accurate up to that time. In 1910, Balke³ published a series of eight determinations of the ratio $2TaCl_5 : Ta_2O_5$, in which he obtained an average of 181.5 ± 0.098 for the constant, and in the following year Chapin and Smith,⁴ in a series of eight determinations of the ratio $2TaBr_5 : Ta_2O_5$, obtained 181.8 ± 0.199 .

Since both Balke, and Chapin and Smith must have had a very pure salt, and since its conversion to the oxide is attended with very little manipulation, it would seem that the principle involved is at fault. The object of this investigation, therefore, was to study the ratios $2TaCl_5 : Ta_2O_5$ and $TaCl_5 : 5Ag$, with respect to their values for the determination of the atomic weight of tantalum, as well as to establish a more accurate value of the constant if possible.

Preparation of Materials.

Chlorine.—The chlorine used throughout this investigation was prepared by allowing hydrochloric acid to drip upon potassium permanganate contained in a large flask. The acid used was prepared by distilling the constant boiling mixture from a large Jena retort. Small quantities of potassium permanganate were put in during the first part of the distillation, and the first portions of the distillate were rejected. The chlorine was passed through three towers filled with glass beads. In the first tower the beads were kept moist with water, while in the other two concentrated sulfuric acid was allowed to drip from time to time. To remove the last traces of moisture, the chlorine was finally passed through a tube about a half meter long, containing glass wool interspersed with phosphorus pentoxide. With the exception of two ground-glass joints at the generator, all the apparatus employed for the

¹ The work described in this paper furnished the basis for a thesis by Mr. Sears presented in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the University of Illinois.

³ *THIS JOURNAL*, **32**, 1127 (1910).

⁴ *Ibid.*, **33**, 1497 (1911).

preparation or use of chlorine or hydrogen chloride throughout this investigation was made continuous.

In order to make sure the chlorine would not be contaminated by the phosphorus pentoxide, the gas was passed for several hours through the above drying train into water, which was subsequently found to give no test for phosphorus.

Sulfur Monochloride.—This compound was prepared by passing a stream of chlorine over molten sulfur, which had been twice recrystallized from freshly distilled carbon disulfide. The apparatus was constructed in such a way that the sulfur monochloride could be redistilled directly from the receiver. The first portions of the distillate were rejected, and the final product distilled directly into sealing bottles through which a current of dry, filtered air had been passed to remove all traces of moisture.

Nitric Acid.—The nitric acid used was distilled from a quartz distilling flask, the middle third being collected in a quartz receiver and retained for use.

Water.—The ordinary distilled water was redistilled, after the addition of alkaline permanganate, from the still used in this laboratory for conductivity water.

Sodium Chloride.—Chemically pure sodium chloride was dissolved in water, filtered, precipitated three times with hydrogen chloride, then recrystallized from water, dried and fused in a platinum crucible in an electric furnace.

Sodium Hydroxide.—The sodium hydroxide used in the absorption flask, was prepared by electrolyzing a solution of Kahlbaum's sodium hydroxide, using a silver anode and a mercury cathode, arranged according to the manner of the Castner-Kellner process. This was found to contain no chloride when tested in the nephelometer.

Hydrofluoric Acid.—The ordinary C. P. hydrofluoric acid was distilled after the addition of small amounts of silver nitrate and potassium hydroxide. A platinum still and receiver were used and the middle portion was retained for use. The acid treated in this way gave no opalescence with silver nitrate.

Silver.—The silver used in this investigation was prepared in essentially the same manner as that used by Richards and Wells¹ in their work on the atomic weights of sodium and chlorine.

Chemically pure silver nitrate was recrystallized three times from nitric acid and reduced with ammonium formate, which had been prepared by distilling ammonia gas into redistilled formic acid until the solution was neutral or slightly acid. The silver was then fused in porcelain crucibles lined with pure carbon² in an electric furnace. The fused silver was cleaned

¹ *Pub. Carnegie Inst. Wash.*, No. 28 (1905).

² Richards and Wells, *Ibid.*, No. 28 (1905).

with sand, etched with nitric acid, carefully washed, dissolved in nitric acid, and again reduced with ammonium formate. This was washed by decantation, dried, and fused in porcelain crucibles lined with pure lime¹ in an electric furnace. It was then carefully cleaned with a bristle brush, etched with nitric acid, and electrolyzed, using a pure silver wire as cathode, the fused silver as anode, and silver nitrate, made by dissolving some of the fused silver in nitric acid, as the electrolyte. This electrolytic silver was carefully washed, dried, and again fused in the pure lime-lined boats in a tube furnace through which was passed hydrogen, prepared from zinc and hydrochloric acid, and purified by passing through wash bottles containing alkaline permanganate, silver sulfate, caustic potash and finally through tubes containing heated platinized quartz and glass wool interspersed with phosphorus pentoxide. The bars of silver thus obtained were carefully cleaned, etched with nitric acid and preserved in a desiccator over solid potassium hydroxide. Before weighing, these bars were cut into pieces, etched to the desired weight with nitric acid, carefully washed and dried by heating for several minutes to approximately 120°.

Tantalum Oxide.—Tantalum oxide free from chloride was prepared by once recrystallizing the potassium fluotantalate from pure water to which had been added a small amount of hydrofluoric acid prepared as above. The oxide obtained from this salt, as described below, was tested for chloride by dissolving it in dilute hydrofluoric acid, contained in a platinum dish, using just enough of the acid to obtain a clear solution, adding silver nitrate and allowing the solution to stand for two days. No precipitate could be detected.

Tantalum Chloride.—Potassium fluotantalate which had been prepared for the earlier investigation was used as the starting point for the preparation of tantalum chloride. The fluotantalate was placed in a platinum dish and covered with sulfuric acid which had been distilled from quartz. The mass was slowly heated till all the hydrofluoric acid had disappeared and sulfuric acid fumes had begun to come off freely. The mixture was then evaporated to dryness, transferred to a large rubber dish and washed by decantation with large amounts of pure water. The material was finally dried, placed in quartz crucibles and strongly ignited in an electric furnace. The apparatus used for the preparation of the chloride is shown in Fig. 1. About 30 g. of the tantalum oxide were placed in the tube F, by means of a funnel through D, and the apparatus sealed together at B, D, H, and I, so that it formed a continuous piece of glass through O. A stream of chlorine was passed through the apparatus by means of the tube A, for several hours, the entire apparatus being warmed with a free flame from time to time, in order to remove any traces of mois-

¹ Richards and Wells, *Pub. Carnegie Inst. Wash.*, No. 28 (1905).

ture that might be present. Sulfur monochloride was then introduced into the bulb E, through C, and heated to boiling, the oxide at the same time being heated to a temperature just below the softening point of the glass. The tantalum chloride formed, together with the excess of sulfur monochloride, collected in Bulb I. When all the oxide had been converted into chloride the excess of sulfur monochloride was driven through the ap-

Fig. 1.

paratus and collected in O. The tantalum chloride was then distilled into K and the apparatus sealed off at J. The two-way stopcock A was then turned so that the chlorine passed through G. The tantalum chloride was then heated to boiling and kept at nearly that temperature while the remainder of the apparatus was heated so that any remaining sulfur monochloride and some tantalum chloride were driven over into O. The apparatus was then sealed off at P and, after cooling, at H.

Considerable difficulty was encountered during the process of distilling off the excess sulfur monochloride on account of a tendency of the mixture to explode. The force of these explosions varied considerably. Sometimes only a slight flash was noticed, but on several occasions the whole apparatus was destroyed. The explosions seemed to occur most frequently when the sulfur monochloride was practically all distilled over and the temperature raised to the boiling point of the tantalum chloride. It was also noticed that their occurrence depended on the rate at which the chlorine had been passed through the apparatus during the formation of the tantalum chloride. The more rapid the current, the less danger was there of an explosion. The cause of these explosions was not definitely determined, though it seems probable that they were due to a spontaneous combustion of the free sulfur which was always present in the mixture when a rapid current of chlorine was not kept up.

In order to replace the chlorine with dry air the tip N was broken off and quickly attached by means of a rubber cement to a glass tube leading through a two-way stopcock to two phosphorus pentoxide tubes, the bulbs M being heated previously in order to prevent the entrance of air when the tip N was broken off. The apparatus was then evacuated by means of

a good water pump attached to one of the pentoxide tubes. The two-way stopcock was then turned and air was allowed to enter slowly through the other pentoxide tube to which a wash-bottle containing sulfuric acid had been attached. This process was repeated until all the chlorine was replaced with dry air. The tantalum chloride was then heated to the boiling point while air was being drawn slowly from the apparatus. After cooling, the evacuation process was continued for two or three times, after which the tantalum chloride was distilled into the small bulbs M, and each sealed off for analysis. The chloride in these bulbs was pure white.

Experimental.

Ratio : $2\text{TaCl}_5 : \text{Ta}_2\text{O}_5$.—In order to test this ratio the purified chloride was transferred from the sealed bulbs to the quartz reaction flask shown in Fig. 2. The transfer in this and all succeeding cases was made as follows: By means of a knife and a hot file a crack was drawn about two-thirds around the neck of the bulb containing the chloride. This, together with the weighed flask, into the mouth of which had been inserted a wide necked funnel, was introduced into an air-tight box, provided with a removable glass top and a pair of rubber gloves fitted into two holes in the sides of the box. In order to insure a perfectly dry atmosphere, dishes containing pumice stone moistened with sulfuric acid were kept in the box and a stream of dry filtered air was passed through it for several hours before the transfer was made. By slipping the hands into the rubber gloves it was possible to break the neck off the bulb and transfer the chloride to the reaction flask without soiling the neck of the flask. After replacing the stopper it was removed from the box and again weighed.

Fig. 2.—A, B, and C are fused transparent silica, D, D', D', are carefully ground joints. Caps E, E', and tubes F, F', are made of soft apparatus glass.

The flask was then connected through an absorption train to an aspirating bottle in such a way that a slow current of moist air was drawn through it for several hours. Then water and a few drops of nitric acid were added and the tantalum oxide evaporated to dryness. The evaporation was repeated two or three times, after which the oxide was ignited

to bright redness. This was done by means of an electric resistance furnace made by winding Ni-chrome wire around an unglazed porcelain cup and insulating with powdered magnesia. By use of a rheostat the temperature was gradually increased to 900° to 1000° . During the ignition a very slow current of dry filtered air was drawn through the flask.

Three determinations were made in this way, but in no case could a constant weight be obtained, though in one case sixteen ignitions of about two hours each were made. On close examination a fine deposit was found in the exit tube, which showed that some of the oxide was being lost, either by volatilization or by being mechanically carried over by the slow current of air that was drawn through the flask. The latter seemed the more probable. In order, however, to test this point two more determinations were carried out in the same way, with the exception that no air was passed through the flask after evaporating to dryness. In the first, after eight ignitions of a half hour each a fairly constant weight was obtained, but on examining the exit tubes a fine deposit was quite noticeable. In the second, nineteen ignitions of a half hour each were made without obtaining a constant weight. The loss during any one ignition varied from a few hundredths to almost a milligram. A fine, white deposit was found in the exit tubes in this determination also.

The result of these two series showed quite conclusively that it would be impossible to obtain a satisfactory ratio by trying to hydrolyze the chloride and ignite to the oxide, since the result depended wholly on the time of heating, a fact which might have escaped detection if the reaction flask had not been supplied with the horizontal exit tubes. In order to determine more satisfactorily the reason for this, the following experiment was carried out: A sample of tantalum chloride was carefully hydrolyzed and evaporated with nitric acid two or three times and finally ignited in the quartz flask, Fig. 2, for two hours in the electric furnace. A part of the resulting oxide was then removed from the flask and fused with potassium pyrosulfate. The gases present in the mixture were at the same time conducted into a solution of silver nitrate. No opalescence in the silver solution was detected, though the melt was boiled for some time after a clear fusion had been obtained. From this it was assumed that the tantalum oxide contained no chloride. The remainder of the tantalum oxide in the flask was weighed and ignited for two-hour periods. The following weights were obtained: 1.2256, 1.2241, 1.2240. A little nitric acid was then added and the mixture evaporated to dryness and ignited for one-hour periods. The weights were as follows: 1.22440, 1.22407.

The result of this experiment, together with the fact that a fine, white deposit was always found in the exit tubes on ignition, shows that tantalum oxide is certainly lost during ignition and also that it occludes a part of

the nitric acid giving it up, if at all, only after long ignition. Ruff and Schiller¹ have shown that when tantalum oxide is ignited with sulfuric acid a part of the acid is held, even after repeated ignitions.

As a result of these experiments it was concluded that the ignition and weighing of tantalum oxide obtained from the chloride could not be used for work of the highest accuracy and, therefore, the method was abandoned.

Ratio : TaCl_5 : 5Ag.—In the beginning of the investigation of this ratio an attempt was made to hydrolyze the tantalum chloride and precipitate the hydrochloric acid formed, with silver in the presence of the tantalic acid. It was soon evident, however, that the silver was being used up by a continual displacement of the equilibrium. In one experiment to determine the nature of this reaction a sample of tantalum oxide was boiled with water and allowed to stand for several days, when the supernatant liquid, which still had a faint opalescence, was poured off and tested with silver nitrate. The opalescence was quite noticeably increased, a fact which indicated that it would be necessary to remove the tantalic acid before precipitating the chloride with silver.

The method which seemed most suitable for the separation of the tantalic acid was to hydrolyze the tantalum chloride as before and distill off the hydrochloric acid. With the idea in mind that it might be possible to obtain the chloride-oxide ratio and the chloride-silver ratio from the same sample of tantalum chloride the quartz reaction flask, Fig. 2, was designed. The apparatus first used for the hydrolysis was the same as that already described in the study of the ratio $2\text{TaCl}_5 : \text{Ta}_2\text{O}_5$. The tantalum chloride was hydrolyzed in the quartz flask and the hydrochloric acid drawn into a liter flask where all but the last traces were absorbed. In order to prevent the escape of any acid, a series of twelve small bulbs was attached to the large absorbing flask. These were arranged with a gentle slope so that the gas was forced to bubble through the liquid in each of the bulbs. A solution containing a little excess of the calculated amount of sodium hydroxide to react with the hydrochloric acid was placed in the absorbing train. As a final guard against loss of chloride a bulb was sealed to the end of the absorbing train in such a way that the liquid in it could be removed and tested for any hydrochloric acid that might escape absorption. The analysis was made in a three-liter Erlenmeyer flask, by precipitation with a weighed amount of silver dissolved in nitric acid. The nephelometer was used here and in all succeeding analyses with silver to obtain the final end point. Standard solutions of silver nitrate and sodium chloride were used for this purpose.

In Table I are the results obtained in the analyses that were carried to completion without the known loss of hydrochloric acid.

¹ *Z. anorg. Chem.*, 72, 329 (1911).

12.....	8.09039	12.16628	66.498	181.40

The poor agreement was thought to be due to the amount of manipulation necessary for the transfer of the solution from the rather extended absorption train, since in none of these did any hydrochloric acid reach the test bulb. To obviate this difficulty it was determined to carry out the whole process of hydrolyzing the tantalum chloride and distilling off the hydrochloric acid in a sealed apparatus under reduced pressure. In order to determine the possibility of completely hydrolyzing the tantalum chloride under these conditions the following experiment was carried out:

A weighed amount of pure sodium chloride was suspended in a glass weighing bottle above a sulfuric acid solution (1 : 1) in a 500 cc. distilling flask which was sealed by means of a glass tube to another flask, used as a receiver. In the receiver was placed the calculated amount of pure sodium hydroxide solution required to neutralize the hydrochloric acid formed. The neck of the reaction flask was then sealed off, the receiver connected with a good water pump and the whole apparatus evacuated, and then closed by sealing the capillary connection between the receiver and the pump. By tipping the apparatus slightly the bottle containing the sodium chloride was dropped into the acid solution. The hydrochloric acid formed was then distilled over into the receiving flask where it was absorbed in the alkali. One determination made in this way gave 0.54189 for the ratio NaCl : Ag, which agrees very well with the value obtained by Richards and Wells¹ (0.54185). In a second experiment two or three grams of tantalum oxide, free from chloride, were placed in the reaction flask with the sodium chloride and the analysis carried out as before. Repeated distillation, however, failed to remove all the hydrochloric acid, though it was finally evaporated to dryness twice after moistening with one or two cubic centimeters of sulfuric acid each time.

From this it was evident that the hydrochloric acid could not be completely removed from the tantalum oxide at the temperature of boiling sulfuric acid. Therefore, a second analysis of sodium chloride in the presence of tantalum oxide was made as before, with the exception that the residue, obtained by twice evaporating the mixture to a syrupy consistency with sulfuric acid, was transferred to a 500 cc. platinum dish by rinsing out the flask with as little water as possible. Enough hydrofluoric

¹ *Pub. Carnegie Inst. Wash.*, No. 28 (1905).

acid was then added to form a clear solution and the chloride determined by adding an excess of silver nitrate and comparing the opalescence to that of standard sodium chloride solution treated in the same manner. The value obtained for the ratio $\text{NaCl} : \text{Ag}$ was 0.54211. A great deal of difficulty was encountered in transferring the residue from the reaction flask because of the fact that it formed with the sulfuric acid a mass of gummy particles which clung so tightly to the walls of the flask that it was impossible to remove it completely. This undoubtedly would account for a considerable part of the variation from the accepted ratio but the result seemed to indicate that the principle involved in the method might be used.

Not yet satisfied, however, that the silver nitrate would not form an insoluble compound with the tantalum under these conditions a sample of tantalum oxide, free from chloride, was dissolved in hydrofluoric acid and silver nitrate was added. No opalescence appeared within twelve hours.

The results obtained from this series of experiments indicated that it would be possible to determine the chloride by precipitation with silver nitrate in the presence of the tantalum fluoride, if enough hydrofluoric acid was used, to hold the tantalum in solution. If too little hydrofluoric acid was used, however, the silver formed an insoluble compound, probably a tantalate. Platinum was the most satisfactory material in which to carry out this reaction. Accordingly, a platinum Erlenmeyer flask having a capacity of about one and three-fourths liters and fitted with a platinum stopper, together with a small platinum weighing bottle was obtained for this work.

The method of analysis was as follows: The weighed platinum bottle together with a bulb containing the purified tantalum chloride was placed in the dry-box and the transfer made as described above. The stopper, also of platinum, was carefully replaced in the bottle and the whole transferred to the balance and weighed. One of Ruprecht's best balances was used throughout the investigation and the weights were carefully standardized. All weighings were made by substitution, using a platinum crucible of approximately the same weight as the bottle for tare. Sufficient pure water to make an approximately fifth normal solution with the tantalum chloride and enough hydrofluoric acid to dissolve the tantalic acid were placed in the platinum flask and warmed to a temperature slightly above that of the surrounding atmosphere. The stoppered bottle was then dropped into the solution and the flask quickly closed. The warm solution soon caused an expansion of the air within the bottle sufficient to force the stopper out and allow the hydrolysis of the tantalum chloride to take place. The calculated amount of silver to precipitate the chloride was weighed out to within one or two milligrams, dissolved in nitric acid

(1 : 1) and the solution made up to about fifth normal. The silver nitrate solution was then poured slowly into the chloride solution while the latter was being gently agitated. After a complete transfer to the silver nitrate, the flask was shaken for some time to insure a thorough mixing and then allowed to stand until the next day, when a sample of the clear supernatant liquid was removed for a nephelometric test. The flask and contents were cooled with ice for several hours before removing the sample in order to reduce the solubility of the silver chloride. The transfer was made to platinum crucibles by means of a pipet coated with pure paraffin. Excess of silver nitrate was added to one and sodium chloride to the other, after which they were allowed to stand for about eight hours before the nephelometric readings were taken.

Considerable difficulty was encountered in obtaining nephelometric tubes that would be sufficiently transparent and yet resistant to the action of the hydrofluoric acid. The ordinary glass tubes were coated with pure paraffin, collodion, etc., but with little success. It was found that they either diffused the light or dialyzed too readily. Finally, however, tubes were constructed by cementing together the edges of strips of celluloid and closing the ends of the cylindrical tubes thus formed with carefully cleaned rubber stoppers over which a thin layer of paraffin was placed. These tubes were found to be very satisfactory.

Table II contains the results of three analyses carried out by this method.

TABLE II.

	Cl = 35.46.	NaCl : Ag = 0.54185.	Ag = 107.88.	
Preparation.	Wt. of TaCl ₅ , (vac.).	Weight of Ag, (vac.).	100 parts of TaCl ₅ equivalent to parts of Ag.	Atomic weight.
I.....	3.53605	5.31834	66.488	181.34
II.....	2.99083	4.49851	66.485	181.32
III.....	6.21118	9.34345	66.476	181.27

Although the agreement here is much better than any previously obtained it did not seem to be as good as the method should produce. The only reason for this that presented itself was that there was something about the equilibrium of the reaction that was not understood. So a study of this was taken up as follows:

Standard solutions of sodium chloride and silver nitrate were prepared, and equivalent amounts of these were mixed and allowed to stand for three days when a portion of the clear liquid was tested in the nephelometer. No difference was detected. In a second determination in which the same solutions were used enough hydrofluoric acid was added to make a 4.4% solution. The nephelometer again showed exact equivalence, which indicated that hydrofluoric acid alone did not affect the equilibrium.

A sample of sodium chloride was then weighed out, dissolved and precipitated with a weighed amount of silver in the usual manner. On the

following day a portion of the clear liquid tested in the nephelometer showed a slight excess of chloride. The calculated amount of silver was added from the standard solution and allowed to stand until the following day when a nephelometric test showed exact equivalence. In this experiment 1.78135 g. of sodium chloride required 3.28748 g. of silver for precipitation which gave 0.54185 for the ratio NaCl : Ag. This is in exact agreement with the value obtained by Richards and Wells. A second determination was carried out in the same way, using 1.79253 g. of sodium chloride to which had been added 0.31 g. of tantalum oxide dissolved in enough hydrofluoric acid to make a 5.5% solution. After a thorough mixing, the whole was set aside till the next day when a nephelometric test was made. This showed a considerable excess of sodium chloride though exact equivalents had been added. This seemed to indicate that equilibrium had not yet been reached, so the solution was again shaken for some time and set aside for another day when a nephelometric test showed a greater excess of sodium chloride than before. The shaking was repeated and a nephelometric test made on the next day showed only a very slight excess, which entirely disappeared on the fourth day. A third determination was made in which the percentage of hydrofluoric was kept the same but the amount of tantalum oxide added was doubled. Nephelometric tests made on the third and fifth days after precipitation showed exact equivalence. Other determinations were made in which the percentage of hydrofluoric acid was decreased but without obtaining satisfactory results.

These experiments indicated that it would be possible to determine accurately the amount of chloride present in a hydrofluoric acid solution containing a sufficient amount of the latter, but that a longer time would be required for the equilibrium to be reached than in the case of sodium chloride. With this in mind five analyses of tantalum chloride prepared by the method already described, but further treated as described below, were carried out and the results are given in Table III.

TABLE III.

	Cl = 35.46.	NaCl : Ag = 0.54185.	Ag = 107.88.	
			100 parts of TaCl ₅ equivalent to parts Ag.	Atomic weight.
Preparation.	Weight of TaCl ₅ (vac.).	Weight of Ag, (vac.).		
A.....	4.03892	6.07417	66.493	181.36
B ₁	3.32164	5.00133	66.417	180.96
B ₄	2.68304	4.04002	66.412	180.93
B _a	3.01453	4.53953	66.406	180.90
B _b	3.95846	5.95931	66.425	181.00

In preparation A the chlorine was replaced with dry air and the tantalum chloride was redistilled under atmospheric pressure. Preparation B was treated in the same manner except that it was redistilled under slightly reduced pressure. In preparation B five samples were obtained of which the third and fourth (B₃ and B₄) were analyzed without further treatment.

Samples 1 and 2, however, were subjected to a further distillation under atmospheric pressure and formed preparation B_a. Sample 5 was treated in as nearly the same manner as was possible at different times and formed preparation B_b.

The results obtained in this series seem to indicate that tantalum chloride either occludes some chlorine which may be removed only with the greatest care or that it is partially decomposed by distillation in dry air. The former would tend to give a low value for the atomic weight while the latter would undoubtedly give a value too high.

Summary.

During the present study of the ratios $2\text{TaCl}_5 : \text{Ta}_2\text{O}_5$ and $\text{TaCl}_5 : 5\text{Ag}$, the following observations were made:

1. Tantalum oxide, prepared from the chloride, not only occludes the nitric acid but is lost on ignition.
2. Silver forms with tantalic acid an insoluble compound, probably a tantalate.
3. Hydrochloric acid cannot be removed completely from tantalic acid by boiling with sulfuric acid either under atmospheric or reduced pressure.
4. Silver can be used to determine hydrochloric acid in the presence of tantalum fluoride if the precipitation is carried out in an approximately 5.5% solution of hydrofluoric acid. Three to four days, however, are necessary for equilibrium to become established.
5. Tantalum chloride, purified by replacing the chlorine atmosphere with dry air and by distilling either under atmospheric or reduced pressure, apparently varies slightly in composition.

In conclusion it may be pointed out that there is now available for the first time a method of analysis sufficiently accurate to detect slight differences in the composition of tantalum chloride. It now remains to make a careful study of the preparation of the chloride with regard to the definiteness of its composition. This problem is now under investigation and as soon as a satisfactory solution is obtained a final series of determinations will be published. It may be added that the possible value of this method of analysis for the determination of the atomic weights of other elements will be investigated.

SOLUBILITY OF MIXTURES OF SODIUM AND POTASSIUM CHLORIDES IN SOLUTIONS OF HYDROCHLORIC ACID.¹

By W. B. HICKS.

Received February 3, 1915.

Some experiments conducted by Dr. R. C. Wells of the Geological Survey on the brines from Great Salt Lake indicated that potassium

¹ Published by permission of the Director of the U. S. Geological Survey.

chloride is more soluble in hydrochloric acid solutions than is sodium chloride, and led to the suggestion that the constant boiling point acid might serve as a useful reagent in the commercial separation and purification of these two salts. In order to investigate the possibilities in this direction, it was decided to determine the solubilities of mixtures of sodium and potassium chlorides in several different concentrations of hydrochloric acid, including that of the constant boiling point acid. For this purpose acid solutions of approximately 8, 17, 20 and 32% were prepared, the exact strength being determined afterwards on the saturated solution of the mixed salts by titration with standard sodium hydroxide solution. While the results, as was to be expected, soon showed that the solubility of these salts in strong acid is too small to admit of the reagent being used commercially under ordinary circumstances, the experiments were not without interest, in that an increase in the potassium-sodium ratio went hand in hand with that of the concentration of the acid.

The apparatus used in all the solubility determinations was in principle similar to that described by C. M. van Deventer¹ and later used by H. Goldschmidt² and others, and is accurately represented in the following diagram.

The glass cylinder *a* is 20 cm. long and 3.8 cm. in diameter and carries two one-hole rubber stoppers *c* and *d*. The tube *e* is used for stirring and carries the pulley *f* by which it is rotated. The enlargement at *g* contains two small holes, *h* and *i*, for the purpose of increasing the efficiency of the stirrer. The hollow wooden cylinder *j* is held in place by the rubber stopper *c*, supports the pulley *f*, and serves as a bearing in which the stirrer *e* rotates. The glass rod *k* carries the rubber stopper *l* which closes the filtering tube *m*. The platinum cone *n* supports the asbestos filter *o*. The syphon *p* is sealed to *m*, and extends through the rubber stopper *q* into the 50 cc. flask *r*. The small tube *s* serves as an outlet for *r*.

Fig. 1.

In conducting the experiments about 15 g. of pure potassium chloride and an equal quantity of sodium chloride were placed in the glass container *a* of the apparatus described above, and then 40 cc. of hydrochloric acid

¹ *Z. physik. Chem.*, **5**, 559 (1890).

² *Ibid.*, **17**, 153 (1895).

approximately of the strength desired were added. The whole apparatus was placed in an electrically controlled thermostat to such a depth that the water reached to within about one inch of the top of the container *a*, and was clamped in place. The thermostat fluctuated less than 0.05° from 25° . The mixture was stirred energetically for 4 hours, when the solution was considered to be saturated, preliminary experiments having shown that ordinarily equilibrium is attained in a much shorter time under such conditions. After allowing the undissolved salts to settle, the rubber stopper was removed from the filter tube by means of the glass rod *k*, and the saturated solution filtered at the thermostat temperature through the asbestos mat into the weighed flask *r*. Suction was applied at *s* to hasten the filtering operation. The whole apparatus was then removed from the thermostat, the flask washed with water at 25° , dried, removed from the apparatus and weighed.

The weighed solution, amounting to about 30 g., was made to definite volume and aliquots taken for analysis. In most cases the determinations were carried out in duplicate. The acidity was determined by titration with standard sodium hydroxide solution, using methyl orange as indicator. The potassium was determined by precipitating as potassium chloroplatinate and weighing the reduced platinum.¹ The total dissolved salts were estimated by evaporating a definite amount of the solution in platinum and weighing the residue after gentle ignition and cooling in a desiccator. The values for sodium were obtained by difference.

TABLE I.—SOLUBILITY OF MIXTURES OF SODIUM AND POTASSIUM CHLORIDES IN HYDROCHLORIC ACID SOLUTIONS AT 25° .

No.	% HCl.	% NaCl.	% KCl.	% NaCl + KCl.	% Na.	% K.	Ratio K/Na.
1.....	0	19.95	10.90	30.85	7.85	5.72	0.73
2.....	8.61	10.65	7.58	18.23	4.19	3.98	0.95
3.....	17.16	3.56	3.80	7.36	1.40	1.99	1.42
4.....	20.65	2.03	2.86	4.89	0.80	1.50	1.87
5.....	32.78	0.18	1.27	1.45	0.07	0.67	9.57

The results of the solubility determinations are given in Table I. In order to make the data more complete, the values of Precht and Wittjen² for the solubility of mixtures of sodium and potassium chlorides in pure water have been included, the figures for 25° having been obtained by interpolation. The results have also been plotted showing graphically the changes in solubility of these salts with variations in the concentration of the acid. This diagram is given in Fig. 2.

The rapid depression in the solubility of sodium and potassium chlorides with the increase in the concentration of the acid is very striking and is

¹ Hicks, W. B., "A rapid modified chloroplatinate method for the estimation of potassium," *J. Ind. Eng. Chem.*, 5, 650 (1913).

² *Ber.*, 14, 1667 (1881).

of the same order as that shown by the individual salts in solutions of hydrochloric acid.¹ It is much more pronounced for sodium chloride than for the potassium salt, so that the curves representing these two solubilities intersect at a point corresponding to 16.2% of hydrochloric acid. Here the solubilities of the two salts are equal, amounting to 4.4%. As the acid solution becomes still more concentrated the saturated mixture con-

Fig. 2.

tains an increasingly larger proportion of potassium than of sodium chloride. However, in such strong acid solutions the solubility of both salts is very small, amounting to only 2.9% of potassium chloride and 2.2% of sodium chloride in the constant boiling point (20.3%) acid. Apparently this precludes the consideration of hydrochloric acid as a reagent in the commercial separation of the two salts in question.

WASHINGTON, D. C.

AMMONOBASIC ALUMINIUM IODIDES.

By EDWARD C. FRANKLIN.

Received January 15, 1915.

Introduction.

Some years ago the observation was made that very considerable quantities of potassium amide may be added to liquid ammonia solutions of aluminium iodide without causing the formation of a permanent precipitate. With further additions of the alkaline amide a precipitate is formed which then dissolves again in an excess of potassium amide.²

In the light of the many demonstrated analogies between the reactions

¹ Engel, *Ann. de Chim. Phys.*, [6] 13, 374 (1888).

² THIS JOURNAL, 27, 849 (1905).

which take place in the two solvents ammonia and water the probable explanation of these observations is, first that the solution to which a limited amount of potassium amide has been added contains a soluble ammonobasic iodide of aluminium; second, that the precipitate is either an insoluble ammonobasic iodide or aluminium amide and, third, that the solution of the precipitate in an excess of potassium amide results in the formation of an ammonoaluminate of potassium.

It was for the purpose of attempting the isolation of a soluble ammonobasic aluminium iodide that the present investigation was undertaken. At the same time it was hoped that the experience in the manipulation of liquid ammonia solutions gained in the interim might enable the experimenter to isolate an ammonoaluminate of potassium and to show the insoluble precipitate studied several years ago¹ to be an ammonobasic salt of definite composition. A beautifully crystalline ammonobasic iodide of aluminium has been isolated and the existence of an insoluble ammonobasic salt is shown to be probable, but the extreme solubility of the product of the action of excess of potassium amide on aluminium iodide has so far rendered ineffectual all attempts to isolate an ammonoaluminate of potassium.

Preparation of Aluminium Iodide.—For the purposes of this investigation a quantity of aluminium iodide was synthesized by the interaction of aluminium turnings and iodine and prepared for use by distillation in vacuum into long glass tubes after the manner described by Fitzgerald.² The salt distills over as a clear, colorless liquid which soon solidifies to a crystalline solid. As a check on the purity of the salt an analysis was made, with the result that it was found to contain 6.6% aluminium and 93.1% iodine. Theoretically aluminium iodide should contain 6.6% aluminium and 93.4% iodine.

Ammonated Aluminium Iodide, $AlI_3 \cdot 6NH_3$ and $AlI_3 \cdot 20NH_3$.—When ammonia gas is brought into contact with aluminium iodide vigorous absorption takes place which, unless the action be restrained, produces sufficient elevation of the temperature to volatilize some of the material. When the salt is introduced into the reaction apparatus contained in sections of glass tubing cut from the containers described by Fitzgerald¹ then the action of the solvent on the salt is accompanied by more or less active boiling of the liquid in immediate contact with the salt, but the large mass of liquid and the small surface of contact between the liquid and the salt effectively prevents too great a rise in temperature. Aluminium iodide is extremely soluble in liquid ammonia. At -33° the very concentrated solution solidifies to a mass of crystals containing about 20 molecules of ammonia of crystallization. At 8° to 13° these

¹ *Loc. cit.*

² THIS JOURNAL, 29, 1694 (1907).

crystals melt, but before fusion is complete there begins the separation of crystals containing less ammonia of crystallization, presumably a compound of the composition represented by the formula $\text{AlI}_2.6\text{NH}_3$. On further elevation of the temperature the quantity of this latter salt separating from the solution greatly increases. On cooling, these crystals again go into solution but usually before they are completely dissolved the whole liquid solidifies to a mass of the more highly ammonated salt. One obviously here observes a transition point similar to the many familiar examples taking place in water solutions.

The composition of one ammonated salt is fixed by the following analytical data. The composition of other more highly ammonated salts remains uncertain though the existence of a compound of the formula $\text{AlI}_3.20\text{NH}_3$ seems to be established.

A portion of the ammonated salt dried in vacuum at 100° to 190° weighed 1.0730 g., one-fourth of which gave 0.0289 g. Al_2O_3 . Another fourth gave 0.3703 g. AgI and a third fourth gave 0.0531 g. N. At -33° this specimen of salt retained in one experiment 0.4763 g. NH_3 , in another 0.5065 g. NH_3 .

	Calculated for $\text{AlI}_2.6\text{NH}_3$.	Found.

I.....	74.7	74.6
N.....	20.0	19.8

Calculated for 14NH_3 , 46.7; found, 44.4 and 47.2.

Soluble Ammonobasic Aluminium Iodide, $\text{Al}(\text{NH}_2)_3.\text{AlI}_2.6\text{NH}_3$.—Pure aluminium iodide dissolves in liquid ammonia to a perfectly clear, colorless solution.¹ When potassium amide is added to such a solution a white, amorphous precipitate is formed which redissolves on mixing the contents of the reaction tube. This operation is continued until a very considerable amount of potassium amide has been added, but is stopped short of the formation of a permanent precipitate. The work described below shows that there is in solution a soluble ammonobasic salt formed in accordance with the equation

and that the permanent precipitate formed by further additions of potassium amide to the solution of aluminium iodide is another ammonobasic salt containing much less iodine.

In order to isolate the soluble ammonobasic salt, the solution prepared as described above its evaporated until a satisfactory crop of crystals is deposited but not so far as to bring about the separation of any crystals of potassium iodide from the solution. The mother liquor is then poured into the second arm of the reaction tube and sufficient solvent is distilled

¹ The suggestion made in an earlier paper (THIS JOURNAL, 27, 849 (1905)) that an insoluble residue left on dissolving aluminium iodide in liquid ammonia was probably an ammonobasic salt is, therefore, erroneous.

from the mother liquor back upon the crystals to bring them into solution. Such portions of the solvent are again evaporated away as will result in a good crop of crystals when the mother liquor is again drained from the crystals. This operation is repeated until, in the judgment of the operator, the compound is pure or until the crop of crystals becomes so small as to render further recrystallization inadvisable. The leg containing the salt is then sealed off from the reaction tube and, after evaporating the excess of ammonia, is weighed preparatory to analysis, for which latter purpose the salt is first hydrolyzed by water and then dissolved in dilute sulfuric acid. The aluminium, iodine and ammonia in the solution thus obtained are determined by the well-known methods; aluminium as the oxide, iodine as silver iodide and ammonia by distillation with sodium hydroxide and titration after the usual manner. Following are recorded the experimental results obtained:

Preparation I.—The salt prepared as described above was recrystallized twice and dried in vacuum at 20°. The specimen weighed 0.5007 g., of which one-fourth gave 0.0222 g. Al_2O_3 . Another fourth gave 0.0287 g. N and another fourth gave 0.1416 g. AgI.

Preparation II.—In this experiment 7.5 g. of aluminium iodide were used and the first crop of crystals obtained was recrystallized three times. Dried in vacuum at 100° the specimen weighed 1.5820 g. One-fourth gave 0.0692 g. Al_2O_3 , another fourth gave 0.4757 g. AgI, one-tenth gave 0.0346 g. N and another tenth gave 0.0343 g. N.

Preparation III.—Ten grams of aluminium iodide were used and the basic salt was recrystallized three times. Dried in vacuum at 130° the specimen weighed 1.7605 g. One-fourth of the specimen gave 0.0783 g. Al_2O_3 , another fourth gave 0.5273 g. AgI and one-tenth gave 0.0365 g. N.

Preparation IV.—This specimen was obtained from the mother liquor from Preparation III. It was recrystallized three times and dried in vacuum at 200°. It weighed 0.7964 g. One-fourth gave 0.0356 g. Al_2O_3 , another fourth gave 0.0425 g. N and one-half gave 0.4802 g. AgI.

Preparation V.—This specimen was made from 4.4 g. of aluminium iodide and was recrystallized four times preparatory to analysis. After sealing apart the two legs of the reaction tube the solution of the salt was found to be milky from the presence of some impurity, presumably a small quantity of the insoluble ammonobasic salt described below. Dried at 165° in vacuum the specimen weighed 1.7343 g., one-fourth of which gave 0.0773 g. Al_2O_3 . Another fourth gave 0.5280 g. AgI and one-tenth gave 0.0370 g. N.

	Calculated for $\text{Al}(\text{NH}_3)_6.\text{AlI}_3.6\text{NH}_3$.	Found.				
		I.	II.	III.	IV.	V.
Al.....	9.2	9.3	9.2	9.4	9.5	9.4
I.....	65.1	61.2	65.0	64.8	65.3	65.8
N.....	21.6	22.2	21.6	20.7	21.4	21.3

A soluble ammonobasic iodide of aluminium therefore results from the action of potassium amide on aluminium iodide in liquid ammonia solution in accordance with the equation given above. It is readily soluble in liquid ammonia, the solubility greatly increasing as the temperature is lowered. At laboratory temperatures the salt separates in beautifully

formed crystals containing six molecules of ammonia which are not given off even at a temperature of 200° . As the temperature of the solution in equilibrium with the hexammonate crystals is lowered, the crystals dissolve and at the still lower temperature furnished by a bath of liquid ammonia the solution solidifies to a mass of needle-like crystals of the composition represented by the formula $\text{Al}(\text{NH}_2)_3 \cdot \text{AlI}_3 \cdot 18\text{NH}_3$.¹ This salt melts in the neighborhood of zero, more or less of the hexammonate separating from the solution at the same time. Obviously one has to do with a transition point similar to that shown by aluminium iodide described above.

Insoluble Ammonobasic Aluminium Iodide, $\text{Al}(\text{NH}_2)_3 \cdot \text{Al}(\text{NH}_2)_2 \cdot \text{I} \cdot \text{NH}_3$ and $\text{Al}(\text{NH}_2)_3 \cdot \text{Al}(\text{NH})\text{I}$.—When potassium amide is added to a solution of the soluble salt described above an amorphous, bulky precipitate of an insoluble basic salt is formed which settles very sluggishly and never to small bulk. The process of washing is therefore exceedingly tedious and time consuming, for which reason the preparation of a second specimen has not been attempted. The precipitate was washed 18 times by decantation, but since only about one-third of the liquid could be removed at each washing there is no certainty that the precipitate was thoroughly washed. The product was prepared for analysis in a manner similar to that described above for the soluble salt.

The specimen, dried in vacuum at 20° , weighed 0.4870 g. Dried at 160° it weighed 0.4135 g. One-fourth of the specimen dried at 160° gave 0.0414 g. Al_2O_3 , another fourth gave 0.0224 g. N and a third fourth gave 0.1043 g. AgI.

From the data thus recorded the following results have been calculated:

	Calculated for $\text{Al}(\text{NH}_2)_3 \cdot \text{AlNH}_2$	Found.
Al.....	22.2	21.2
N.....	22.9	21.6
I.....	52.0	54.4

	Calculated for $\text{Al}(\text{NH}_2)_3 \cdot \text{Al}(\text{NH}_2)_2 \cdot \text{I} \cdot \text{NH}_3$	Found.
Al.....	19.4	18.1
N.....	30.2	30.8
I.....	45.6	46.2

It seems probable, therefore, that an ammonobasic iodide of aluminium of the composition represented by the formula $\text{Al}(\text{NH}_2)_3 \cdot \text{Al}(\text{NH}_2)_2 \cdot \text{I} \cdot \text{NH}_3$ is formed by the action of potassium amide on a solution of aluminium

¹ As is the case with the more highly ammonated iodide of aluminium the amount of ammonia contained in this compound above six molecules appears to be difficult to fix. Four determinations of the amount of ammonia retained by the hexammonate at -33° gave 36.0, 38.3, 40.6 and 38.8%. Twelve molecules require 34.9%, 14 molecules requires 40.7%. Because of the time-consuming nature of the operations involved in establishing equilibrium between an ammonated salt and ammonia in the case of ammonated salts showing a considerable vapor tension at low temperatures further attempts to fix the composition of this compound were abandoned.

iodide¹ and that the compound thus formed loses two molecules of ammonia on being heated to 160°. In view of the amorphous character of the precipitate, however, the existence of a definite compound of the composition given cannot be certain. At all events it is an insoluble ammonobasic product.

Summary.—A soluble ammonobasic iodide of aluminium is formed in accordance with the reaction represented by the equation $2\text{AlI}_3 + 3\text{KNH}_2 = \text{Al}(\text{NH}_2)_3.\text{AlI}_3 + 3\text{KI}$, when potassium amide in limited amount is added to a liquid ammonia solution of aluminium iodide. At ordinary temperature the salt separates from solution with six molecules of ammonia of crystallization as represented by the formula $\text{Al}(\text{NH}_2)_3.\text{AlI}_3.6\text{NH}_3$, at low temperatures a highly ammonated salt containing from 18 to 20 molecules of ammonia separates from the solution.

An insoluble ammonobasic iodide of aluminium, the composition of which is represented by the formula $\text{Al}(\text{NH}_2)_3.\text{Al}(\text{NH}_2)_2\text{I}.\text{NH}_3$ is precipitated when potassium amide is added to a solution of the above soluble basic salt. When heated this compound loses two molecules of ammonia to form a product to which the formula $\text{Al}(\text{NH}_2)_3.\text{AlNHI}$ has been given.

STANFORD UNIVERSITY, CALIFORNIA.

POTASSIUM AMMONOARGENTATE.

By EDWARD C. FRANKLIN.

Received January 15, 1915.

Some years ago while studying the action of potassium amide on liquid ammonia solutions of silver salts, the observation was made that silver amide dissolves readily in excess of potassium amide solution.² Since this is a behavior which recalls the similar action of water solutions of potassium hydroxide on certain metallic hydroxides it was surmised that the observed action of potassium amide solution on silver amide probably results in the formation of an ammonoargentate of potassium.

It was for the purpose of attempting the isolation of such a compound that this investigation was undertaken.

When, in one of the two-legged reaction tubes which have been elsewhere described,³ a liquid ammonia solution of potassium amide is run into a similar solution of a silver salt a precipitate of silver amide is formed which, as the addition of potassium amide is continued, increases in amount until all the silver is precipitated. With further addition of the precipitant the precipitate dissolves to a clear, colorless solution. When, after a proper adjustment of the concentration, the solution thus obtained is cooled in a bath of liquid ammonia a crop of beautiful crystals separates from the

¹ Cf. analytical results given in *THIS JOURNAL*, 27, 849 (1905).

² *THIS JOURNAL*, 27, 835 (1905).

³ *Ibid.*, loc. cit.

solution. The salt is purified by recrystallizing several times from solvent distilled over from the second arm of the reaction tube. After separating the two legs of the reaction tube containing, respectively, the mother liquor and the solution of the pure salt, the excess of ammonia is removed from the latter and the pure, dry salt, together with its container, is weighed. In order to hydrolyze the specimen and get the hydrolytic products into aqueous solution preparatory to analysis, the dried salt is allowed to lie over night in contact with water vapor. The hydrolytic products were then treated successively with liquid water and dilute sulfuric acid. It was expected that the salt, which has been shown to have the composition represented by the formula AgNHK.NH_3 , would hydrolyze in accordance with the equation $2\text{AgNHK} + 3\text{H}_2\text{O} = \text{Ag}_2\text{O} + 2\text{KOH} + 2\text{NH}_3$. Contrary, however, to expectations it was found that considerable quantities of metallic silver and nitrogen gas are always liberated during this treatment of the compound. Furthermore, when the salt was prepared directly from iodide of silver in the manner described above, small quantities of the latter salt were always found mixed with the metallic silver. This contamination was not a portion of the original iodide of silver used in the experiment, but resulted from the action of potassium iodide, which had not completely removed from the salt by the process of purification to which it was submitted, on the silver sulfate formed by the action of the dilute sulfuric acid on the products of hydrolysis. The metallic silver was recovered from the mixture of silver and silver iodide by dissolving in dilute nitric acid and precipitating it as silver chloride. The silver chloride thus obtained is marked (a) in the analytical data below. The silver iodide, which was filtered off, washed, weighed and is marked (b) below, gives a measure of the amount of potassium iodide with which the specimen was contaminated. The silver contained in the sulfuric acid solution was precipitated as the chloride and is given under (c) in the analytical data. The total nitrogen was made up of two parts, that present in the sulfuric acid solution as ammonium sulfate and that set free during the hydrolysis of the ammono salt. The free nitrogen and metallic silver were found to be formed in equivalent quantities.

Preparation I.—In this experiment somewhat more than two equivalents of potassium amide were added to a solution of 2.35 g. of silver iodide in liquid ammonia and the resulting solution, after proper concentration, was cooled to -40° . The crop of beautiful crystals which separated from the solution was dissolved and recrystallized once for analysis.

The specimen dried in vacuum at 20° weighed 0.8880 g. The specimen contained 0.4636 g. Ag, calculated from (a) 0.4506 g. AgCl, (b) 0.1268 g. AgI and (c) 0.0525 g. AgCl from three-fifths of the sulfuric acid solution. The other two-fifths of this solution gave 0.0429 g. N. The free nitrogen collected amounted to 0.0142 g. One-fifth of the filtrate from (c) gave 0.0557 g. K_2SO_4 .

Preparation II.—The same quantities of silver iodide and potassium amide were used as in the preceding experiment.

The salt, recrystallized four times and dried in vacuum at 20° , weighed 0.5479 g. The specimen contained a total of 0.3211 g. Ag, calculated from (a) 0.3755 g. AgCl, (b) 0.0078 g. AgI and (c) 0.0465 g. AgCl from the whole of the sulfuric acid solution, and a total of 0.0867 g. N, calculated from the nitrogen equivalent of metallic silver (a) and 0.0186 g. N obtained from one-fourth of the filtrate from AgCl (c). Another fourth of this filtrate gave 0.0688 g. K_2SO_4 .

Preparation III.—In this experiment slightly more than three equivalents of potassium amide were added to a solution of 2.5 g. of silver iodide with the object in view of ascertaining whether possibly a salt containing two atoms of potassium may be obtained.

The specimen, which was recrystallized four times, weighed 0.4603 g. when dried in vacuum at 20° . It was found to contain a total of 0.2732 g. Ag, calculated from (a) 0.3075 g. AgCl, (b) 0.0065 g. AgI and (c) 0.0386 g. AgCl from three-fourths of the sulfuric acid solution. One-fourth of this solution gave 0.0158 g. N, which, together with the nitrogen equivalent of (a), gives a total of 0.0732 g. N. One-half of the filtrate from AgCl (c) gave 0.0826 g. K_2SO_4 .

Preparation IV.—Finding the silver persistently low in the above preparations, as the result of contamination with potassium iodide, it was determined to prepare pure silver amide and dissolve this in a solution of potassium amide with the expectation that a pure specimen of potassium ammonioargentate would result. Accordingly a three-legged reaction tube was prepared and into one leg was introduced 1 g. of silver nitrate and into each of the other two one equivalent of metallic potassium together with a minute quantity of platinum black.¹ Ammonia was distilled into the apparatus and after all the potassium had been converted into potassium amide the solvent from one of the legs containing potassium amide was evaporated away, leaving the ammonio base clinging to the walls and bottom of the tube. This potassium amide was reserved for dissolving the pure silver amide. The preparation and purification of silver amide was then carried on in the other two legs of the reaction tube after the manner previously described.² After thoroughly washing the silver amide, liquid ammonia was distilled from the washings and distributed between the two legs containing the precipitate and the reserve potassium amide, respectively. The leg containing the washings was then sealed off leaving a two-legged tube in which the operations of dissolving the silver amide and purifying the resulting salt were carried on in the usual manner. The crop of crystals obtained was recrystallized once preparatory to analysis.

Dried in vacuum at 100° the specimen weighed 0.4852 g. The metallic silver formed during the hydrolysis of the salt was dissolved in dilute nitric acid and added to the sulfuric acid solution. From the combined solutions 0.3877 g. AgCl

¹ Platinum black accelerates the reaction between the ammonia and potassium.

² *Loc. cit.*

was obtained. One-half of the filtrate from the silver chloride gave 0.0310 g. N, which, together with 12.7 cc. N measured over water at 20° and 760 mm., gives a total of 0.0765 g. N. The other half of the filtrate gave 0.1169 g. K_2SO_4 .

The following results have been calculated from the above data:

	Calculated for $AgNHK.NH_3$.	Found.			
		I.	II.	III.	IV.
Ag.....	60.3	52.3	58.6	59.3	60.2
N.....	15.6	13.7	15.8	15.9	15.7
K.....	21.8	23.4	22.5	21.4	21.6
I.....	0.0	7.7	0.9	0.7

A compound of the composition represented by the formula $AgNHK.NH_3$ or $AgNH_2.KNH_2$ is therefore formed by the action of a solution of potassium amide on the amide of silver in accordance with a reaction represented by the equation

The salt separates from concentrated solutions in the form of beautiful crystals which are unaffected at a temperature of 100°. It is gradually discolored and decomposed by contact with the air. When heated over the open flame it decomposes vigorously but without explosive violence. In contact with water it decomposes but does not explode. This behavior is in marked contrast with that of silver amide which, it will be remembered, explodes with great violence on the slightest provocation, frequently without any assignable cause whatever. Liquid ammonia solutions of acids decompose potassium ammonoargentate, precipitating first silver amide which dissolves on further addition of the acid to form a silver salt of the acid used.

Summary.—It is shown in this paper that silver amide dissolves in a liquid ammonia solution of the ammono base, potassium amide, to form potassium ammonoargentate, an ammono salt of the composition represented by the formula $AgNHK.NH_3$ or $AgNH_2.KNH_2$.

Introduction.

In the first paper (I)² of this series, the electronic conception of positive

¹ Read before the Cincinnati Section, Am. Chem. Soc., Dec. 9, 1914.

² Fry, *THIS JOURNAL*, 36, 248 and 262 (1914).

and negative valences and the electronic formula for benzene were employed to interpret the anomalous behavior of many of the derivatives of benzene. In the second paper (II)¹ halogen substitution in the benzene nucleus and in the side-chain was considered from the same points of view. In each of these papers the theoretical deductions presented and applied were shown to be in accord with the experimental facts under consideration.

The present papers (III, IV, V) of the series are presented under one cover because they relate in general to the interpretation of the problems encountered in the simultaneous formation of ortho-, meta-, and para-disubstituted derivatives of benzene, and likewise to the simultaneous formation of the more complicated polysubstituted derivatives of benzene.

In Part III (A Continuation of the Interpretation of the Brown and Gibson Rule) a further analysis of this rule, based upon experimental facts, leads to deductions which are employed throughout the subsequent papers.

Part IV presents (1) an explanation of the simultaneous formation of ortho-, meta-, and para-substituted derivatives of benzene based upon the conception of *electronic isomerism* and the existence of *electromers in dynamic equilibrium*, i. e., *electronic tautomerism*. (2) A mechanism of these changes is described. (3) Holleman's proposed mechanism of, and hypotheses relating to, substitution are interpreted in terms of the electronic conception of positive and negative valences. (4) It is shown that there is a direct correlation of the author's electronic formula for benzene and rule for substitution with Holleman's hypotheses.

Part V presents a direct reply to each of the objections which Holleman has just recently published² against the author's electronic formula for benzene (abbreviated formula, Fig. 1) and general rule of substitution. This rule maintains that when substituents are of the same sign or polarity they occupy positions which are meta to each other, but if two substituents are of opposite sign or polarity they will occupy positions either ortho or para to each other. This follows from the fact that the electronic formula of benzene is the only formula which presents a structural basis and an electronic interpretation for the relations between the ortho and para positions and substituents in contradistinction to the meta positions and substituents.

III. A CONTINUATION OF THE INTERPRETATION OF THE BROWN AND GIBSON RULE.³

(A) The Brown and Gibson Rule.⁴

The numerous instances in which certain monosubstituted derivatives

¹ THIS JOURNAL, 36, 1035 (1914).

² Holleman, *Ibid.*, 36, 2495 (1914).

³ See Fry, *Z. physik. Chem.*, 76, 385 and 398 (1911) for a detailed description of this rule and the derivation of the electronic formulas of benzene.

⁴ *J. Chem. Soc.*, 61, 366 (1892).

of benzene yield chiefly ortho and para disubstituted compounds, while other mono derivatives yield chiefly meta disubstituted products, have led to the formulation of the Brown and Gibson rule, the essential features of which must be briefly outlined. In the following abridged table,

A.	B.	C.	D.	E.
C_6H_5X	X	H.X	HO.X	...
C_6H_5Cl	Cl	H.Cl*	HO.Cl	<i>o-p</i>
$C_6H_5CH_3$	CH_3	H. CH_3 *	HO. CH_3	<i>o-p</i>
$C_6H_5NH_2$	NH_2	H. NH_2 *	HO. NH_2	<i>o-p</i>
C_6H_5OH	OH	H.OH*	HO.OH	<i>o-p</i>
$C_6H_5NO_2$	NO_2	H. NO_2	HO. NO_2 *	<i>m</i>
C_6H_5COH	COH	H.CO H	HO.CO H *	<i>m</i>
C_6H_5COOH	COOH	H.CO OH	HO.CO OH *	<i>m</i>
$C_6H_5SO_2OH$	SO $_2$ OH	H.SO $_2$ OH	HO.SO $_2$ OH*	<i>m</i>

Column A contains the formulas of a few monosubstituted derivatives; Column B, a few of the common substituents; Column C, the hydrogen compounds of these substituents; Column D, the hydroxyl compounds of the same substituents; Column E, the letters (*o-p*) or (*m*), according as the mono-derivatives give chiefly a mixture of ortho- and para-derivatives, or chiefly meta-derivatives. Brown and Gibson maintained that those substances marked with an asterisk in Column C "are *not* capable, by *direct oxidation in one step*, of being converted into the corresponding hydroxyl compound" in Column D. On the other hand, those substances asterisked in Column D can be formed by direct oxidation from the corresponding hydrogen compounds in Column C. Whenever the hydrogen compound is asterisked we find (*o-p*) in Column E. Whenever the hydroxyl compound is asterisked we find (*m*) in Column E. Brown and Gibson accordingly state their rule in these words: "...when X is naturally to be regarded as a derivative of HX, then C_6H_5X gives ortho- and para-derivatives; and when X is naturally to be regarded as a derivative of HOX, then C_6H_5X gives meta-derivatives." With very few exceptions (which are based upon the question of "direct oxidizability" of HX to HOX, to be considered later) the Brown and Gibson rule has been found to be capable of most rigorous application. Its authors did not look upon it as a law because there was "no visible relation to any mechanism by which substitution is carried out in one way rather than in another way."

It has been shown in detail in previous papers¹ that there is a very definite relation to a mechanism, which becomes evident when we determine the difference between X in HX and X in HOX. In the ordinary structural formulas no difference is apparent but from the electronic point of view, when H is positive and O is negatively divalent, it necessarily follows that X in HX functions negatively while X in HOX functions positively; as is evident in the electronic formulas $H \overset{+}{-} X$ and $H \overset{+}{-} O \overset{-}{-} X$.

¹ Fry, *Loc. cit.*

Accordingly, a mono-substituted derivative may be either $C_6H_5.X$ as a derivative of $H.X$, or $C_6H_5.X$ as a derivative of $HO.X$. Therefore, when X in $C_6H_5.X$ is negative and the entering substituent is positive, then ortho- and para-derivatives result. On the other hand, when X in $C_6H_5.X$ is positive and the entering substituent Y is positive, then meta-derivatives are formed. The following typical equations illustrate the above principles:

Thus, the electronic formula of benzene is correlated with the electronic interpretation of the Brown and Gibson rule, thereby showing a visible relation to a mechanism by which substitution is carried out in one way rather than in another way. In nuclear substitution it is assumed that the entering substituent is always positive as indicated in the above equations with the consequent elimination of $H.OH$ (or some other binary compound of the type $H.X$) conforming in general to the double decomposition type of reaction. Some substitution reactions involve oxidation and reduction as explained in a previous paper.¹ The entrance of Y as a positive substituent does not preclude its reverting to a negatively functioning substituent in accordance with the principle of "electronic tautomerism." These assumptions will be explained in detail and will be shown to accord with experimental facts.

(B) A Further Analysis of the Brown and Gibson Rule.

In presenting a further analysis of the Brown and Gibson rule it is necessary, first, to bring out the hidden significance of the difference between compounds of the type HX which are not directly oxidizable to HOX and those which are directly oxidizable to HOX .

Some writers have taken exception to this point of view which Brown

¹ The substitution of chlorine in the side chain is an oxidation and reduction phenomenon depending upon the reaction, $Cl^+ \longrightarrow Cl^- + 2\oplus$. Fry, THIS JOURNAL, 36, 1043 (1914).

and Gibson assumed as their basis of classifying substituents. For instance, Holleman¹ states that the rule,

"although remarkable and representing very well many of the observed facts, does not give satisfaction since it depends entirely upon the question of the direct oxidation of the hydrogen compounds of the substituents. Thus, at the time (1892) when Brown and Gibson published their rule, methane, $\text{H}.\text{CH}_3$, could not be oxidized directly to methyl alcohol, $\text{HO}.\text{CH}_3$; hence, according to the rule, the radical CH_3 should direct the entering substituent to the ortho and para positions. But since the time of the publication of the rule, Bone has proved that the primary oxidation product of methane during combustion is methyl alcohol. As a consequence, the radical CH_3 should then direct the entering substituent to the meta position. This discovery of Bone renders the rule inexact. While it is perfectly true that one can not directly transform $\text{H}.\text{Cl}$ to $\text{HO}.\text{Cl}$, yet on the other hand no one is certain that this will always be impossible."

Therefore, Holleman contends that with the progress of science the Brown and Gibson rule becomes less and less applicable.

Now this criticism of Holleman is only apparently justified, because Brown and Gibson unfortunately based their classification of substituents upon the debatable standpoint of the direct oxidizability in one step of HX to HOX . It has been shown that the chief point of distinction between the two classes of substituents is not the direct oxidizability of HX to HOX but rather depends upon the electronic interpretation of the rule in conjunction with the electronic formula of benzene, and the fact that X in HX is negative while X in HOX is positive. These points of view invalidate Holleman's criticism of the Brown and Gibson rule.

Further light may be thrown upon the nature of the substituents (X) commonly found in the benzene nucleus by considering the behavior of certain HOX compounds as oxidizing agents, and the susceptibility to oxidation of certain HX compounds, thus placing the Brown and Gibson classification on a different basis. Consider, first, a few of those substituents (OH , NH_2 , Cl and CH_3) which Brown and Gibson regarded as naturally derived from HX , not directly oxidizable to HOX . It is particularly noteworthy that the hydroxyl compounds of each of these substituents may function as an oxidizing agent while their hydrogen compounds are not oxidizing agents in the common sense of the word. Furthermore, the hydroxyl compounds of these substituents are less stable than their corresponding hydrogen compounds, *i. e.*, the entropy of the HX compound is less than the entropy of the HOX compound. When HOX functions as an oxidizing agent ($\text{HOX} \rightarrow \text{HX} + \text{O}$) yielding HX and oxygen (either free or combined) there is a change in the polarity of X from $\overset{+}{\text{X}}$ to $\overset{-}{\text{X}}$. This change may be represented as involving either an oxidation

of negative hydroxyl ions by positive chlorine ions ($\text{HO}.\text{Cl} = \text{HO} +$

¹ Sur les regles de substitution dans le noyau benziq-ue-Conference faite devant la Societe chimique de France, le 2 juin 1911. *Bull.*, 1911, 4e Serie 9. pp. 1-xlv.

$\overset{+}{\text{Cl}} \rightarrow \overset{+}{\text{H}} + \overset{-}{\text{Cl}} + \text{O}$)¹ or an intramolecular oxidation and reduction ($\overset{+}{\text{H}} - \overset{-}{\text{O}} - \overset{+}{\text{X}} \rightarrow \overset{+}{\text{H}} - \overset{-}{\text{O}} - \overset{+}{\text{X}} \rightarrow \overset{+}{\text{H}} - \overset{-}{\text{X}} + \text{O}$)². Now, since the compounds of the type HOX are less stable than those of the type HX, as shown by oxidation reactions, and since these oxidations involve the transition from $\overset{+}{\text{X}}$ to $\overset{-}{\text{X}}$, we may accordingly assume that $\overset{-}{\text{X}}$ is more stable than $\overset{+}{\text{X}}$.³ In other words, the tendency for X to function negatively is more pronounced than its tendency to function positively, but it may function either way as its $\overset{+}{\text{H}}\overset{-}{\text{X}}$ and $\overset{-}{\text{H}}\overset{+}{\text{O}}\overset{+}{\text{X}}$ compounds show. This may be postulated as a general property of those substituents which Brown and Gibson regarded as naturally derived from HX not directly oxidizable to HOX.

In order to complete the analysis of the Brown and Gibson rule it will be necessary to consider from the same points of view a few of those substituents, namely CO₂H, COH, SO₃H and NO₂, which were formerly regarded as belonging to the type HOX derivable by direct oxidation of HX. In fact, each of these HX compounds may be oxidized directly to the corresponding HOX compound, but it should be noted that X is a complex radical and the oxidation involves fundamental changes both in the number and polarity of the valences of certain atoms comprising these radicals. These features may be illustrated by the electronic equations for the oxidations in which oxygen as O functions as the oxidizing agent through the acquisition of electrons and the consequent conversion of certain negative valences in the radical X to positive valences,⁴

The complete electronic equations for the oxidations of (1) formic acid, (2) formaldehyde, (3) sulfurous acid, and (4) nitrous acid are as follows: (1-4)

¹ For a more complete analysis of this change and the conditions under which it proceeds see Fry, *THIS JOURNAL*, 36, 267 (1914); *Ibid.*, 1044 (1914).

² Intramolecular oxidation and reduction has been described in detail by Jones, *Am. Chem. J.*, 50, 414 (1913); *THIS JOURNAL*, 36, 1268 (1914).

³ For the relation of this conception to the "nascent state" cf. Fry, *THIS JOURNAL*, 36, 272 (1914).

⁴ Oxidation and reduction reactions are presented from the positive and negative standpoint by Stieglitz, *Qual. Chem. Anal.*, Vol. 1, Chaps. XIV and XV.

⁵ This change is comparable to keto-enol tautomerism. An electronic interpretation of same has been given by Fry, *Z. physik. Chem.*, 76, 405 (1911).

garded as naturally derived from HOX which results from the direct oxidation of HX.

Other points of significance may be noted in Equations 1-4 above. In formic acid, Equation 1, three of the carbon valences are positive while the fourth is negative. In carbonic acid, four carbon valences are $+-$ positive. Prior to the action of O, formic acid is in equilibrium with a tautomeric modification in which the carbon atom is bivalent and shows one free positive and one free negative valence. These free valences unite $+-$ with O and, either simultaneously or subsequently, the negative carbon valence is oxidized to a positive valence and oxygen $+-$ (O) thereby becomes negatively divalent $--$ (O). The tautomeric modification of formic acid, showing a free positive and a free negative valence, would through the polarization of these valences present an illustration of a bivalent carbon compound.¹ Another illustration is shown in Equation 2.

Furthermore it should be noted in Equation 3 that sulfurous acid ($\text{H.SO}_3\text{H}$) is ordinarily written ($\text{HO.SO}_2\text{H}$), in which the sulfur atom (comparable to the carbon atom above shows a free positive and a free negative valence, and the polarization of these valences renders sulfur tetravalent; but, on oxidation to sulfuric acid, the sulfur atom becomes hexavalent. In precisely the same manner nitrous acid (H.NO_2) is commonly written (HO.NO) in which nitrogen is trivalent; but oxidation to nitric acid renders nitrogen pentavalent. Now Equations 1-4 show that formaldehyde, formic acid, sulfurous acid and nitrous acid belong to the same class and same type of oxidizable compounds. Since the sulfur atom in sulfurous acid increases its valence by two on oxidation to sulfuric acid, and since the nitrogen atom in nitrous acid likewise increases its valence by two when oxidized to nitric acid, it follows, similarly, that the carbon atom in formaldehyde and in formic acid must undergo likewise an increase of two in its valence when the compounds are oxidized to formic acid and carbonic acid, respectively. In other words, this classification of the substituents and the electronic system of oxidation lends further support to and an electronic interpretation of the existence of bivalent carbon compounds.

Summary of Part III.

The extended interpretation and analysis of the Brown and Gibson rule brings out the following facts:

¹ Stieglitz (*Loc. cit.*, Vol. I, pp. 269-298) has given a detailed account of the oxidation of carbon compounds, in particular formaldehyde, showing by means of the chemometer that there is involved an actual transfer of electrical charges. The classification of sulfurous and nitrous acids with formaldehyde in the present discussion leads to the suggestion that certain sulfites and nitrites might lend themselves to similar significant demonstrations. See also Stieglitz, *Science*, 27, 774 (1908).

1. Certain substituents (OH, Cl, Br, I, NH₂, CH₃, etc.) lead to the formation chiefly of ortho and para derivatives of benzene, because their tendency to function negatively is more pronounced than their tendency to function positively. This tendency may be formulated thus: $\overset{-}{X} > \overset{+}{X}$.

2. Certain other substituents (CO₂H, COH, SO₃H, NO₂, etc.) lead to the formation chiefly of meta derivatives of benzene, because their tendency to function positively is more pronounced than their tendency to function negatively. This tendency may be formulated thus: $\overset{+}{X} > \overset{-}{X}$.

3. The objections which have been directed against the Brown and Gibson rule have been based upon the question of the direct oxidizability of HX to HOX. These objections are invalid, because the distinction between the two classes of substituents rests upon the facts summarized in paragraphs (1) and (2) above, and the fact that X in HX is negative while X in HOX is positive. These distinctions, in conjunction with the electronic formula of benzene, show why certain monosubstituted derivatives of benzene yield chiefly ortho- and para-disubstituted derivatives, while others yield chiefly meta-disubstituted derivatives.

IV. THE SIMULTANEOUS FORMATION OF ORTHO-, META- AND PARA-SUBSTITUTED DERIVATIVES OF BENZENE.

Previous papers¹ relating to substitution in the benzene nucleus from the electronic point of view have interpreted the formation of ortho and para compounds on the one hand, and meta-compounds on the other, as distinct and separate processes because, as a general rule, a given mono substituted compound yields chiefly a meta-derivative or a mixture of ortho- and para-derivatives. But in many reactions there results a mixture of ortho-, meta-, and para-disubstituted derivatives in which the quantities of the isomers vary. Consequently it becomes necessary to explain (A) the simultaneous formation of ortho-, meta- and para-disubstituted derivatives; and also (B), the simultaneous formation of polysubstituted derivatives. These explanations involve the electronic formula of benzene, the rule of substitution, and the conception of *electronic isomers or electromers in dynamic equilibrium, i. e., electronic tautomerism*.

The substituents (X) commonly found in the benzene nucleus were shown in Part III to function either positively or negatively according to $\overset{-}{X}$ or $\overset{+}{X}$, respectively. Now it has also been shown in a previous paper² that a number of these substituents may function either negatively or positively when in combination with carbon atoms of the benzene nucleus. For instance, chlorine is

¹ Fry, *Loc. cit.*, THIS JOURNAL, and *Z physik. Chem.*

² Fry, THIS JOURNAL, 36, 265 (1914).

negative in *o*- and *p*-chloronitrobenzenes, but positive in *m*-chloronitrobenzene and in 2,4,6-trichloroacyl nitrogen chloride. A particularly noteworthy example is afforded by the (SO_3H) radical, which in phenylsulfonic acid functions either negatively or positively, depending upon certain conditions. For instance, phenylsulfonic acid on hydrolysis (1) in alkaline solution yields phenol and sulfurous acid while (2) in acid solution the products of hydrolysis are benzene and sulfuric acid. Hence, the following equations:

In connection with the facts that certain substituents in the benzene nucleus may function either positively or negatively, consider the following quotation from a previous paper:¹

"The hypothesis of positive and negative valences suggests the possibility of there being at least two distinct types or electromers of a binary compound. Hence two mono substituted derivatives of benzene, $\overset{+}{\text{C}_6\text{H}_5}\text{---X}$ and $\overset{-}{\text{C}_6\text{H}_5}\text{---X}$, should be possible while only one is known. Therefore, if both electromers exist and only one substance is identified, it follows that the electromers are either not distinguishable by (present) physical methods, or that one electromer is transformable into the other through the transposition of electrons: $\overset{+}{\text{C}_6\text{H}_5}\text{---X} \rightleftharpoons \overset{+}{\text{C}_6\text{H}_5}\text{X} \rightleftharpoons \overset{-}{\text{C}_6\text{H}_5}\text{---X}."$

This quotation presented the first definition of the conception of "electronic tautomerism," that is, the existence of electromers in dynamic equilibrium.²

At the present time *tautomerism* is applied to that state of substances in which only the equilibrium mixture of the structural isomers is known. Correspondingly, the term *electronic tautomerism* is applied herewith to substances in which only the equilibrium mixture of the *electronic isomers* or *electromers* is known. From this point of view phenylsulfonic acid may be regarded as an equilibrium mixture of the electromers $\overset{+}{\text{C}_6\text{H}_5}\text{X}$ and $\overset{-}{\text{C}_6\text{H}_5}\text{X}$, and any other mono- or polysubstituted derivative of benzene may be regarded similarly, as will be shown later.

(A) The Simultaneous Formation of Ortho-, Meta- and Para-Disubstituted Derivatives of Benzene.

Electronic tautomerism of monosubstituted derivatives of benzene will

¹ Fry, *Z. physik. Chem.*, **76**, 390 (1911).

² The conception of electronic tautomerism has been applied in many significant ways. See articles by L. W. Jones (*Am. Chem. J.*, **50**, 414 (1913)); THIS JOURNAL, **36**, 1268 (1914); Stieglitz, *Loc. cit.*, THIS JOURNAL, **36**, 272 (1914); Bray and Branch, THIS JOURNAL, **35**, 1440 (1913); see also article on the existence of electromers of nitrogen chloride by W. A. Noyes, *Ibid.*, **35**, 767 (1913).

now be employed to explain the simultaneous formation of ortho-, meta-, and para-disubstituted derivatives of benzene. Consider any mono-substituted derivative of the general formula C_6H_5X which is now regarded as $(C_6H_5.X \rightleftharpoons C_6H_5.X)$. Indicating the polarities of the hydrogen atoms of the nucleus the equilibrium is represented thus:

Note particularly that the change in the polarity of the substituent X involves simultaneously a change in the polarities of the hydrogen atoms, but that in each electromer those atoms (or substituents) ortho and para to X are opposite in sign to X, while those atoms (or substituents) meta to X are of the same sign as X. This, of course, is the essential feature of all of the electronic formulas of benzene, namely that hydrogen atoms or substituents in positions 1, 3, and 5 of any given electromer are opposite in sign to the hydrogen atoms or substituents in positions 2, 4 and 6 of the same electromer, otherwise the symmetry, and consequently the stability, of the benzene nucleus could not be maintained. A detailed mechanism of the transpositions of electrons, the centric valences, etc., involved in the electronic tautomerism of benzene derivatives will be given later in this paper. For the present, the simpler formulas involving only the hydrogen atoms and substituents are sufficient.

It is a well established fact that in a mixture of two isomers ($A \rightleftharpoons B$), capable of changing one into the other with such readiness that the balance between them is rapidly restored, the addition of a given substance C will result in reaction either with A, or with B, or with both A and B. If interaction occurs between A and C, B will be transformed into A on account of the disturbance of the equilibrium. The mixture then reacts as though it consisted wholly of A. If C reacts only with B, the mixture behaves, for the same reason, as though B were the only substance present. In some instances two simultaneous independent reactions may occur, namely, the interaction of A and C simultaneously with the interaction of B and C. In a precisely similar manner a given reagent, $HO.Y$, in the presence of a tautomeric mixture of electromers ($C_6H_5.X \rightleftharpoons C_6H_5.X$) may react with the one electromer or the other, or with both electromers. A complete scheme of interaction is shown in the following electronic equations:

It should be observed that if HO^-Y^+ reacts only with $\text{C}_6\text{H}_5.\text{X}$ (electromer A), then only ortho- and para-disubstituted derivatives (A' and A'') are formed. If HO^-Y^+ reacts only with $\text{C}_6\text{H}_5.\text{X}$ (electromer B), then only a meta-disubstituted derivative (B') results. If HO^-Y^+ interacts simultaneously with both electromers (A and B) then ortho-, meta-, and para-disubstituted derivatives (A' , B' and A'' , respectively) will be formed. The possibility and the extent of these reactions (as in all reactions with tautomeric substances) are dependent upon several conditions such as the solvent medium, catalytic agent, temperature, concentrations of the electromers, the speed of transition of one electromer into the other, and the respective speeds of interaction of the substituting agent with the respective electromers. These conditions are the problems which confront us in all research involving tautomers and likewise will be met in the case of electronic tautomers.

Having given a general scheme for the simultaneous formation of ortho-, meta- and para-disubstituted derivatives, one of the many examples which are in accord with and, therefore, confirm the scheme should now be considered. For instance, in the nitration of toluene, the substituent (X) already present in the nucleus is the methyl radical, which may function either positively or negatively; but in Part III it has been shown that its tendency to function negatively is more pronounced than its tendency to function positively, *i. e.*, $\text{CH}_3^- > \text{CH}_3^+$. Hence, in the tautomeric equilibrium, $\text{C}_6\text{H}_5.\text{CH}_3^- \rightleftharpoons \text{C}_6\text{H}_5.\text{CH}_3^+$, the former electromer would predominate and interaction with HO^-NO_2 would lead to a greater yield of *o*- and *p*-nitrotoluenes than of *m*-nitrotoluene. The predominance or preponderance of the electromer $\text{C}_6\text{H}_5.\text{CH}_3^-$ over the electronic tautomer $\text{C}_6\text{H}_5.\text{CH}_3^+$ may be correlated with the speeds of re-

action with nitric acid, *i. e.*, if the former electromer reacts more rapidly than does the latter electromer, then the yield of *o*- and *p*-nitrotoluenes would exceed that of *m*-nitrotoluene.¹ These assumptions are confirmed by experimental facts, since toluene when nitrated yields 56.00% of the *o*-, 40.90% of the *p*-, and 3.10% of the *m*-nitrotoluene. The simultaneous formation of the three isomers is indicated in the following scheme:

Consider now, on the other hand, the nitration of benzoic acid. The substituent (X) already present in the nucleus is CO₂H, which may function either positively or negatively, but CO₂H⁺ > CO₂H⁻, *i. e.*, the tendency for the carboxyl radical to function positively is more pronounced than is its tendency to function negatively.² Accordingly in the equilibrium, C₆H₅.CO₂H⁺ ⇌ C₆H₅.CO₂H⁻, the latter electromer (in which the carboxyl radical is positive) would predominate, and if its speed of interaction with HO.NO₂ is greater than the speed of interaction between C₆H₅.CO₂H⁺ and HO.NO₂ then the yield of *m*-nitrobenzoic acid should exceed that of the ortho and para compounds. These assumptions are confirmed by the facts, since benzoic acid on nitration yields 80.30% of the meta compound, 18.50% of the ortho, and 1.20% of the *p*-nitrobenzoic acid. The electronic equations conform to the general scheme given above.

Many other examples³ of the simultaneous formation of ortho-, meta-,

¹ The predominance of one electromer over the other may be regarded as equivalent to a greater concentration of the one electromer. Since concentration is a principle factor of the velocity of reaction, it is evident that a direct relationship exists between the predominance or preponderance of a given electromer and the velocity of the substitution reaction in which it is engaged.

² Other relationships between the properties of the carboxyl radical and its polarity are given by Fry, *THIS JOURNAL*, 36, 254-262 (1914).

³ Holleman, *Loc. cit.*, tabulations on p. 23.

and para-disubstituted derivatives of benzene might be presented in detail. They are in complete agreement with, and accordingly confirm, the principle of the electronic tautomerism of the electromers of the benzene derivatives, the general rule for substitution, and the scheme for the simultaneous formation of ortho-, meta-, and para-disubstituted derivatives of benzene.

(B) The Simultaneous Formation of Polysubstituted Derivatives of Benzene.

The principles underlying the simultaneous formation of polysubstituted derivatives of benzene are identical with those just given in the preceding section (A), and may be illustrated by considering the introduction of a third substituent (Z) into (1) an ortho-, (2) a para-, and (3) a meta-disubstituted derivative, C_6H_4XY .

Scheme (1).—Introduction of a Third Substituent Into an Ortho-Disubstituted Derivative.

Here the electronic tautomerism involves two electromers of an ortho-diderivative. These electromers will be designated by the letters A and B while their substitution products will be indicated by A', A'', etc., and B', B'', etc., respectively. The general scheme (1) for the introduction of the third substituent Z is as follows.

Theoretically and electronically four trisubstituted isomers are obtainable, namely, A' and A'' from electromer A, and B' and B'' from electromer B. A remarkable experimental confirmation of this scheme is found in the work of Wibaut¹ who showed that the nitration at 0° of *o*-chlorotoluene yielded all four possible mononitro compounds in considerable quantity. The electronic interpretation is embodied in the following equations, which are perfectly comparable to the equations of scheme (1) above. The percentage yield of each isomer will be indicated beneath the appropriate electronic formula.

¹ Wibaut, *Recueil*, 32, 244 (1913).

In section (B) of Part III it was shown that $\text{Cl} > \text{Cl}$, and $\text{CH}_3 > \text{CH}_3$, *i. e.*, the chlorine and methyl radicals tend to function negatively rather than positively, but in *o*-chlorotoluene (either electromer, A or B) the substituents must be opposite in polarity. This leads to the consideration of a significant question, namely, will the polarities of the substituents present in the nucleus predetermine in any way the relative quantities of the isomeric derivatives which are formed? In the simultaneous formation of the isomeric disubstituted derivatives of benzene the polarities of the substituents and the tendencies of certain substituents to function in one way rather than in another way were shown to be related to the relative quantities of the isomers (ortho and para on the one hand, and meta on the other) which were formed. Now in the case of *o*-chlorotoluene the two substituents present naturally tend to function negatively, but since one must function negatively while the other functions positively another question arises, namely, is the tendency for chlorine to function negatively more pronounced than the tendency for methyl to function negatively? The answer to this important question can be derived in an indirect way by comparing the general stability of methyl alcohol ($\text{HO} \cdot \text{CH}_3$) with that of hypochlorous acid ($\text{HO} \cdot \text{Cl}$). The latter is undoubtedly the less stable, since it is readily decomposed by light or heat, whereas methyl alcohol is a comparatively stable compound. Now, the instability and decomposition of hypochlorous acid involves the change, as previously shown, from Cl to Cl , and since $\text{HO} \cdot \text{Cl}$ is less stable than $\text{HO} \cdot \text{CH}_3$, naturally it may be assumed that the tendency for chlorine to function negatively is more pronounced than the tendency for methyl to function negatively, *i. e.*, $\text{Cl} > \text{CH}_3$. Or in equivalent terms, the tendency for methyl to function positively is more pronounced than the tendency

for chlorine to function positively,¹ i. e., $\overset{+}{\text{CH}_3} > \overset{+}{\text{Cl}}$, since $\overset{-}{\text{HO}}.\overset{+}{\text{CH}_3}$ is more stable than $\overset{-}{\text{HO}}.\overset{+}{\text{Cl}}$.

These relationships lead to the conclusion that of the two electromers (A and B) of *o*-chlorotoluene, the one (A), in which (Cl) is negative and (CH_3) is positive, would predominate, which in turn would indicate that the nitration of *o*-chlorotoluene might yield a greater quantity of the nitrochlorotoluenes A' and A'', than of the nitrochlorotoluenes B' and B''. These assumptions are confirmed by the facts, since Wibaut (*loc. cit.*) has determined the yields of the four mononitro-*o*-chlorotoluenes to which are assigned, herewith the abbreviated electronic formulas in conformity with the preceding scheme of substitution:

Electromer (A) \longrightarrow (A'), $\overset{+}{\text{C}_6\text{H}_5}.\overset{-}{\text{CH}_3}.\overset{+}{\text{Cl}}.\overset{+}{\text{NO}_2}$ (1,2,3).....	18.8%
Electromer (A) \longrightarrow (A''), $\overset{+}{\text{C}_6\text{H}_5}.\overset{-}{\text{CH}_3}.\overset{-}{\text{Cl}}.\overset{+}{\text{NO}_2}$ (1,2,5).....	43.4%
	62.2%
Electromer (B) \longrightarrow (B'), $\overset{-}{\text{C}_6\text{H}_5}.\overset{+}{\text{CH}_3}.\overset{+}{\text{Cl}}.\overset{+}{\text{NO}_2}$ (1,2,6).....	20.7%
Electromer (B) \longrightarrow (B''), $\overset{-}{\text{C}_6\text{H}_5}.\overset{+}{\text{CH}_3}.\overset{-}{\text{Cl}}.\overset{+}{\text{NO}_2}$ (1,2,4).....	17.0%
	37.7%

The combined yields of A' and A'' total 62.2% as against 37.7%, the combined yields of B' and B''.

Scheme (2).—Introduction of a Third Substituent Into a Para-Disubstituted Derivative.

Consider now the introduction of a third substituent into a para-disubstituted derivative of benzene according to the following scheme (2):

Theoretically and electronically two and only two trisubstituted derivatives are possible, namely, A' and B' from electromers A and B, respectively. One of several series of experiments which confirm the above scheme is the nitration at 0° of *p*-chlorotoluene by Holleman,² who demonstrated that only two mononitro-*p*-chlorotoluenes were produced. The

¹ The tendency for a radical to function in one way rather than in another way may be defined as its "polar stability." Other methods of determining the polar stability of a given radical will be described in a subsequent paper of this series.

² Holleman, *Recueil*, 28, 408 (1909).

correlation of these facts with the electronic formulas is embodied in the following scheme:

Since, as previously indicated, $\text{Cl}^- > \text{CH}_3^+$ and $\text{CH}_3^- > \text{Cl}^+$, electromer A would predominate and, accordingly, the nitration of *p*-chlorotoluene would be expected to yield a greater quantity of A', $\text{C}_6\text{H}_4(\text{CH}_3)(\text{Cl})(\text{NO}_2)$ (1, 4, 3), than of B', $\text{C}_6\text{H}_4(\text{CH}_3)(\text{Cl})(\text{NO}_2)$ (1, 4, 2). This assumption also is confirmed by the actual yields, namely, 58.00% of A' and 42.00% of B'.

Scheme (3).—Introduction of a Third Substituent Into a Meta-Disubstituted Derivative.

The introduction of a third substituent into a meta-disubstituted derivative of benzene corresponds to the following general scheme (3):

Since the substituents X and Y occupy positions meta to each other they must be of the same polarity, *i. e.*, both are negative in A while both are positive in B. Some interesting theoretical and experimental results present themselves depending upon the tendencies of X and Y to function positively or negatively. If both X and Y belong to that class of substituents which lead to the formation chiefly of ortho and para derivatives (which is the case when $\text{X}^- > \text{X}^+$ and $\text{Y}^- > \text{Y}^+$), then electromer A would predominate and the chief substitution products would be A', A'', and A'''. Furthermore, since X and Y are meta to each other and each is naturally negative, electromer A might predominate to the exclusion of electromer B; and the introduction of a third substituent Z

would lead to the formation of only three isomeric trisubstitution products, namely, A', A'', and A'''. Just such a case is found in the nitration at 0° of *m*-chlorotoluene by Wibaut (*loc. cit.*). The percentage yields of the isomers are indicated in the scheme:

Now it has been shown that the tendency for chlorine to function negatively is more pronounced than the tendency for methyl to function negatively, *i. e.*, $\text{Cl} > \text{CH}_3$. This leads to the assumption that the entering positive nitro radical would be more subject to the directing influence of Cl than of CH_3 . Now Cl directs NO_2 to the para position rather than to the ortho position, since chlorobenzene on nitration yields 69.90% of *p*-nitrochlorobenzene and 30.10% of *o*-nitrochlorobenzene. On the other hand, CH_3 directs NO_2 to the ortho position rather than to the para positions since toluene on nitration yields 56.00% of the *o*- and 40.90% of the *p*-nitrotoluene. Accordingly, when *o*-chlorotoluene is nitrated, one should expect the greatest yield to be that of isomer (A') in which NO_2 occupies a position para to Cl and ortho to CH_3 . A smaller yield would be predicted for that isomer (A'') in which NO_2 is ortho to Cl and para to CH_3 . The smallest yield would be predicted for the isomer (A''') in which NO_2 is ortho to Cl and ortho to CH_3 . These assumptions are fully confirmed by the facts since the respective yields of the three isomers, A', A'', and A''', are, respectively, 58.00%, 32.00%, and 8.80%.¹

Returning again to the general scheme (3) above, it should be noted that if X and Y belong to that class of substituents which lead to the formation chiefly of meta derivatives, which is the case when $X > X$ and $Y > Y$, then electromer B would predominate. Accordingly, the introduction of a third substituent Z would lead to the formation chiefly of the trisubstitution product in which all three substituents (X, Y and Z) are positive. Many examples are found in the literature which show that

¹ This constitutes a further proof that the polarities of the substituents in the nucleus and their tendencies to function in one way rather than in another way pre-determine not only the type of substitution but also the relative quantities of the isomers produced.

when the substituents in the nucleus are positive, the entering substituent assumes a position meta to those present, and the predominating isomer corresponds to B', the derivative of electromer B. Exact quantitative data upon the amounts of the other possible isomers have not been found in the literature.

Having considered all of the possibilities which might be encountered in the introduction of a third substituent Z into an ortho-, a para-, and a meta-disubstituted derivative, C_6H_4XY , of benzene, and having shown that experimental facts and data are in agreement with the theoretical deductions, with the electronic formulas, and the principle of electronic tautomerism, and with the general electronic rule for substitution, it should be added that the formation of other poly-substituted derivatives of benzene will conform in general to the principles and rule previously developed and illustrated. This claim is warranted by a careful study of the numerous tables of the variously substituted derivatives of benzene which have been compiled with great care and presented by Holleman in his extended work¹ on the influence of the substituents in the benzene nucleus, and the principles of substitution.²

(C) The Mechanism of Electronic Tautomerism of Benzene Derivatives.

The important part played by the principle of electronic tautomerism in the explanation of substitution in the benzene nucleus leads to the consideration of a mechanism which involves the centric valences of the carbon atoms of the nucleus. The key to this mechanism is embodied in the assumption (to be substantiated by experimental facts) that when a given hydrogen atom or substituent is negative it is united to a carbon atom which possesses a positive centric valence. On the other hand, when a hydrogen atom or substituent is positive it is united to a carbon atom which possesses a negative centric valence. These assumptions are embodied in the following formulas illustrating more completely

¹ Die direkte Einführung von Substituenten in den Benzolkern.

² Sur les règles de substitution dans le noyau benzique (*Loc. cit.*).

the electronic tautomerism of a monosubstituted derivative. The electronic tautomerism of a polysubstituted derivative would conform to the same principles and scheme.

When $\overset{-}{X}$ becomes $\overset{+}{X}$ ($\overset{-}{X} \rightarrow \overset{+}{X} + 2\ominus$) the polarity of the carbon valence binding X is changed from positive to negative, *i. e.*, in terms of the electronic conception of oxidation and reduction, the positive valence has been reduced to a negative valence. On the other hand, when $\overset{+}{X}$ becomes $\overset{-}{X}$, the valence binding X is changed from negative to positive, *i. e.*, it is oxidized. Simultaneously, corresponding changes occur in the polarities of each of the other hydrogen atoms or substituents and the carbon valences binding same. In other words, for each oxidation there is a corresponding reduction; otherwise, the symmetry and consequently the stability of the benzene nucleus would be destroyed.¹

Another important point to be observed in the above scheme is that the transition from the one electromer to the other involves a change in the polarity of each centric valence. This type of change has been defined as "centric rearrangement." A complete scheme of the several possible centric formulas of benzene and their transitions to the Kekulé formulas has been shown to involve changes from double bonds of the type $\overset{+}{C} \equiv \overset{-}{C}$, defined as "contraplex," to double bonds of the type $\overset{-}{C} \equiv \overset{+}{C}$, defined as "diplex." Such changes, "contraplex-diplex transitions," take place in those compounds which show distinct bands in their absorption spectra.² Accordingly, they serve as a structural basis for the relationship between chemical constitution and absorption spectra. In other words, the rearrangements of the centric valences and the concomitant contraplex-diplex transitions cause a disturbance in the vibrations of the systems of electrons, whereby light of correlated period is absorbed in accordance with the theory of resonance. By means of the various electronic formulas of benzene and their systems of dynamic equilibria, I have been able to demonstrate that a definite relationship exists between the oscillation frequencies of the seven bands in the absorption spectrum of benzene and the numbers of contraplex-diplex transitions involved, which function as the origin of the respective absorption bands. This relationship is that of a linear function expressed by the equation, $y = 21.60628x + 3679.509$, in which (y) is the oscilla-

¹ An explanation of the stability of the benzene nucleus based upon the fact that the number of positive hydrogen atoms of the nucleus must be equal to the number of negative hydrogen atoms, is given by Fry, *THIS JOURNAL*, 36, 270 (1914).

² The definitions and principles indicated in this paragraph are fully described in a paper on the absorption spectra of benzene, Fry, *Z. physik. Chem.*, 76, 398 (1911).

tion frequency of a given band, and (x) is the number of contraplex-diplex transitions functioning as the origin of the given band. The deviations of the calculated frequencies from the observed frequencies were less than the limits of error in experimental observation. Other similar and exact relationships were developed and found to hold for the oscillation frequencies of the absorption bands of naphthalene,¹ chlorobenzene and bromobenzene,² and for the fluorescence bands of anthracene and phenanthrene.³ This work has been briefly indicated here because through these physical measurements an experimental confirmation is offered for the hypothesis of contraplex-diplex transitions which involve centric rearrangements, *i. e.*, changes in the polarities of the centric valences of benzene. These centric valences and rearrangements will now be shown to play a very definite part in the further development of the mechanism of substitution on the benzene nucleus.

(D) The Mechanism of Substitution in the Benzene Nucleus and an Electronic Interpretation of the Hypothesis of Holleman.

Holleman in his work on "Die direkte Einführung von Substituenten in den Benzolkern" has described and discussed the various hypotheses which have been advanced at different times to explain the rules of substitution, but he is of the opinion that none of these hypotheses are able to give a satisfactory explanation of the facts. Furthermore, Holleman, in a very recent paper⁴ makes this statement:

"Notwithstanding the fact that the problem of substitution in the benzene nucleus has been studied intensively enough of late, there still remains a fundamental question which has not yet been solved; it is the question of knowing the reason why such or such group directs a new substituent chiefly to the para-ortho positions or chiefly to the meta position."

A propos of this statement, it has been shown in Part III, Section B, of this series of papers (and in previous papers) that the electronic formula of benzene and the electronic interpretation of the Brown and Gibson rule afford an explanation, in the sense that if the substituent in the nucleus is negative then the entering positive substituent must assume a position either ortho or para to the substituent already present; and, if the substituent in the nucleus is positive, then the entering positive substituent must assume a position meta to the one already present. This hypothesis has been substantiated by numerous examples of substitution. The mechanism, or schemes, for these reactions as previously presented involved the simplified electronic formulas for benzene indicating only the polarities of the hydrogen atoms and substituents,

¹ Fry, *Z. physik. Chem.*, **76**, 591 (1911).

² Fry, *Ibid.*, **82**, 665 (1913).

³ Fry, *Ibid.*, **80**, 29 (1912).

⁴ *Recueil*, **33**, 1 (1914).

and the electronic formulas of the substituting reagents; but, since it is generally conceded that substitution in the nucleus involves (1) the addition of the substituting reagent (for example, $\overset{-}{\text{HO}}\overset{+}{\text{Y}}$) and (2) the elimination of certain elements (for example, $\text{H}\cdot\overset{+}{\text{OH}}$), it follows that any mechanism proposed to account for these changes (1 and 2) must consider the part played by the centric valences or the double bonds of the nucleus. For the present, it is simpler to indicate the part played by the free centric valences in effecting the addition of the substituting reagent, rather than to picture the part as played by the "opening up" or "breaking" of the double bonds. In either case, the mechanism of the change involved would amount to one and the same thing, since the centric formula is simply an intermediate phase between those Kekulé formulas or phases which possess double bonds.

From the above points of view a more complete mechanism of substitution will be indicated; first, for the formation of an ortho-disubstituted derivative, in which case the substituent (X) present in the nucleus functions negatively and the entering substituent (Y) is positive. The formulas will indicate only the polarities of the bonds or valences which are immediately related to the particular changes.

The formation of a para-disubstituted derivative also involves the electromer in which X is negative and the entering substituent Y, positive.

On the other hand, the formation of a meta-disubstituted derivative involves the electromer in which X is positive and the entering substituent Y is positive.

In each of the above schemes, the addition of the radicals of the substituting reagent ($\text{HO}\cdot$ and $\text{Y}\cdot$) engages only two of the six centric valences. The remaining centric valences lend themselves to the formation of double bonds in the addition product. This addition reaction is followed by the

elimination of $\overset{+}{\text{H}}$ and $\overset{-}{\text{OH}}$ as water and a consequent return to the centric formula of the disubstituted derivative.

The substitution of halogen ($\text{Y}_2 = \overset{+}{\text{Y}} + \overset{-}{\text{Y}}$) would correspond to the addition of $\overset{+}{\text{Y}}$ and $\overset{-}{\text{Y}}$ to the centric valences with the subsequent elimination of $\overset{+}{\text{H}}\cdot\overset{-}{\text{Y}}$ and the fixing of $\overset{+}{\text{Y}}$ in the nucleus either ortho or para to $\overset{+}{\text{X}}$, or meta to $\overset{+}{\text{X}}$. In paper II of this series (*loc. cit.*) a mechanism was given for the action of halogen carriers in effecting nucleus substitution which is also readily correlated with the above schemes. The halogen carrier forms an unstable addition compound with the radicals $\overset{+}{\text{Y}}$ and $\overset{-}{\text{Y}}$ of the halogen molecule Y_2 . This unstable addition compound either induces the direct combination of $\overset{+}{\text{Y}}$ and $\overset{-}{\text{Y}}$ with centric valences, or the dissociation products of the addition compound itself combine with the centric valences. In either event, subsequent elimination of $\overset{+}{\text{H}}\cdot\overset{-}{\text{Y}}$ and the carrier results in the nucleus substitution of $\overset{+}{\text{Y}}$.

An examination of the preceding mechanisms of substitution shows that the *polarity of the substituent X present in the nucleus and the polarities of the centric valences predetermine the types of substitution which result in the formation either of ortho- and para-derivatives, or of meta-derivatives.* If both electromers ($\text{C}_6\text{H}_5\cdot\overset{+}{\text{X}}$ and $\text{C}_6\text{H}_5\cdot\overset{-}{\text{X}}$) interact with $\text{HO}\cdot\overset{+}{\text{Y}}$, simultaneous formation of ortho-, para-, and meta-derivatives follows as previously described and confirmed by extended experimental facts and data.

It may now prove interesting to show that the mechanism for the formation of ortho-para and meta classes of derivatives as proposed by Holleman may be correlated with the electronic formulas and substitution schemes presented in this paper.

On the basis of the Kekulé formula (the centric formula would apply equally well) Holleman supposes that the substituent X, already present in the nucleus, may either promote or retard the addition of the radicals

of the substituting reagent to the double bonds (or centric valences). If X promotes addition, the ortho and para compounds are formed, addition having taken place in position 1,2 (or 1,6) and 1,4, respectively. Conjugation is assumed to cause the addition in the para (1,4) position according to Thiele's hypothesis. On the other hand, the addition of the substituting reagent to the double bond (or centric valences) of carbon atoms 2 and 3 cannot be greatly influenced by X, because X is not in direct relation with these atoms. In other words, under the influence of X, the speed of addition to position 1,2 (or 1,6) and 1,4 is either accelerated or retarded, while the speed of addition to position 2,3 (or 5,6) is about the same as in the unsubstituted benzene itself. Accordingly, when X accelerates the reaction, substitution takes place in positions ortho and para; when the acceleration is great, the ortho and para products will be formed exclusively, for the quantity of the meta product which could be formed simultaneously through addition to position 2,3 is then so small that it is not perceptible. When, on the other hand, the acceleration is not so great, the meta isomer may also be formed.

In the case where X retards the reaction, the addition to position 2,3 predominates and proceeds more rapidly than the addition to position 1,2 (or 1,6) and 1,4. The meta isomer then becomes the principal product.

Holleman illustrates the mechanism of these types of addition by supposing C_6H_5X to undergo nitration, in which case nitric acid adds as HO and NO_2 . The addition compounds are as follows:

By the subsequent removal of H and OH as water, an ortho, a para or a meta compound is formed.

Now it should be noted that the above addition compounds as formulated by Holleman are identical with the electronic formulas for the addition compounds previously indicated, but with this important exception: the electronic formulas, by indicating the polarities of the hydrogen atoms, the substituents, the centric valences, and the radicals of the substituting reagent, make possible a formula-mechanism by which addition must take

place in one way rather than in some other way. On the other hand, the ordinary Kekulé and centric formulas cannot, *per se*, indicate why addition should proceed in one way rather than another. For instance, the addition of $\text{HO}.\text{NO}_2$ in Holleman's scheme unites OH to carbon atom 1, and NO_2 to carbon atom 6. Now as far as the regular Kekulé or centric formula is concerned OH might just as well unite to atom 6 while NO_2 unites to atom 1. Other additions are structurally possible in positions 1,4 and 2,3. In other words, six types of addition instead of the three as indicated by Holleman are possible from the standpoint of the ordinary structural formulas. Hence, it is evident that some qualification or limitation of the types of addition must be made. This, of course, is true of any hypothesis which deals with structural formulas and proposed mechanisms of reaction, but the marked superiority of electronic formulas over ordinary structural formulas lies in the fact that the valences of the atoms and radicals may be qualified, in conformity with facts of experiments, as positive or negative, a distinction which cannot be embodied in the ordinary formulas. Therefore, a valence hypothesis which permits of such qualifications possesses greater significance in the interpretation of chemical phenomena than the ordinary valence hypothesis.

It may now be demonstrated that Holleman's formulas for the ortho, para, and meta addition compounds may be interpreted in terms of positive and negative valences. Furthermore, this interpretation logically leads to the same electronic formulas that were proposed for these addition compounds in the first part of this section (D). This necessarily follows if we admit that the electronic formulas of water and nitric acid are $\overset{+}{\text{H}}.\overset{-}{\text{OH}}$ and $\overset{-}{\text{HO}}.\overset{+}{\text{NO}_2}$, respectively; and, that the benzene molecule is symmetrically constituted, *i. e.*, from the electronic point of view that for every positive charge or valence there is a corresponding negative charge or valence. The correlation of Holleman's formulas with the electronic formulas is as follows:

In Holleman's ortho addition compound, the union of OH with carbon atom 1 and $\overset{+}{\text{NO}_2}$ with carbon atom 2 or 6 means that the free valence of atom 1 is positive while that of atom 2 or 6 is negative. In the para addition compound, $\overset{+}{\text{NO}_2}$ unites to carbon atom 4 which, accordingly, possesses a free negative valence. In other words, the ortho and para addition compounds show that the centric valences of positions 2, 4, and 6 are negative while 1 is positive. Consequently, from the symmetry standpoint, the centric valences of positions 3 and 5 are positive just as 1 is positive.

The polarities of the hydrogen atoms and substituents of the nucleus are indicated by Holleman's assumption that the disubstituted derivative

is formed through the elimination of water, H.OH . In Holleman's formula for the ortho addition compound, the hydrogen atom of position 2 or 6 is eliminated with the hydroxyl radical of position 1; and in the para addition compound the hydrogen atom of position 4 is likewise eliminated with hydroxyl of position 1. Since the elimination of water is the union of H and OH, it follows that the hydrogen atoms of positions 2, 4, and 6 of the ortho and para nitrocompounds of Holleman are positive. Consequently, from the symmetry standpoint, the hydrogen atoms or substituents of position 1, 3, and 5 are negative. As a matter of fact, the ortho and para nitrocompounds, in which $\text{X} = \text{Cl}$ or Br , readily exchange X for hydroxyl on treatment with aqueous potassium hydroxide: since OH is negative, X is accordingly negative.

Having correlated Holleman's ortho and para compounds with the electronic formulas, consider, on the other hand, his formula for the meta addition compound. Here, HO unites with the free valences of carbon atoms 2 or 6, while NO_2 combines with those of atoms 3 or 5. Hence, the free or centric valences of positions 2 and 6 are positive while those of positions 3 and 5 are negative; and from the electronic symmetry standpoint, the remaining centric valences of positions 1 and 4 must be negative and positive, respectively. Thus in the meta nitrocompound the centric valences of carbon atoms 1, 3, and 5 are negative while those of atoms 2, 4 and 6 are positive. Considering the polarities of the hydrogen atoms and substituents, NO_2 replaces the hydrogen atom of position 3 or 5, which is accordingly positive. From the symmetry standpoint X of position 1 should also be positive. As a matter of fact, when $\text{X} = \text{NO}_2$, as in nitrobenzene ($\text{C}_6\text{H}_5\text{NO}_2$), the entrance of a second NO_2 is in positions 3 or 5, meta to position 1. Furthermore, when $\text{X} = \text{Cl}$ or Br in the meta nitrocompounds, X is not directly replaceable by negative hydroxyl and is presumably positive. The atoms of positions 1, 3 and 5 being positive, those of positions 2, 4 and 6 are negative.

From the above it is evident that Holleman's formulas and mechanism of substitution may be interpreted in terms of positive and negative valences, and the electronic formulas thereby developed are correlated with the electronic formulas and principles previously presented. Therefore, the numerous cases of substitution which have been interpreted by Holleman's hypothesis are also interpreted by the electronic formulas and principles which possess the added significance of showing why certain substituents (which are negative) lead to the formation of ortho- and para-derivatives, while others (which are positive substituents) lead to the formation of meta-derivatives.

The remaining features of Holleman's substitution hypothesis to be considered from the positive and negative viewpoint relate to the velocities of the substitution reactions and their dependence upon the nature of the substituents which are present in the nucleus. Thus, when a substituent, X, accelerates the substitution reaction, substitution follows the ortho-para rule which may lead to the exclusion of any meta compound. If X has no such accelerating effect, smaller or larger quantities of the meta compound will be formed. These facts make it possible to predict the place that a third substituent C will occupy in the nucleus of a disubstituted derivative, C_6H_4AB . This place is determined by Holleman by measuring the speeds of substitution of C in C_6H_5A and in C_6H_5B , and by ascertaining the proportions in which the isomers of C_6H_4AC and C_6H_4BC are formed in each case. A comparative study from these points of view enables Holleman to determine the relative effects of different substituents upon the speeds of substitution reactions. Thus, one substituent, HO, is found to have a greater accelerating effect than another, NH_2 (represented thus, $OH > NH_2$); and a comparison of these relative effects leads to a series. For instance, the substituents which lead to the formation of ortho- and para-derivatives are arranged thus: $OH > NH_2 > \text{halogens} > CH_3$. The substituents which lead to the formation of meta-derivatives present the series: $CO_2H > CHO > SO_3H > NO_2$.

A *propos* of his hypothesis, Holleman has just recently stated¹ that the cause for the different accelerating effects of the different substituents has not yet been explained. This "cause" may be interpreted in terms of the electronic conception of positive and negative valences, since I have shown that the types of substitution are directly related to the polarities of the substituents present in the nucleus and the tendencies of these to function in one way rather than in another way. For instance, as shown in Part III, those substituents which lead chiefly to the formation of ortho- and para-derivatives are the substituents which tend to function negatively rather than positively ($\overset{-}{X} > \overset{+}{X}$), while those substituents which lead chiefly to the formation of the meta compound are the very substituents which tend to function positively rather than negatively ($\overset{+}{X} > \overset{-}{X}$). Moreover, a substituent which is naturally negative may manifest a greater tendency to function negatively than another negative substituent, thus ($\overset{-}{X} > \overset{-}{Y}$); and analogously for positive substituents there exists the relation ($\overset{+}{X} > \overset{+}{Y}$). These respective tendencies were shown in Sections A and B of Part IV to account for the preponderance of one electromer over another in the electronic tautomerism of benzene derivatives. This preponderance or increased concentration, in turn, accounted for the rela-

¹ *Recueil*, 33, 1 (1914).

tive yields of the several possible isomers. Therefore, if the greater concentration of one electromer in the equilibrium system is determined by the tendencies of its substituents to function in one way rather than in another way, and since the speed of a reaction is a factor of the concentrations of the interacting substances, it follows that the speed of a substitution reaction is dependent upon the polarities of the substituents present in the nucleus and their respective tendencies to function in certain ways. From this point of view it follows that Holleman's series ($\text{OH} > \text{NH}_2 > \text{halogens} > \text{CH}_3$) may be represented thus: $\text{OH} > \text{NH}_2 > \text{halogens} > \text{CH}_3$. The other series is as follows: $\text{CO}_2\text{H} > \text{CHO} > \text{SO}_3\text{H} > \text{NO}_2$.

If the tendency for a substituent to function in one way rather than in another way be defined as the "polar stability of the substituent," it follows that the velocities of substitution reactions in the benzene nucleus are functions of the polar stabilities of the substituents of the nucleus. In other words, the polar stabilities of the substituents determine the concentrations of the electromers, which concentrations are the principle factors in determining the velocities of the substitution reactions.

A summary of Part IV may be omitted since the several topics discussed have been presented in separate sections with contents indicated. This paper, however, should be concluded with the following general statements: The conception of the electronic tautomerism of the derivatives of benzene furnishes an explanation of (1) the types of substitution and the simultaneous formation of ortho-, para-, and meta-substituted derivatives; (2) it renders possible the prediction of the relative yields of the isomers which are dependent upon the preponderance or increased concentration of one electromer over the other; (3) the concentrations of the electromers are predetermined by the "polar stabilities" of the substituents in the nucleus; (4) the velocities of substitution reactions are functions of the polar stabilities of the substituents. Accordingly all facts that are explained in terms of the velocities of reactions may be interpreted in terms of the polar stabilities of the substituents. This phase of substitution in the benzene nucleus will be considered in detail in a subsequent paper.

V. A REPLY TO A. F. HOLLEMAN.

In a recent paper¹ entitled "Substitution in the Benzene Nucleus," Dr. A. F. Holleman has taken exceptions to the electronic formula for benzene and the general rule for substitution; and has offered a number of objections. In view of the principles developed in the preceding

¹ THIS JOURNAL, 36, 2495 (1914).

Part III, and the many applications of the conception of the electronic tautomerism of benzene derivatives presented in Part IV, it may now be shown that the chief objections offered by Holleman actually confirm and substantiate the electronic formulas for benzene and the rule for substitution. Other incidental objections will be considered in course of the reply.

In Holleman's paper the several objections are presented in separate paragraphs numbered 1-6. The present reply will consider the contents of each of these paragraphs in the same order.

(1) Holleman's first objection is directed against the assumption that monochlorobenzene may be an equilibrium mixture of two tautomeric electromers, $\overset{+}{\text{C}_6\text{H}_5}.\overset{-}{\text{Cl}}$ and $\overset{-}{\text{C}_6\text{H}_5}.\overset{+}{\text{Cl}}$. Granting such to be the case, Holleman maintains that if $\overset{+}{\text{C}_6\text{H}_5}.\overset{-}{\text{Cl}}$ is stable, $\overset{-}{\text{C}_6\text{H}_5}.\overset{+}{\text{Cl}}$ would be unstable. This I also admit provided we qualify this stability or instability in terms of the tendency for chlorine to function negatively rather than positively, *i. e.*, $\overset{-}{\text{Cl}} > \overset{+}{\text{Cl}}$, which tendency explains the preponderance or greater concentration of the one electromer over the other and the consequent increase in its reaction velocity. But to Holleman's statement that

("in *o*- $\text{C}_6\text{H}_4\text{Cl}_2$ and *p*- $\text{C}_6\text{H}_4\text{Cl}_2$, where one atom is negative and the other positive, we have perfectly stable compounds,")

the reply may be made that the existence of a perfectly stable compound is questionable. Stability is only a relative term and a given compound, so to speak, may be perfectly stable under one set of conditions, but unstable under others. Furthermore, a given atom or radical may be reactive in one compound but nonreactive in another: for example, the replacement of chlorine in *o*- and *p*-chloronitrobenzene by OH on interaction with $\overset{+}{\text{K}}.\overset{-}{\text{OH}}$; and the nonreplacement of chlorine in *m*-chloronitrobenzene under the same conditions. Again, in one and the same compound such as *o*- and *p*-dichlorobenzene (compounds which Holleman regards as perfectly stable) there exist differences in the reactivities of their chlorine atoms, depending upon one being positive while the other is negative. This is evidenced by the fact demonstrated by de Mooy in Holleman's laboratory that each of these compounds exchanges one chlorine for OCH_3 on interaction with sodium methylate. This difference in the reactivities of the chlorine atoms is illustrated by the following electronic equation:

In this connection it should be noted that if halogen (X) is introduced into the benzene nucleus (either through interaction with $\overset{-}{\text{HO}}.\overset{+}{\text{X}}$ or through

the action of a halogen carrier such as SbX_3) the resultant electromer $\text{C}_6\text{H}_5.\overset{+}{\text{X}}$ would revert chiefly to the tautomer $\text{C}_6\text{H}_5.\overset{-}{\text{X}}$, because of the tendency $\overset{-}{\text{X}} > \overset{+}{\text{X}}$. This tendency for $\overset{-}{\text{X}}$ to function negatively rather than positively is a distinctive property and should not be confused with the replaceability of $\overset{-}{\text{X}}$ by $\overset{-}{\text{OH}}$ or by $\overset{-}{\text{OCH}_3}$.

Again, Holleman maintains that if chlorobenzene is a mixture of $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$ and $\text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$, the nitration of such a mixture ought to yield *o*- and *p*-chloronitrobenzenes (derived from $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$) and *m*-chloronitrobenzene (derived from $\text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$), when, in reality, only the ortho- and para-disubstituted compounds are formed. In reply, recall the facts presented in Part IV, Sections A and B, showing that $\overset{-}{\text{Cl}} > \overset{+}{\text{Cl}}$, which tendency accounts for the preponderance or increased concentration of $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$ over $\text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$. Accordingly, the speed of interaction of the former electromer with nitric acid would exceed that of the latter electromer. Now in terms of Holleman's own hypothesis on the speeds of reaction and type of substitution, if the speed of substitution is sufficiently great, *o*- and *p*-chloronitrobenzenes would be formed to the exclusion of the meta compound. Therefore, Holleman's experimental demonstration that chlorobenzene yields only *o*- and *p*-chloronitrobenzenes may be accepted as proof that in the tautomeric equilibrium, $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}} \rightleftharpoons \text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$, the former electromer interacts exclusively with $\text{HO}.\text{NO}_2$. In contending that both electromers must interact with nitric acid, Holleman has disregarded the general principle that in a tautomeric equilibrium mixture, either one or the other, or both tautomers may interact with a given reagent. See Part IV, Section B, third paragraph, for further description and electronic equations.

(2) In his second paragraph Holleman states that:

"Fry maintains that the iodine is positive in iodobenzene, since it is formed from sodium benzoate and iodine chloride, the latter having the formula $\text{Cl}-\overset{+}{\text{I}}$. But iodobenzene also yields para and ortho compounds on nitration, just as the other halogen-benzenes, though in these the halogen is admitted to have a negative charge."

In reply, Holleman has misstated me with reference to iodobenzene since the reaction in question is that of $\text{Cl}-\overset{+}{\text{I}}$ upon silver benzoate (not sodium benzoate)¹ showing that the iodine atom in iodobenzoic acid (and not iodobenzene) is positive. The nitration of iodobenzene from the electronic point of view is identical with the nitration of the other

¹ As described in THIS JOURNAL, 36, 254-255 (1914).

halogen-benzenes, $\text{C}_6\text{H}_5.\overset{+}{\text{X}} \rightleftharpoons \text{C}_6\text{H}_5.\overset{-}{\text{X}}$, in which the former electromer may predominate to the exclusion, of the latter, whereupon only ortho- and para-derivatives are formed.

Further, Holleman states:

"It is somewhat striking that Fry admits on p. 252, *Loc. cit.*, that chlorobenzene has the formula $\text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$, whereas he declares on p. 264, that it has been impossible so far to prove directly, whether the chlorine atom in monochlorobenzene is positive or negative."

In reply, the first part of the above statement is a misinterpretation since my original statement was as follows (*loc. cit.*, pp. 251-2): "According to the principles previously developed from the Crum Brown and Gibson Rule, the electronic formula of chlorobenzene is $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$ while that of nitrobenzene is $\text{C}_6\text{H}_5.\overset{+}{\text{NO}_2}$." In other words, chlorobenzene is a derivative of $\text{H}.\overset{+}{\text{Cl}}$ from the standpoint of the Brown and Gibson Rule, and, accordingly, is regarded as $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$. In the further development of this rule and the electronic tautomerism of benzene derivatives, chlorobenzene is $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}} \rightleftharpoons \text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$. My statement (*loc. cit.*, p. 264): "it has been impossible so far to prove directly whether the chlorine atom in monochlorobenzene is positive or negative"—was made with reference to the possibility of hydrolyzing chlorobenzene so as to obtain: (1) from $\text{C}_6\text{H}_5.\overset{+}{\text{Cl}}$, the products $\text{C}_6\text{H}_5.\overset{+}{\text{OH}}$ and $\text{H}.\overset{+}{\text{Cl}}$; and (2) from $\text{C}_6\text{H}_5.\overset{-}{\text{Cl}}$, the products $\text{C}_6\text{H}_5.\overset{-}{\text{H}}$ and $\text{HO}.\overset{-}{\text{Cl}}$. This has not been possible with chlorobenzene but similar hydrolyses have been accomplished with benzene sulfonic acid (*loc. cit.*, p. 265).

The objections presented in paragraph (2) are thus shown to involve a misstatement and a misinterpretation neither of which invalidates the electronic formula for benzene or the rule for substitution.

(3) In his third paragraph Holleman states that:

"According to Fry, 'the radical SO_3H in phenylsulfonic acid may function either positively or negatively.' He deduces this from the fact that this acid yields benzene on heating with water or acids, but phenol on melting with alkali. But since in *o*- and *p*-phenylene disulfonic acid one SO_3H should be positive when the other is negative, these acids should yield phenol exclusively on melting with alkali. In reality they yield pyrocatechol and hydroquinol."

In reply this objection is apparently justified but it is invalidated by Holleman's failure to take into account the fact that whether the SO_3H radical be positive or negative, in alkaline solution it functions negatively. For instance, since phenylsulfonic acid is a mixture of tautomeric electromers ($\text{C}_6\text{H}_5.\overset{+}{\text{SO}_3\text{H}} \rightleftharpoons \text{C}_6\text{H}_5.\overset{-}{\text{SO}_3\text{H}}$), the former would revert to the latter in acid solution, but in alkaline solution the latter reverts to the

former, *i. e.*, SO_3H^+ becomes SO_3H^- and is replaced by OH^- on hydrolysis. Applying this principle to *o*- or to *p*-phenylene disulfonic acid, each containing (SO_3H^+) and (SO_3H^-) , fusion with alkali would cause both radicals to function negatively with consequent replacement by negative hydroxyl yielding pyrocatechol and hydroquinol:

At once it will be contended that these electronic formulas are exceptional since the general rule has consistently maintained that substituents ortho and para to each other are of opposite polarity. Granting the above formulas to be exceptions we are presented with evidence that substantiates a fundamental principle, namely, that if the polarities of the hydrogen atoms or substituents of the nucleus do not conform to the general electronic formula for benzene, then the stability of the benzene nucleus is radically affected. Now this ensuing instability actually manifests itself in the fact that *o*-, *m*-, and *p*-bromobenzenesulfonic acids, and *m*- and *p*-phenylene disulfonic acids, all yield one and the same dihydric phenol—namely, the *meta* compound, resorcinol, on fusion with potassium hydroxide. Perkin and Kipping,¹ commenting upon these anomalies state that the ortho and para dihydric compounds which are first produced from the corresponding bromosulfonic acids (or from the corresponding phenylene disulfonic acids) are unstable and are converted into the more stable *meta*-derivative by intramolecular change. Now the electronic hypothesis readily furnishes an interpretation of this instability as due to the disarrangement of the electronic symmetry of the electrical charges when radicals ortho or para to each other are of the same sign. For instance, all of the changes involved in the conversion of *p*-phenylenedisulfonic acid to resorcin are illustrated in the following electronic formulas and scheme:

¹ "Organic Chemistry," pp. 436-7 (1911).

Formula 1 is the natural symmetrical *p*-disulfonic acid. In alkaline medium SO_3H becomes SO_3H^- , *i. e.*, the negative valence of C-atom 4 is converted to a positive valence (by the loss of two electrons which render SO_3H negative) and the resulting Formula 2 is not symmetrical. Hydrolysis yields the nonsymmetrical and unstable dihydric phenol of Formula 3 which undergoes intramolecular rearrangement. This rearrangement may be attributed to two tendencies: first, $\text{OH} > \text{H}$, and second, $\text{H} > \text{H}$. The first is fulfilled when OH occupies position 3 meta to OH in position 1. The second leads to the change in the polarity of carbon valence 4, H becoming H^+ (as in Formula 5) which completes the transition to the symmetrical and stable resorcin.

(4) In the fourth paragraph, Holleman indicates the electronic formulas of *p*-chlorotoluene and *p*-chlorobromobenzene and maintains that if Fry's rule were correct we should obtain, on nitration, only one nitrochlorotoluene and only one nitrochlorobromobenzene; when, as a matter of fact, Wibaut and Heineken proved that in both cases, considerable quantities of two isomers are obtained. In reply, this objection is invalidated because Holleman failed to take into account the two electromers (electronic tautomers) of each of these para compounds. A detailed explanation of the introduction of a third substituent Z ($= \text{NO}_2$) into a paradisubstituted derivative, $\text{C}_6\text{H}_4\text{XY}$ ($\text{X} = \text{Cl}$; $\text{Y} = \text{CH}_3$ or Br) is given in detail in Part IV, Section B, Scheme 2, which shows that the researches of Wibaut (as quoted by Holleman) actually confirm the electronic tautomerism of the derivatives and rule for substitution.

Again, Holleman states that the nitration of *o*-chlorotoluene yields, as shown by Wibaut, all four possible isomers of nitrochlorotoluene, while Fry's rule predicts the formation of only two isomers. In reply, Holleman again fails to consider the part played by both tautomeric electromers of *o*-chlorotoluene on nitration. In Part IV, Section B, Scheme 1, I have shown that the introduction of a third substituent into an ortho-disubstituted derivative yields four possible isomers. The work of Wibaut, discussed in this section, affords a striking confirmation of the electronic tautomerism of *o*-chlorotoluene and the electronic scheme for its nitration.

The fact that Holleman obtains only two isomers when *o*-chlorobromobenzene is nitrated accords with the fact that only one of the electromers enters into reaction with nitric acid. This is perfectly analogous to the nitration of monochlorobenzene in which only one electromer enters into reaction with consequent formation of only two isomers.

In concluding this part of the reply, each of the objections cited by Holleman in the fourth paragraph of his criticism, accords with and, therefore,

substantiates the electronic formulas, the schemes of electronic tautomerism and the rule for substitution as resented in Part IV, Section B.

(5) In his fifth paragraph Holleman states:

"Fry's explanation of the fact that the chlorination of nitrobenzene yields *m*-nitrochlorobenzene, can neither be accepted. He supposes that $\text{HO} \cdot \text{Cl}$ is the chlorinating agent 'since absolutely anhydrous chlorine does not react with anhydrous reagents.' However, this introduction of chlorine is only possible, when a large quantity of SbCl_5 is added ($1/5$ of the weight of the nitrobenzene). All traces of water must be taken away by it."

In reply, it cannot be asserted absolutely that all traces of water are removed by SbCl_5 because its interaction with water is a decidedly reversible reaction which may be represented electronically as follows:

Holleman then continues:

"The only plausible explanation is, that SbCl_6 is formed which transports chlorine to the nitrobenzene. As there can be little doubt that SbCl_5 is SbCl_5 (always according to the views of Fry), chlorine ought to replace an *o*- or *p*-H-atom in $\text{C}_6\text{H}_5\text{NO}_2$, when NO_2 in it is positive."

In reply to this statement, I am perfectly willing to admit that SbCl_5 may act as a halogen carrier through the intermediate formation of SbCl_6 , but I have never claimed (as attributed to me by Holleman) that SbCl_6 is SbCl_6 , which as an electronic formula is meaningless. The electronic formula for SbCl_5 is given in the hydrolysis equation above, and its combination with chlorine to act as a halogen carrier is as follows:

Now, in Part II of this series, THIS JOURNAL, 36, on page 1042, I have given an explanation and scheme for the action of halogen carriers in effecting the nucleus substitution of *positive halogen*. The action of SbCl_5 as a halogen carrier conforms perfectly with this explanation and scheme for the nucleus substitution of positive chlorine which must assume a position meta to the positive nitro radical in nitrobenzene. See the complete electronic scheme for the formation of a meta-disubstituted de-

rivative in Part IV, Section D, which also shows that positive chlorine must replace a meta-hydrogen atom in $\text{C}_6\text{H}_5.\text{NO}_2$ and not an ortho or para hydrogen atom as incorrectly attributed to my hypothesis by Holleman.

(6) In the sixth paragraph, Holleman, admitting Fry's explanation of the replacement of negative chlorine in *o*- and *p*-chloronitrobenzenes by negative hydroxyl, and the nonreplacement of positive chlorine in *m*-chloronitrobenzene, states:

"One chlorine should also be replaceable by OCH_3 in *o*- and *p*-dichlorobenzene, $\text{Cl.C}_6\text{H}_4.\text{Cl}$, but not in *m*-dichlorobenzene, $\text{Cl.C}_6\text{H}_4.\text{Cl}$ (or $\text{Cl.C}_6\text{H}_4.\text{Cl}$). However, deMooy (work not yet published) has proved in my laboratory, that the latter also reacts with sodium methylate, and that the velocity of this reaction is even greater than for the para and ortho isomers, one Cl-atom being replaced in all three compounds."

In reply, this is just what the electronic hypothesis would naturally predict, for if *m*-dichlorobenzene is a mixture of the electronic tautomers, $\text{Cl.C}_6\text{H}_5.\text{Cl} \rightleftharpoons \text{Cl.C}_6\text{H}_5.\text{Cl}$, then the former electromer in which chlorine is negative would naturally predominate (since $\text{Cl}^- > \text{Cl}$) and lend itself to interaction with Na.OCH_3 according to the equation:

Furthermore, I have shown in Part IV, Section B, under Scheme 3, that in a meta-disubstituted derivative, if both substituents tend to function negatively rather than positively (as is the case in *m*-dichlorobenzene) then that electromer will tend to predominate to the exclusion of the other electromer. Hence, the predominance or increased concentration of the electromer $\text{Cl.C}_6\text{H}_4.\text{Cl}$ explains its greater speed of interaction with Na.OCH_3 . An analogy is afforded in the greater speed of interaction between $\text{C}_6\text{H}_5.\text{Cl}$ and nitric acid than between $\text{C}_6\text{H}_5.\text{Cl}$ and nitric acid, previously considered. Accordingly the velocity of reaction between $\text{Cl.C}_6\text{H}_4.\text{Cl}$ and sodium methylate would be greater than the velocity of reaction between $\text{Cl.C}_6\text{H}_4.\text{Cl}$ (*o* or *p*) and sodium methylate.

Thus the experimental facts presented by Holleman in his sixth paragraph of objections are found to be in harmony with the electronic principles previously developed and applied.

In his concluding paragraph, Holleman states:

"I wish, finally, to call attention to two further points. In the first place, it would probably be very difficult to designate what charge a given substituent has. In most cases it might as well be positive as negative. This naturally leads to a great uncertainty in the explanation of reactions."

In reply, it may be admitted that difficulties are sometimes encountered in determining the charge of a given substituent, but this is not always so. For instance, W. A. Noyes, Stieglitz, L. W. Jones, Falk and Nelson, Bray and Branch, and others, have made extended and highly significant applications¹ of the electronic conception of positive and negative valences, and have demonstrated that the reactions of hydrolysis may be employed frequently to determine the polarity or charge of certain radicals. Furthermore, in Part III of this series, in the further analysis of the Brown and Gibson rule, I have shown that those various substituents which lead to the formation of ortho- and para-derivatives do so by virtue of their *negative polarity*, while those various substituents which lead to the formation of meta-derivatives do so by virtue of their *positive polarity*. In other words, the *ortho-para* and *meta* types of substitution in the benzene nucleus afford a key to the determinations of the polarities of numerous substituents.

While it is true that a given substituent may function either positively or negatively, I have shown that said substituent possesses a definite and a pronounced tendency to function in one way rather than in another way. This fact has been of great importance to the conception of electronic tautomerism and the explanation of (1) the simultaneous formation of ortho-, meta- and para-derivatives, (2) the velocities of substitution reactions, and (3) the relative yields of the possible isomers. Further confirmations of these principles are reserved for subsequent papers. Hence, we may conclude that the determination of the polarity of a substituent is neither so difficult nor as uncertain as some might be inclined to judge. Further developments of the electronic conception of positive and negative valences are certain to throw more light upon this phase of the subject.

Finally, Holleman states:

"In the second place, I might direct attention on the consequences of the hypothesis in the case of open chains. For these it leads to the formula

$$\begin{array}{ccccccc} & + & - & + & - & + & - \\ & | & | & | & | & | & | \\ \text{C} & - & \text{C} & - & \text{C} & - & \text{C} \\ 1 & & 2 & & 3 & & 4 \end{array}$$

for the linking of the C-atoms comes about by C-atom 1 giving off an electron to C-atom 2, this sending off an electron in its turn to C-atom 3, and so on. This must cause the C-atoms at both ends of the open chain to have opposite signs. This would involve the consequence that the Br-atoms, *e. g.*, in a polymethylene dibromide, ought to show a different behavior, which is also in contradiction with the experimental facts."

In reply, this final objection of Holleman is itself subject to criticism because his assumption relative to the electronic nature of the open carbon chain is arbitrarily limited to only one type of linking. It is equally possible to have carbon chains of several types. For example, the following type would accommodate halogen atoms of the same polarity at each

¹ See references to the articles of these authors throughout the present series of papers.

end of the chain: $\overset{+}{\text{C}}-\overset{+}{\text{C}}-\overset{-}{\text{C}}-\overset{-}{\text{C}}-\overset{+}{\text{C}}-\overset{+}{\text{C}}-\overset{-}{\text{C}}-\overset{-}{\text{C}}-\overset{+}{\text{C}}-\overset{+}{\text{C}}$. I shall also show in a later paper that halogen atoms at the ends of an open carbon chain are of opposite polarity just as are the halogen atoms on carbon atoms 1 and 4 of the benzene nucleus in *p*-dichlorobenzene.

In conclusion, it may be said that criticisms of a hypothesis should be and are welcomed because they serve to develop either its merits or demerits. The electronic hypothesis of positive and negative valences, while comparatively new, is a rapidly growing conception as is evidenced by the articles of the authors noted above who have presented many significant applications, interpretations, and deductions. The present series of papers relating chiefly to the constitution of benzene and its derivatives, has interpreted many hitherto unexplained phenomena. The fact that electronic formulas, in many instances, have proven to be of greater significance than the ordinary structural formulas lends support to the idea that the electronic conception of positive and negative valences may become not only a significant but possibly a necessary adjunct to the structure theory. This however, must depend upon the extent of its applications and experimental verifications, and upon the part that is played by just criticisms in bringing to light the relative merits and demerits of its applications.

CINCINNATI, O.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF SYRACUSE UNIVERSITY.]

A METHOD FOR THE SEPARATION AND IDENTIFICATION OF CERTAIN HOMOLOGOUS α -DIKETONES.

By J. M. JOHLIN.

Received January 25, 1915.

The author has made the observation that diacetyl occurs in considerable quantities in pyroligneous acid, and generally in smaller amounts in the distillate resulting from the destructive distillation of carbohydrates, such as pure cellulose, cane sugar, glucose, and lactose.

The fact that nickel readily precipitates as the salt of dimethylglyoxime was adapted for the precipitation of diacetyl with nickel chloride and hydroxylamine-hydrochloride. Repeated preliminary tests with synthetically prepared diacetyl showed that one part of diacetyl in one hundred thousand parts of water still gives a decided precipitate of the nickel salt of dimethylglyoxime when a few drops each of solutions of nickel chloride, hydroxylamine-hydrochloride and ammonium hydroxide are added. Although diacetyl itself is very volatile it is evident that, after adding the reagent necessary for its precipitation, concentration to any necessary extent can be effected without further loss.

Dimethylglyoxime, which can be prepared in a very pure state and accurately weighed, was found by repeated determinations to be quanti-

tatively precipitated from solution when the proper amounts of sodium acetate, nickel chloride and ammonium hydroxide were added.

	Wt. of di- oxime taken. G.	Wt. of nickel salt precipitated. G.	Wt. of di- oxime found. G.	Loss. %.
1.....	0.1012	0.1259	0.1012	0.00
2.....	0.1001	0.1244	0.1000	0.10
3.....	0.1003	0.1243	0.0999	0.39

Since the nickel salt of dimethylglyoxime is practically insoluble in water, it should be possible to precipitate any of its three components quantitatively, using the other two as reagents. As diacetyl always occurs in acid solution, and since hydrochloric acid is one of the products of the reaction when it is precipitated in the form of the nickel salt of its dioxime, an exactly neutral solution is difficult to obtain. The solubility of the nickel salt in acid solution depends upon its dissociation into the nickel salt of the acid present and into dimethylglyoxime. This dissociation is less with acetic acid than with any of the mineral acids. Sodium acetate then not only sets free acetic acid in place of hydrochloric, but also furnishes a common acetate ion. That the addition of sodium acetate lessens the solubility of the nickel salt of the dioxime in dilute acetic acid solutions was shown experimentally. Though the amount of nickel salt dissolved by a solution of one part of acetic acid in fifty thousand parts of water is small, it is sufficiently large to be visibly reprecipitated when minute quantities of sodium acetate are added. Ammonium hydroxide when carefully added is more effective than sodium acetate in aiding complete precipitation. An excess of ammonium hydroxide must be avoided since it also dissolves small amounts of the nickel salt of the dioxime. The presence of ammonium chloride is necessary to prevent the precipitation of nickel hydroxide.

This method applied to the quantitative determination of diacetyl in pyrolygneous acid gave results which made it evident that other homologous diketones were present, thus giving rise to the necessity of a qualitative scheme for their separation and identification.

The possibility of identifying these diketones occurring in so small amounts in the presence of each other depends upon a detailed knowledge of the properties of their dioximes and of the nickel salts of these.

The dioxime of diacetyl, that of its higher homolog acetylpropionyl, and that of its lower homolog methylglyoxal, a keto-aldehyde, were prepared according to the method of Diels¹ and Jost as modified by Gandarin² for the preparation of dimethylglyoxime. In each case the proportionate amounts of methyl ethylketone, of diethylketone, and of acetone were oxidized with iso-amylnitrite to the isonitroso compound and after

¹ *Ber.*, 35, 3290 (1902).

² *J. prakt. Chem.*, 77, 414 (1908).

adding hydroxylamine hydrochloride extracted with ether in the form of the dioximes. From the dioximes their respective nickel salts were prepared.

All three dioximes readily sublime when heated and can, by resubliming, be separated from other nonvolatile matter. According to their solubility in hot and cold water the two higher homologs can readily be freed from the lowest by recrystallizing them from water.

The nickel salt¹ of dimethylglyoxime is practically insoluble in both hot and cold water. That of the higher homolog is very sparingly soluble even in hot water. That of the lower homolog is slightly soluble in cold water and sufficiently soluble in hot water to make possible its recrystallization from large amounts of this solvent.

Dilute ammonium hydroxide very readily dissolves the nickel salt of the lowest homolog, while the nickel salt of dimethylglyoxime is but sparingly soluble even in stronger solutions of ammonia. Ether which has been thoroughly dried dissolves the nickel salt of methylethylglyoxime, while that of dimethylglyoxime is practically insoluble and that of methylglyoxime but sparingly soluble in the same solvent.

The insolubility of the nickel salts of the dioximes of the diketones in neutral solutions, then, makes it possible to precipitate them completely even where they occur in minute quantities. The physical properties of the nickel salts and of the free dioximes give further evidence that it is possible to separate them from each other, to recover the free dioxime from each salt individually, to purify it, and by means of its melting point to identify the diketone of which it is a derivative.

A known mixture containing 0.1 g. each of nickel methylglyoxime, of nickel dimethylglyoxime, and of nickel methylethylglyoxime was used to test the efficiency of such an analysis. The amounts of these nickel salts taken represent, respectively, 0.056 g. of methylglyoxal, 0.061 g. of diacetyl, and 0.064 g. of acetylpropionyl.

The mixture was first subjected to an extraction with ether dried over sodium. It required but two extractions with 200 cc. of dried ether to completely remove all of the nickel salt of methylethylglyoxime, along with traces of the nickel salt of methylglyoxime. The ether extract was concentrated to about 50 cc. and then thoroughly shaken with an equal volume of 5% sulfuric acid until the yellow color of the ether extract and precipitated nickel salt had entirely disappeared. The ether layer now contained all of the methylethylglyoxime and traces of methylglyoxime, while the acid layer contained all of the nickel in the form of its sulfate. After separating the two layers the ether was evaporated and the methyl-

¹ Sufficient detail regarding the physical properties of these nickel salts is in some instances not supplied by Tschugaeff. In other instances, where the Russian literature was not available, abstracts of the original articles were too brief to mention physical properties at all.

ethylglyoxime purified by recrystallization from a small amount of water. The material thus recovered was found to melt¹ sharply at 171°.

The residue of nickel salts left by the ether extraction was now thoroughly shaken with dilute ammonium hydroxide. After filtering, the filtrate was acidified with dilute sulfuric acid to a point where any precipitated nickel salt of methylglyoxime redissolved and the solution instead of having a golden yellow color had become colorless. The mixture was now extracted with ether. The methylglyoxime obtained from the ether extract was freed from traces of dimethylglyoxime by redissolving both in water containing a few drops of dilute ammonium hydroxide and adding to this solution a few drops of very dilute nickel chloride. Since the nickel salt of dimethylglyoxime is practically insoluble in so dilute a solution of ammonia, traces of it would thus be precipitated and can be removed by filtration. This procedure was continued until there was sufficient indication that all of the dimethylglyoxime had been removed. The complete removal of dimethylglyoxime is shown by the appearance of the precipitation of the scarlet modification of the nickel salt of methylglyoxime which readily changes over into the more stable yellow modification, and further by the appearance of a yellowish solution due to the solubility of nickel methylglyoxime in ammonia solutions. The solution was again made just acid with dilute sulfuric acid and the methylglyoxime extracted with ether and resublimed. The resublimed dioxime thus recovered melted¹ at 155-156°.

The residue containing the nickel salt of dimethylglyoxime left by the ammonia extraction was thoroughly shaken with 50 cc. of 5% sulfuric acid and an equal volume of ether. The ether layer containing the free dioxime was evaporated and the dioxime recrystallized from water. The substance thus recovered and purified was found to melt¹ at 234-235°.

The accompanying diagram graphically outlines the course of the analysis which isolates from a mixture containing minute quantities of the insoluble nickel salts of the dioximes of these α -diketones, the pure dioximes whose melting point identifies each homolog.

THE SEPARATION OF ETHANE AND ETHYLENE BY FRACTIONAL DISTILLATION IN A VACUUM AT LOW TEMPERATURES.²

By G. A. BURRELL AND I. W. ROBERTSON.

Received February 15, 1915.

This paper shows some experiments made by the authors, at the Pittsburgh Experiment Station of the Bureau of Mines, in separating ethane and ethylene by fractional distillation in a vacuum at low temperatures. In previous communications there was shown the separation of gases

¹ Cf. Glyoxime, Beilstein, *Organische Chemie*.

² Published by permission of the Director of the Bureau of Mines.

whose boiling points are wide apart: (1) the separation of the constituents in natural gas,¹ and (2) the separation of the illuminants in artificial gas.² Some of the constituents of the latter were separated in pairs, *i. e.*, ethane, b. p. -93° , and ethylene, b. p. -103° , were separated together, as were propane, b. p. -45° , and propylene, b. p. -51° . They were finally analyzed together by burning them in oxygen. From the carbon dioxide and contraction produced, the percentage of each was calculated.

It was desirable to learn something of the limitations of this method of separating gases; for instance, just how tedious would be the work involved in separating the gases ethane and ethylene, whose boiling points are only 10° apart, when the percentage of each present was large.

Experimental.

Preparation of Ethane.—Ethane was prepared by the electrolysis of a saturated solution of sodium acetate. The carbon dioxide evolved with the ethane was removed with caustic potash. Air or other gases trapped with the ethane were removed by fractional distillation in a vacuum at temperatures ranging from that of liquid air to -120° .

Preparation of Ethylene.—Ethylene was prepared by heating ethyl alcohol and sulfuric acid together at a temperature of 160° . The evolved gases were purified in the same way as the ethane. The purity of the two gases was determined by combustion analysis.

Vapor Pressures of Ethane and Ethylene.—It was first necessary to determine temperatures at which the separation could be effected, *i. e.*, temperatures at which the vapor pressure of ethane is practically nil and that of ethylene high enough so that the latter could be withdrawn from the mixture, finally leaving all of the ethane behind. It was found that ethane has a vapor pressure at 160° of 1 mm. of mercury, while that of ethylene at the same temperature is 4 mm. At -170° the vapor pressure of ethylene was found to be 1 mm., while the manometer did not register any pressure for ethane. These pressures are accurate to 1 mm. at the lower temperature.³ Temperature readings were made with a pentane thermometer. A wide variation in temperature represented only a small pressure change at the lowest temperatures. The foregoing vapor pressures showed that the separation could probably be accomplished at temperatures of -170° or slightly higher.

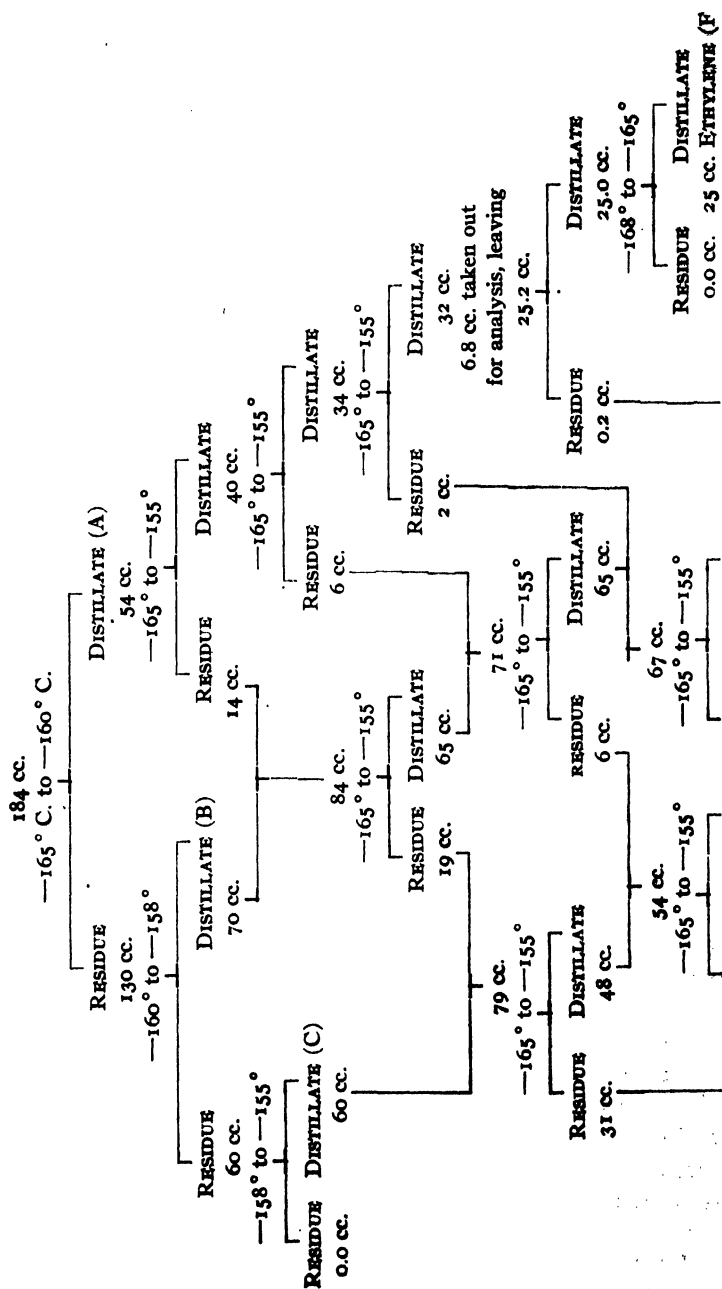

Separation of the Gases.—The two gases were mixed in equal proportions, 92 cc. of ethane and 92 cc. of ethylene. The fractionation was first tried at temperatures close to -170° , but so much ethylene was present, its removal so slow, and so much difficulty was experienced in maintaining a constant temperature for a long time, that higher temperatures and a

² J. Ind. Eng. Chem., 7, 17-21 (1915).

³ These vapor pressure measurements will be given in a subsequent paper.

FIGURE I.—FRACTIONAL DISTILLATION OF ETHYLENE AND ETHANE

wider range was employed to first make an approximate separation. Hence the first fractionations were made at -160° to -155° , the second at -165° to -155° , the third at -168° to -165° , and the last ones at -170° to -168° .

At -165° to -160° .—There was obtained a distillate of 54 cc. This is marked distillate A on the diagram, Fig. 1. The residue from this distillation was refractionated at -160° to -158° . There was obtained 70 cc. of distillate (distillate B). The residue from this second distillation was refractionated at -158° to -155° and there was obtained 60 cc. of distillate (distillate C). No residue was left. It should be stated that at any of these temperatures all of the gas could be removed as a distillate in a comparatively short time by continuing the pumping long enough. The object was simply to divide the original portion into several fractions, each containing considerably more of one constituent than another, so that an excessive amount of gas would not have to be removed at lower temperatures, where the distillation proceeds more slowly.

Second Series of Fractionations.—The first distillate of 54 cc. (A) was refractionated at temperatures ranging from -165° to -155° . A distillate of 40 cc. was obtained. To the residue of 14 cc. there was added distillate B (70 cc.). This total (84 cc.) was distilled at -165° to -155° . The distillate amounted to 65 cc. and the residue to 19 cc. To the latter there was added distillate C (60 cc.). This total (79 cc.) was distilled at temperatures ranging from -165° to -155° . The distillate amounted to 45 cc. and the residue to 31 cc.

The foregoing illustrates the general procedure. All told, 18 fractionations were made. The diagram, Fig. 1, shows the various steps.

There was finally obtained 88.5 cc. of ethane and 79 cc. of ethylene. Two portions, one of 6.8 cc. and one of 9.7 cc. (total 16.5 cc.) had been removed during the fractionation as noted on the diagram, in order to determine by combustion analysis the purity of the fractions. In each case the separation was found to be incomplete. When this portion (16.5 cc.) is added to the final ethane and ethylene total (88.5 + 79 cc.) there results 184.0 cc., a quantity equal to the original amount.

Purity of the Fractions.—There are given below analyses of the various fractions to show their purity. They were examined by burning them with oxygen. The percentage of each constituent was calculated from the contraction and carbon dioxide produced.

According to the reaction, $\text{C}_2\text{H}_6 + 3.5\text{O}_2 = 2\text{CO}_2 + 3\text{H}_2\text{O}$, there result two volumes of CO_2 and a contraction of 2.5 volumes when ethane reacts with oxygen. It will be noted that the observed data correspond well with the theoretical equation.

TABLE I.

Analysis of Ethane.—Three of the following analyses were made of the residue marked *D* in the diagram. The total quantity of gas collected at this point was 82 cc. Three analyses were made. The data show analysis of ethane fraction.

The analysis in last column was made of the distillate marked (*E*) on the diagram (6 cc.):

Analysis No.	1. Cc.	2. Cc.	3. Cc.	4. Cc.
Gas taken for analysis.....	9.00	20.23	21.03	6.00
Oxygen added.....	63.47	83.37	97.82	75.43
Total volume.....	72.47	103.60	118.85	81.43
Volume after burning.....	49.84	53.22	66.57	66.43
Contraction.....	22.63	50.38	52.28	15.00
Volume after CO ₂ absorption.....	31.77	12.81	24.45	54.71
CO ₂ produced.....	18.07	40.41	42.12	11.72
Ethane calculated from contraction.....	9.05	20.15	20.91	6.00
Ethane calculated from CO ₂	9.04	20.20	21.06	5.88

TABLE II.

ANALYSES OF THE ETHYLENE FRACTIONS.

Two of the following analyses were made of the ethylene distillate marked (*F*) on the diagram (25 cc. of distillate) and one of the distillate marked (*G*):

Analysis No.	1. Cc.	2. Cc.	Analysis of distillate <i>G</i> . Cc.
Sample taken.....	9.00	9.20	19.55
Oxygen added.....	47.10	43.76	73.25
Total volume.....	56.10	52.96	92.80
Volume after burning.....	38.45	34.87	53.81
Contraction.....	17.65	18.09	38.92
Volume after CO ₂ absorption.....	20.70	16.70	14.82
CO ₂	17.75	18.17	38.99
Ethylene calculated from the contraction.....	8.83	9.05	19.46
Ethylene calculated from the CO ₂	8.87	9.08	19.50

According to the reaction $C_2H_4 + 3O_2 = 2CO_2 + 2H_2O$, there result 2 volumes of carbon dioxide and a contraction of 2 volumes when ethylene reacts with oxygen. The carbon dioxide and contraction in the foregoing analyses correspond with this reaction. In the case of analysis No. 1 the ethylene was not 100% pure, however, probably due to the intrusion of a trace of air. This point was not tested.

Conclusions.

Although the foregoing separation is complete within the error of making the analyses, the work involved is too tedious to be entirely satisfactory when the proportions of each constituent are present in considerable quantity. The ease of separation of gases whose boiling points are widely separated¹ is in sharp contrast to the separation recorded in this paper.

Constant temperatures were too difficult to maintain, and the removal of the gas by the pump too irregular at any particular temperature to

¹ *Loc. cit.*

obtain a ratio between the quantity of gases removed at different temperatures. As is invariably the case with liquids that tend to separate into two components, the less volatile one of the two (the ethane) was easier to obtain in a pure state. It is intended to repeat the work with a smaller percentage of one of the gases present than of the other and with the use of a thermostat such as was devised by F. Henning.¹ In another communication will also be shown the application of this method of separation to substances that are liquids at ordinary temperatures. In some separations the advantages over the use of high temperatures are: (1) The elimination of complicated still heads, and (2) the avoidance of loss by evaporation because high temperatures are not used. A different means of trapping the liquid had to be devised than that used in handling liquid gases.

All temperatures are in degrees centigrade. Details of the apparatus used are given in previous communications.

PITTSBURGH, PA.

[FROM THE CHEMICAL LABORATORY OF THE COLORADO AGRICULTURAL COLLEGE.]

ON THE OXIDATION OF ETHER.

By R. M. ISHAM AND C. E. VAIL.

Received February 5, 1915.

It seems somewhat surprising to the authors that the subject of the oxidation of ether should have received but slight attention from the writers of our texts on organic chemistry. While the behavior of the alcohols and aldehydes on oxidation is considered in some detail, as representing important type reactions of these substances, the majority of our texts have nothing at all to say regarding the behavior of the closely related ethers. This is the more remarkable in consideration of the fact, which we shall show, that ether is very readily oxidized to aldehyde and acetic acid.

In the third American edition of Richter's "Organic Chemistry," Vol. I, p. 133, we find the statement that "When oxidized they (the ethers) yield the same products as their alcohols." Stoddard's "Introduction to Organic Chemistry," p. 73, states that "Oxidation (of ether) by means of nitric or chromic acid produces the same products as those obtained by the oxidation of alcohol—aldehyde and acetic acid." On the other hand, the 1907 edition of Roscoe and Schorlemmer's "Treatise on Chemistry," Vol. II, p. 1002, states that "Chromium trioxide dissolves without alteration. . . . in pure ether," a statement which we were by no means able to verify. Aside from the above we have not, in a neces-

¹ *Z. Instrumentenkunde*, 33, 33 (1913). This thermostat was installed by the authors just before this article went to press. With it temperatures can be controlled within 0.03°.

sarily somewhat incomplete survey of the texts, found any reference to this subject.

Löw¹ has shown that ether vapor, when mixed with air and passed over a heated superficially oxidized copper spiral, is oxidized to aldehyde.

W. H. Perkin² found that when ether vapor mixed with oxygen, in a quantity insufficient to produce total oxidation, was passed through a tube heated to temperatures between 260° and dull redness, a pale luminous flame resulted, and the ether was oxidized, chiefly to aldehyde. Similarly, Dunstan and Dymond³ found the incomplete *combustion* of ether to give aldehyde and acetic acid as chief products.

Richardson and Forty⁴ obtained evidence of a photochemical oxidation to aldehyde and acetic acid, on exposing a vessel containing ether and oxygen, in contact with water, to direct sunlight for a period of five weeks.

Aside from the above we have been able to find no reference to the direct oxidation of ether by means of air or oxygen.

We have been able to show that ether vapor is readily oxidized to aldehyde and acetic acid, when mixed with air or oxygen, without the use of any catalyst and at temperatures very much below that at which luminous combustion begins.

The attention of one of us was first directed to this subject when a strong odor of acetaldehyde was noted issuing from a Freas electric oven, in which the residues from the ether extraction of some wheat samples were being dried at a temperature of 110°. The natural inference that the aldehyde resulted from the oxidation of ether was shown to be correct by saturating some filter papers with ether and placing them in the oven, when, after heating for some time at 110°, a strong odor of aldehyde was noted on opening the oven. Since the literature on this subject seemed to be somewhat incomplete we were lead to carry out some further experiments.

A three-holed Woulff bottle of 750 cc. capacity was fitted with an inlet tube extending to the bottom of the bottle, an exit tube extending only through the stopper, and a thermometer, and the whole placed in an air bath.

In a preliminary experiment a side-neck test tube, containing 10 cc. of pure ether, and provided with an inlet tube for oxygen, extending to the bottom, was connected to the inlet tube of the Woulff bottle, and a Liebig condenser attached to its exit tube. The temperature of the Woulff bottle was brought to 120°, while the temperature of the ether was maintained at 12° ± 1, at which temperature, and at our normal barometric

¹ *J. prakt. Chem.*, 141, 323.

³ *Ibid.*, 57, 574 (1890).

⁴ *Ibid.*, 69, 1352 (1896).

pressure (ca. 635 mm.), a mixture of its saturated vapor with oxygen should be nearly equimolecular, as required for the equation:

Oxygen was bubbled through the ether at such a rate that evaporation was complete in a little less than two hours, so that the mixed gases were exposed to the elevated temperature of the Woulff bottle for an average period of about ten minutes. A very strong odor of aldehyde was apparent in the vapors issuing from the condenser, and a couple of drops of the condensed product, which consisted largely of ether, immediately restored the color to a little Schiff fuchsin-aldehyde reagent.

The formation of aldehyde having thus been proven, it was decided to so modify our apparatus as to permit of quantitative experiments. For this purpose, the condenser was replaced by a thistle-tube, connected to the exit tube of the Woulff bottle, and extending to the bottom of a cylinder which contained a little strong ammonia water, and was surrounded by a freezing mixture of snow and salt.

In our first experiment with the modified apparatus the temperature of the Woulff bottle was maintained at $132^\circ \pm 2$, and that of the ether at $12^\circ \pm 1$. 10 g. of ether were taken, and oxygen was bubbled through at such a rate that evaporation was complete in an hour and forty minutes. Assuming that the oxygen was saturated with ether vapor, the average time of exposure of the mixture to the elevated temperature was approximately ten minutes. The passage of oxygen was continued until all ether and aldehyde vapor had been swept out of the Woulff bottle. The thistle-tube was then disconnected and rinsed down into the cylinder, the contents of which consisted of an aqueous ammoniacal layer and an ether layer. These liquids were then transferred to an Erlenmeyer flask. No attempt was made to distinguish between the amount of ether which had been oxidized to aldehyde, and that which had been oxidized to acetic acid, but the total amount oxidized was determined as follows, using a modification of the method of Blank and Finkenbeiner:¹ 50 cc. of pure hydrogen peroxide and 50 cc. 0.5 *N* sodium hydroxide solution were added. The solution was warmed until oxidation of the aldehyde was complete and the excess of peroxide decomposed, then boiled until the last trace of ammonia was expelled. It was then cooled, the sides of the flask rinsed down, and the excess of sodium hydroxide titrated with 0.5 *N* sulfuric acid, using litmus as indicator. 43.3 cc. of acid were required, showing that 6.7 cc. of 0.5 *N* sodium hydroxide, equivalent to 0.47 g. of acetic acid or 0.29 g. ether, had been neutralized by the oxidation products. Hence the ether was oxidized to the extent of 2.9%.

In another experiment all conditions were maintained the same, except that a bypass for oxygen was installed, so that approximately double

¹ *Ber.*, 31, 2979 (1898).

molecular quantities of oxygen acted on the ether vapor, and the time of the experiment was prolonged to eight hours, whereby the time of exposure of the gas mixture to the elevated temperature was considerably lengthened. We were very much surprised, on titration of our product, to find that the extent of oxidation was identical with that obtained in the former experiment, namely, 2.9%, a coincidence which we do not attempt to explain.

In an effort to obtain a more complete oxidation of the ether we further modified our apparatus by dispensing with the bypass for oxygen and introducing a Wouff bottle of 1400 cc. capacity in place of the smaller one. In our later experiments we maintained the temperature in the Wouff bottle at 160°. Three experiments were carried out under these conditions. In the last of these we determined on one aliquot portion of the distillate the total percentage of ether oxidized, according to the method given above, and on another aliquot the percentage oxidized to acetic acid. This last determination was made as follows: The distillate, collected as before in a cylinder containing strong aqueous ammonia, surrounded by a freezing mixture, was made up to 500 cc. and an aliquot portion of 100 cc. taken. 50 cc. of 0.5 *N* sodium hydroxide solution were added and the solution boiled until ammonia and aldehyde were expelled. A slight resinification of the aldehyde was indicated by the fact that the solution became yellow as the boiling proceeded. After all ammonia was expelled, the solution was cooled and the excess of alkali titrated with 0.5 *N* sulfuric acid, using litmus indicator. The results of the three experiments are summarized in the appended table:

Expt. No.	Grams ether taken.	Duration of expt. Min.	Ave. time of exposure to 160° temp.	% ether oxidized		
				to ald.	to acid.	total.
1.....	10	160	35	32.5
2.....	5	70	30	35.2
3.....	5	70	30	11.6	23.9	35.5

As may be seen from the results of the third experiment, the major part of the aldehyde produced was further oxidized to acetic acid. Since the ether vapor and oxygen were originally present in equimolecular proportions as required for the equation

it will be seen that there was only enough oxygen present to convert one-half of the ether to acetic acid according to the equation

From the results of this experiment we see that $2 \times 23.9 + 11.6$ or 59.4% of the oxygen was used in oxidizing 35.5% of the ether. This result would indicate that the introduction of more oxygen was essential to secure complete oxidation of the ether. When, however, we attempted to carry out experiments using a larger proportion of oxygen, we found that even with initial temperatures as low as 150° the reaction was so rapid that the gas

mixture was subject to sudden rises in temperature and subsequent explosions. Consequently we were obliged to abandon the attempt to show that ether can be quantitatively oxidized under these conditions.

In an effort to check the apparent contradiction in the literature on the effect of chromic anhydride on ether, some pure chromic anhydride was prepared, and added to pure ether. A very violent reaction, with evolution of aldehyde vapors, and separation of green chromic oxide, resulted. When the ether was cooled in a freezing mixture to -10° and the chromic anhydride added, a yellow solution was momentarily produced, but reaction began almost at once with the same results as before.

Summary.

1. Ether vapor is oxidized to aldehyde and acetic acid, when heated with air or oxygen.
2. This oxidation begins at temperatures as low as 110° , and is very rapid at 160° .
3. Chromic anhydride does not dissolve without alteration in pure ether.

A CONTRIBUTION TO THE STUDY OF THE CONSTITUTION OF THE HYDROXYAZO COMPOUNDS. THE ACTION OF UNSYMMETRICAL BENZOYLPARATOLYLHYDRAZINE UPON BENZOQUINONE AND ITS HOMOLOGS.

BY WILLIAM MCPHERSON AND GEORGE WEATHERWORTH STRATTON.

Received March 6, 1915.

Theoretical.

It has been shown by Nef and McPherson¹ that unsymmetrical (or α) benzoylphenylhydrazine condenses with paraquinones forming the corresponding quinonehydrazones. For example, with benzoquinone the reaction is represented by the following equation:

The resulting hydrazones proved to be, not identical, but isomeric with the benzoyl derivatives of the corresponding hydroxyazo-compounds. Thus the hydrazone obtained by the action of unsymmetrical benzoylphenylhydrazine on benzoquinone according to Equation 1 given above, is isomeric with the benzoyl derivative of hydroxyazobenzene prepared by the reaction expressed in the following equations:

¹ *Ber.*, 28, 2418 (1895); *Am. Chem. J.*, 22, 364 (1899); 25, 485 (1901).

Now both the hydrazone derivative formed as represented in Equation 1 above and the isomeric hydroxyazo compound formed according to Equation 2 yield on saponification the same compound, namely, hydroxyazobenzene (benzeneazophenol). The reactions are represented by the following equations:

It is evident, therefore, that in the saponification of one of the compounds a migration of the hydrogen atom replacing the benzoyl group takes place. If the migration occurs in the hydrazone, the hydrogen atom which takes the place of the benzoyl group passing from the nitrogen to the oxygen, then the constitution of the resulting hydroxyazobenzene must be represented by Formula I. On the other hand if the migration takes place in the hydroxyazo compound then Formula II correctly represents the constitution of the hydroxyazobenzene. From the general results obtained in different investigations,¹ it seems probable that the migration actually takes place in the hydrazone and that Formula I is the correct one for hydroxyazobenzene. This indicates that the molecule represented by the formula

is unstable, rearranging as fast as formed to the more stable compound

It was thought that by varying the radicals it might be possible to obtain a stable body of the general formula, $\text{R} \begin{array}{l} \text{O} \\ \parallel \\ \text{N} - \text{NHR}' \end{array}$ and consistent

efforts have been made in this laboratory to isolate a compound of this constitution. If such a compound could be isolated, it would throw much light upon the general question of the constitution of the parent

¹ THIS JOURNAL, 33, 1525.

hydroxyazo compounds. In the present investigation, the action of the unsymmetrical benzoyl-*p*-tolylhydrazine upon some of the *p*-quinones was investigated. It was found that hydrazones are formed in accordance with the following equation:

The resulting hydrazones when saponified yield not the parent hydrazones, but hydroxyazo compounds (Equation A) and these when benzoylated (Equation B) give derivatives that are not identical but isomeric with the original benzoylhydrazones:

Experimental Part.

Preparation of *p*-Tolylhydrazine.—This is most readily obtained from *p*-toluidine by methods similar to those used in preparing phenylhydrazine from aniline. The following method gave good results: To 18 g. of *p*-toluidine was added 150 cc. of water and then 30 cc. of hydrochloric acid (sp. gr. 1.2). The resulting mixture was then stirred until all of the toluidine dissolved. The clear liquid so obtained was cooled to 5° and diazotized by the addition of the theoretical quantity of sodium nitrite (12 g.). To the resulting solution there was added, slowly at first and with constant stirring, 120 g. of stannous chloride dissolved in 100 cc. of concentrated hydrochloric acid. The tolylhydrazine hydrochloride separated out as a thick, white solid. It was removed by filtration and the filtrate salted out to obtain the hydrochloride which remained in solution. The yield of the hydrochloride was from 65 to 75% of the theoretical quantity. In order to obtain the free tolylhydrazine, the hydrochloride was neutralized with a concentrated solution of sodium hydroxide. The tolylhydrazine separated out on the surface of the liquid as a yellow oil which solidified to an almost white solid when the solution cooled. The solid was removed and the remaining solution extracted with ether in order to dissolve out any remaining hydrazine. The crude compound was purified by recrystallizing from ether.

Preparation of β -Acetyl-*p*-tolylhydrazine, $\text{CH}_3\text{C}_6\text{H}_4\text{—NH—NHCOCH}_3$.—This compound was first prepared by Gattermann, Johnson and Holze¹ by boiling a solution of the tolylhydrazine in glacial acetic acid. The

¹ *Ber.*, 25, 1080 (1892).

following method was found to give an excellent yield of the pure compound:

The theoretical quantity of acetic anhydride was slowly added to an ethereal solution of 25 g. of the tolylhydrazine. The rapid evaporation of the ether during the reaction keeps the temperature down and gives a pure product. Before all the anhydride was added the acetylhydrazine began to separate, and at the end of the experiment a large percentage of it had settled to the bottom of the vessel. This was filtered from the ether and washed once or twice with ether—a procedure which obviated the troublesome recrystallization from hot water. The pure compound melting at 130° was thus readily obtained.

α -Benzoyl- β -acetyl- p -tolylhydrazine, $\text{CH}_3\text{C}_6\text{H}_4\text{N}(\text{COC}_6\text{H}_5)\text{NHCOC}_6\text{H}_5$.—Upon benzoylating β -acetyl- p -tolylhydrazine in benzene solution by means of benzoyl chloride the benzoyl group enters in the α -position as shown in the following equation:

In carrying out the reaction the acetyl compound was dissolved in benzene (25 g. in 250 cc. of benzene) in a flask which was then connected with a reflux condenser. The theoretical quantity of benzoyl chloride was added through the condenser and the solution boiled until hydrogen chloride ceased to be evolved. The addition of benzoyl chloride causes the formation of a precipitate which dissolves, however, when the mixture is heated.

If the benzene solution is allowed to cool slowly the α -benzoyl- β -acetylhydrazine separates out as a hard cake which adheres firmly to the bottom of the flask. It was found better to pour the hot solution into a beaker, evaporate a portion of the benzene and cool rapidly, constantly agitating the liquid. In this way it was obtained in the form of finely divided crystals. The yield was almost quantitative.

α -Benzoyl- β -acetyl- p -tolylhydrazine is very slightly soluble in ligroin, rather more soluble in ether and alcohol and chloroform, and very soluble in benzene. It may be purified by crystallizing from benzene or benzene-ligroin. From these solvents it is obtained in compact nodules of small crystals, which melt sharply at 135° .

Calc. for $\text{C}_{18}\text{H}_{18}\text{N}_2\text{O}_2$: N, 10.45; C, 71.64; H, 5.97; found: N, 10.38; C, 71.76; H, 5.96.

α -Benzoyl- p -tolylhydrazine, $\text{CH}_3\text{C}_6\text{H}_4\text{—N}(\text{COC}_6\text{H}_5)\text{NH}_2$.—This compound is prepared by the saponification of α -benzoyl- β -acetyl- p -tolylhydrazine.

The process was carried out as follows: 25 g. of α -benzoyl- β -acetyl-

p-tolylhydrazine was placed in a flask and 150 cc. of water added. The flask was connected with a reflux condenser and the mixture heated to boiling. Alcohol was then poured in, a little at a time, until the solid was just dissolved. Sulfuric acid (25 g.) was then added and the solution boiled until the odor of ethyl benzoate could be detected. As the solution cooled the sulfate of the α -benzoyl-*p*-tolylhydrazine separated. It was always found to be mixed with some unchanged α -benzoyl- β -acetyl-*p*-tolylhydrazine. Different concentrations of sulfuric acid were tried with the idea of eliminating this difficulty, but the most satisfactory results were obtained with the dilution given.

The sulfate obtained by the above process was purified by washing it first with chloroform and then with ether. It is a white solid, but slightly soluble in the common organic solvents excepting alcohol. To obtain the free hydrazine the sulfate was dissolved in dilute alcohol, neutralized with sodium carbonate and the resulting solution extracted with ether. Upon evaporation of the ether an oil was obtained which would not solidify. By extracting this oil several times with ligroin, combining the ligroin extracts and evaporating them slowly, an oil was finally obtained which, on standing for several days, changed almost entirely into fine, white crystals which were grouped together in nodules. They were purified by washing rapidly with ether. The pure α -benzoyl-*p*-tolylhydrazine thus obtained is very soluble in the common organic solvents. It melts at 68–70°.

Calc. for $C_{14}H_{14}N_2O$: N, 12.39; C, 74.34; H, 6.19; found: N, 12.32; C, 73.90; H, 6.25.

α -Benzoyl-*p*-tolylhydrazinehydrochloride.—The hydrochloride of α -benzoyl-*p*-tolylhydrazine was prepared from the free compound by dissolving the latter in benzene and passing dry hydrogen chloride into the solution. It separated out as a pinkish white solid which was purified by washing with benzene and ether.

The Action of Tolyldiazine upon *p*-Quinones.—It has long been known¹ that phenylhydrazine acts as a reducing agent upon quinones of the benzene series, converting them into the corresponding hydroquinones. With α -naphthoquinone, on the other hand, condensation takes place and a hydroxyazo compound is produced. It was found that *p*-tolylhydrazine acts in a similar way. Thus by its action in benzene solution, benzo-, tolu- and thymo-quinones are converted into the corresponding hydroquinones, while α -naphthoquinone gives tolueneazo- α -naphthol. In the first three cases nitrogen is evolved and the hydroquinones precipitate on standing. The reaction with α -naphthoquinone is represented by the following equation:

¹ Ber., 16, 1563 (1883).

The Action of α -Benzoyl-*p*-tolylhydrazine Hydrochloride (or Sulfate) on Benzoquinone; Benzoquinone- α -benzoyl-*p*-tolylhydrazone.—The sulfate or hydrochloride of α -benzoyl-*p*-tolylhydrazine condenses with benzoquinone, yielding the corresponding hydrazone:

The reaction must be carried out in dilute alcoholic solution, since in concentrated solutions decomposition results.

One gram of benzoquinone was dissolved in 200–250 cc. of 95% alcohol. Water was added to this solution until the total volume was about 600 cc. To this solution was then added 4 g. of α -benzoyl-*p*-tolylhydrazine sulfate dissolved in 600 cc. of dilute alcohol of the same strength as the solvent for the quinone. The mixture was stirred and allowed to stand for 24 hours. The hydrazone separated as a yellowish solid which slowly settled to the bottom of the flask. It was filtered by suction, dried on the hot plate at 100° and recrystallized several times from benzene-ligroin and finally from ligroin. It was thus obtained in the form of finely divided, yellow crystals which melted at 141°. The yield of the crude product was 3 g. The compound is very soluble in ether, alcohol, benzene and chloroform and slightly soluble in ligroin.

Calc. for $\text{C}_{20}\text{H}_{16}\text{N}_2\text{O}_2$: N, 8.86; C, 75.95; H, 5.06; found: N, 8.95; C, 75.63; H, 5.07.

Action of Saponifying Agents upon Benzoquinone- α -benzoyl-*p*-tolylhydrazone,

When saponified with hot alcoholic potash or concentrated sulfuric acid

the hydrazone is converted into *p*-tolueneazophenol and benzoic acid as shown in the above equation. The best results were obtained by dissolving the hydrazone in concentrated sulfuric acid and pouring the resulting solution into a large volume of water. The impure phenol separated at once. It was purified by dissolving it in a 20% sodium hydroxide solution, filtering and neutralizing the filtrate with hydrochloric acid. Further purification was accomplished by repeated recrystallization from ligroin and benzene-ligroin. The finely divided orange-yellow crystals thus obtained melted sharply at 152° . This compound was found to be identical with tolueneazophenol prepared by the action of *p*-diazotoluenechloride upon phenol. Each of the two compounds as well as a mixture of the two melted sharply at 152° . All efforts to obtain the free benzoquinone-*p*-tolylhydrazone failed, indicating its probable unstable character.

The Benzoate of *p*-Tolueneazophenol.—This compound was prepared from tolueneazophenol by the Baumann-Schotten reaction. The crude product was purified with ligroin. It forms reddish yellow needles melting at 159° .

This benzoate, according to its method of preparation, must be represented by Formula I below. It is not identical but isomeric with benzoquinone- α -benzoyl-*p*-tolylhydrazone, the constitution of which is represented by Formula II below:

The colors and crystalline forms of the two compounds as well as their melting points are different. Moreover, the melting point of a mixture of the two, while indefinite, was considerably below that of either of the pure compounds.

The Action of α -Benzoyl-*p*-tolylhydrazine on Toluquinone; Toluquinone- α -benzoyl-*p*-tolylhydrazone.—The action of the tolylhydrazine on toluquinone takes place according to the following equation:

This condensation was effected under the same conditions that were used in the preparation of the corresponding benzoquinonehydrazone.

One gram of toluquinone was dissolved in 250 cc. of 95% alcohol and water added until the total volume was about 700 cc. To this solution was then added 3 g. of α -benzoyl-*p*-tolylhydrazine sulfate dissolved in 700 cc. of dilute alcohol (3 parts of 95% alcohol to 4 parts of water). The hydrazone began to separate at once and at the end of 24 hours the reaction was complete. Two grams of the crude product were obtained. Purification was effected by repeated recrystallization from ligroin and benzene-ligroin. The fine, yellow crystals obtained melted at 178°. They are somewhat lighter in color than the crystals of the corresponding benzoquinone hydrazone. The compound is very slightly soluble in dilute alcohol. It is not very soluble in ligroin but dissolves readily in other organic solvents.

Calc. for $C_{21}H_{19}N_2O_2$: N, 8.49; C, 76.37; H, 5.45; found: N, 8.53; C, 76.16; H, 5.52.

Saponification of Toluquinone- α -benzoyl-*p*-tolylhydrazone.—The saponification takes place in accordance with the following equation:

It was effected by dissolving the hydrazone in concentrated sulfuric acid and pouring the resulting solution into a large volume of water. The crude product thus obtained was treated with a 20% caustic potash solution which dissolved the hydroxyazo compound. This was reprecipitated by means of hydrochloric acid, and was purified by repeated crystallization from ligroin. In this way it was finally obtained in the form of orange-yellow crystal clusters melting at 135°. This compound was found to be identical with tolueneazo-*o*-cresol, prepared by treating a diazotized solution of *p*-toluidine with an alkaline solution of *o*-cresol:

The benzoate of tolueneazo-*o*-cresol was prepared by the Baumann-Schotten method. By crystallizing from ligroin it was obtained in the form of orange-yellow crystal clusters melting at 165°. It is not identical but isomeric with the compound obtained by the action of α -benzoyl-

p-tolylhydrazine on toluquinone. The formulas of the two compounds are as follows:

The Action of α -Benzoyl-*p*-tolylhydrazine on Thymoquinone: Thymoquinone- α -benzoyl-*p*-tolylhydrazine.—Thymoquinone condenses with benzoyl-*p*-tolylhydrazine as shown in the following equation:

The condensation was carried out in the following way: One gram of thymoquinone was dissolved in 300 cc. of 95% alcohol and the solution diluted to 700 cc. To this was added 3 g. of α -benzoyl-*p*-tolylhydrazine sulfate dissolved in dilute alcohol (3 parts of 95% alcohol to 4 parts of water). After standing 48 hours the crude hydrazone (1.5 g.) was removed by filtration and purified by repeated crystallizations from ligroin. It was obtained in the form of light yellowish green crystals melting at 125°.

Calc. for $C_{24}H_{24}N_2O_2$: N, 7.53; C, 77.42; H, 6.45; found: N, 7.78; C, 77.25; H, 6.59.

Saponification of Thymoquinone- α -Benzoyl-*p*-tolylhydrazine.—The saponification was effected both by sulfuric acid and by potassium hydroxide. In each case the reaction took place according to the following equation:

The crude product was dissolved in a dilute solution of potassium hydroxide and reprecipitated by the addition of hydrochloric acid. Finally it was crystallized a number of times from ligroin. It was then obtained in the form of yellow crystals which melted at 117°.

This compound proved to be identical with *p*-tolueneazothymol prepared in the following way: A solution of diazotoluene chloride was added to the theoretical amount of an alkaline solution of thymol. The resulting solid proved to be a mixture of the *o*- and *p*-tolueneazothymol. This mixture was treated with a solution of sodium hydroxide which dissolved the para compound only. This was then precipitated, dried and purified by crystallization from ligroin. The resulting yellow crystalline solid melted at 117°. A mixture of the solid and the product obtained by the saponification of thymoquinonebenzoyl-*p*-tolylhydrazone likewise melted sharply at 117°, thus proving the identity of the two compounds.

Upon benzoylating the tolueneazothymol according to the Baumann-Schotten method, a compound was obtained which crystallized from ligroin in short, red, needle-shaped crystals melting at 127°. A mixture of this compound and thymoquinone- α -benzoyl-*p*-tolylhydrazone melted considerably lower than either constituent. These two compounds are therefore not identical but isomeric as shown in the following formulas:

(1) Hydrazone.

(2) Hydrazo compound.

Summary.

(a).—The preparation of α -benzoyl-*p*-tolylhydrazine is given and the properties of the compound described.

(b).—The action of α -benzoyl-*p*-tolylhydrazine upon benzoquinone, toluquinone and thymoquinone is described. The resulting compounds are shown to be not identical but isomeric with the benzoyl derivatives of the corresponding compounds prepared by the action of diazotoluene chloride upon phenol, *o*-cresol and thymol, respectively.

(c).—The corresponding isomeric compounds when saponified give the same compound, namely, a hydroxyazo compound.

(d).—While it is possible to obtain the α -benzoyl derivatives of the quinone hydrazones, no evidence was obtained of the existence of the parent quinone hydrazones in stable form.

(e).—The bearing of the reactions upon the constitution of the hydroxyazo compounds is discussed.

CICUTOXIN: THE POISONOUS PRINCIPLE IN WATER HEMLOCK (CICUTA).

BY C. A. JACOBSON.

Received December 31, 1914.

Introductory.

Water hemlock is a very widely distributed poisonous plant, whose botanical character varies with its geographical location. Several different species are described as occurring, not only in the same country, but in restricted areas of the same country. Two or perhaps three distinct varieties may be recognized in this country: the eastern *Cicuta maculata* and *Cicuta bulbifera* and the western *Cicuta occidentalis*. The *maculata* appears to be identical with the tall variety of the French Ciguë Vireuse and the German Wasserschierling (*Cicuta virosa*). These varieties are, however, to be clearly distinguished from the spotted hemlock (*Conium maculatum*) of Socrates fame, which is a different genus.

A very complete bibliography of water hemlock literature was published by Marsh and Clawson,¹ but among the dozens of publications on the subject there is but one, namely, Pohl's,² purporting to give a chemical discussion of the poisonous principle of the plant.

The effect of the poison on frogs has been investigated by Wikszemski,³ and the effect on dogs and cats by Boehm.⁴ A great deal of experimentation on the plant has been carried out in several of our agricultural experiment stations, but with conflicting and indefinite results. The reason for this may be found in the fact that the chemical character of the poison itself has not been understood. Extractions of the plant have been made and fed to stock, and in some cases found to be poisonous, while in others not. One man states that swine are immune from the poison, another describes the death of two sows after eating the roots. In one case an experimenter fed as high as 41 pounds of the water hemlock roots to a sheep weighing 91 pounds without pronounced effects, but when he fed 2.5 pounds of the roots to another weighing 93 pounds, the sheep died. Nothing was said about the character of the roots nor when they were dug.

These are instances of the mass of conflicting data found on the subject, and the problem of undertaking to get more reliable and definite results seemed well worth while. Hendrick⁵ estimates that over 100 cattle were lost in Oregon in one year from this source, and Chestnut and Wilcox⁶ record 150 deaths among sheep and cattle in Montana in one year. Several cases of cattle poisoning and two suicides among Indians,

¹ U. S. Dept. Agric., *Bull.* 69.

³ Dissertation, Dorpat (1875).

⁴ *Archiv. Exp. Pathol.*, 5, 279 (1876).

⁵ Oregon Agr. Exp. Station, *Bull.* 46 (1897).

⁶ U. S. Dept. of Agric., *Bull.* 26.

caused by eating the roots of this plant, have come to the author's attention during the progress of this work.

The main efforts in the present investigation have been directed along purely chemical lines, although the work had to be supplemented by toxicological experiments in order to trace the poisonous constituent in the various chemical transformations. For these experiments, rabbits, cats and guinea pigs were used.

Botanical.

Water hemlock belongs to the Umbelliferae, or Parsley family. It is a bulbiferous annual plant, two to five feet tall, growing along the edges of streams, ditches and lakes, and in marshy ground. Nine or ten species

of *cicuta* have been recorded as occurring in this country. About thirty-five foreign varieties are found in the literature, a number of which are already known to be duplications.

The following experimental work was carried out with the *Cicuta vagans*, Greene, which in the opinion of the author is identical with *Cicuta occidentalis*, Greene, and whose essential parts are shown in the accompanying cut. The small greenish white to white flowers are dispersed in clusters of clusters. The leaves are compound, lanceolate and medium serrate. The stem is smooth and hollow with nodes four to eight inches

Water hemlock (*cicuta vagans*).

apart. The seed is smooth, compound and markedly ribbed, and when ripe separates easily into two carpellary parts. The rootstalk from which the stem or stems grow, varies in size from that of a hazel nut to that of a man's fist. Its shape is not uniform. It has one to four or five tapering roots and these are covered with fine, white root hairs. The rootstalk is transversely chambered and next to the layer of brown cells is a fibro vascular region containing ducts from which the poisonous liquid exudes.

Chemical.

When the water hemlock rhizome, described in the foregoing section, is cut in two, drops of a yellowish balsam-like liquid ooze out upon the cut surface. A penetrating aromatic odor is observed, which is characteristic of this substance. In about a minute the light yellowish color of the droplets changes to light red, then to ruby red and reddish brown. The color change is not wholly produced by light, nor is it an oxidation process.

This yellowish viscid liquid is the poisonous principle of the plant. It is also found in the stem, particularly in the lower portions, but in relatively small amount. A Frenchman by the name of M. Brandes, recorded by Trumel,¹ named this poison cicutoxine. At least thirty-eight years later, Prof. Boehm,² of Dorpat, Russia, apparently not aware of the Frenchman's name for the substance, renamed it with the same name. The name cicutoxin has since been woven into the literature so extensively that it would hardly seem advisable to rename it, although this could now be done upon a rational chemical basis.

Methods of Preparation.—Boehm² describes three methods for the preparation of cicutoxin, but expresses doubt as to the purity of the substance obtained by all of them. In the first method he extracts the *dried* and finely ground tubers with ether, the ethereal residue is then treated with 70% alcohol and finally extracted with petrolic ether. The petrolic ether insoluble portion he calls cicutoxin. His second method consists in the extraction of the *dried* and ground roots with boiling water and subsequent treatment of the residue with 95% alcohol and petrolic ether, while his third method employs 70% alcohol containing 10% strong ammonium hydroxide as the solvent, subsequently precipitating the poison with lead acetate.

The method employed by Pohl² differs from all three of Boehm's methods in that warm 95% alcohol is used for extracting the sliced and *air-dried* tubers. The dissolved cicutoxin is precipitated from the alcohol with lead acetate, the lead removed from the filtrate with sodium sulfate and the final residue taken up in dilute alcohol and shaken out 20-30 times with petrolic ether.

¹ *Thèse-Faculté de Médecine de Paris*, No. 239, p. 6 (1838).

² *Loc. cit.*

From the following chemical discussion it will be seen that this substance polymerizes and decomposes easily at temperatures above 50°, and especially when in contact with alcohol or hot water. Experiments have also shown that when the cicuta tubers are extracted with 95% alcohol a sugar or glucoside is extracted simultaneously with the toxic substance, which has a sweet taste, and when hydrolyzed gives a strong reduction of Fehling's solution. In fact, a yellow osazone was prepared from the water solution of one of these hydrolyses, which formed in 5-6 minutes' heating and melted with decomposition at 203-204°. It was unquestionably glucosazone.

In view of the above facts the following method of preparation was adopted for obtaining the purest possible product: The fresh water hemlock tubers were ground to a fine pulp in a meat chopper and extracted with ether at room temperature, pouring the ethereal solution from flask to flask, so as to obtain it as concentrated as possible. No attempt was made to get a complete extraction, except for one quantitative determination. The ethereal solution was dried by shaking with anhydrous copper sulfate, filtered and allowed to evaporate in the air or in a stream of dry air. The residue, after all the ether had apparently passed off, continued to lose weight for several weeks. When the loss in weight amounted to 0.05% or less for a period of 24 hours the substance was considered sufficiently dry for analytical purposes. It was discovered that the substance could be precipitated as an amorphous solid from petrolic ether (b. p. 25-45°) having a temperature of 6-10°; consequently some of the ethereal residue obtained above was dissolved in a small quantity of absolute alcohol and poured, drop by drop, with constant stirring into the cold petrolic ether. The precipitate was washed by decantation with more cold petrolic ether, the solvent allowed to drain off and the residue dried in a stream of dry air.

Combustions were run on two different lots of the poisonous product, with and without precipitating from petrolic ether, yielding the following results:

	Grams cicutoxin.	CO ₂ .	H ₂ O.	% C.	% H.
(Without precipitating from petrolic ether.)					
Lot 1 (a).....	0.2804	0.7818	0.2180	76.04	8.70
Lot 1 (b).....	0.2341	0.6535	0.1830	76.13	8.75
Lot 2 (c).....	0.2219	0.6194	0.1701	75.38	8.34
Lot 2 (d).....	0.2261	0.6287	0.1699	75.10	8.17
			Mean,	75.66	8.49
(Precipitated from petrolic ether.)					
Lot 1 (e).....	0.2013	0.5618	0.1587	76.11	8.82
Lot 2 (f).....	0.2075	0.5724	0.1500	75.23	8.07
			Mean,	75.67	8.44
Calculated composition for C ₁₅ H ₂₂ O ₂ :				75.44%	8.67%

The above results go to show that the ether does not dissolve any other substance from the tubers to an appreciable extent, and that the precipitation from petrolic ether does not influence the composition of the product. The less handling, and the fewer transformations to which the substance is subjected, the purer it will be. When cicutoxin is allowed to stand in contact with alcohol for some time, especially warm alcohol, or is heated with water, it decomposes and yields a petrolic ether soluble constituent having, in alcohol, a greenish fluorescence and non-toxic properties. This substance, Boehm calls umbelliferon. It is in all probability a decomposition product of cicutoxin.

Yield.—The yield of cicutoxin obtained by the ether extraction was found to be between 0.3% and 0.4% of the weight of the green tubers.

Molecular Weight.—Molecular weight determinations were made on the purified cicutoxin, resulting as follows:

Cryoscopically, with glacial acetic acid as solvent, 268.5, 265.4, 288.2; ebullioscopically, with alcohol as solvent, 926, 418, 798; with chloroform as solvent, 601.2. The molecular weight of cicutoxin calculated from analytical results is 302.21.

Empirical Formula.— $C_{19}H_{28}O_8$.

The low values obtained for the molecular weight by the freezing-point method are in all probability due to impurities, while the high and erratic results by the boiling point are due to polymerization. In the first experiment three molecules polymerized into one, and in the last one with chloroform, two molecules. This polymerization process is continuous after the cicutoxin has been removed from the plant, but proceeds very much slower at ordinary temperatures. Complete polymerization with the accompanying decomposition destroys the toxicity of the substance. The polymerization of cicutoxin diminishes its volume without perceptibly affecting its weight.

Properties of Cicutoxin.—It is a yellowish liquid resin, viscous like ordinary cane sirup, polymerizing spontaneously into a semisolid body of a ruby-red to reddish brown color. It has an odor like that described for the rhizome, a very bitter taste which persists for several minutes. The polymerization is apparently accompanied by a disengagement of a volatile or gaseous substance, for when cicutoxin is kept in a glass-stoppered bottle the polymerization is very slow compared to what it is when exposed to the air. When the substance is kept in an evacuated desiccator over concentrated sulfuric acid, the process is the most rapid and after some hours visible decomposition sets in, shown by the liberation of gas. The substance darkens and carbonizes, the acid in the desiccator assuming a ruby-red color. The visible decomposition may be retarded or entirely inhibited by lowering the temperature, increasing the pressure, or both. It cannot be dried over sulfuric acid.

Cicutoxin is very sensitive to an increase in temperature above that

normal to its formation in the plant, and differences have been observed in the products obtained in April and October from those obtained in July and August. The former is the yellower product and the more toxic, gram for gram, but the midsummer tubers contain the larger quantity of material. When cicutoxin is heated quite rapidly in a melting-point tube, it begins to decompose at 100° , the decomposition becoming pronounced at 115° and strong at $125-130^{\circ}$. At 150° the substance chars in a few minutes. When a larger quantity of the substance is heated in a test tube connected with a delivery tube, gases come off between 120° and 148° , and at the latter temperature there seems to be a pause in the decomposition process.

Cicutoxin is readily soluble in ethyl and methyl alcohol, ether, acetone, chloroform, phenol and glacial acetic acid, but is very slightly soluble in carbon tetrachloride, benzene and petroleic ether. It is insoluble in water, glycerol and aniline.

Cicutoxin has never been obtained in crystalline form, but is precipitated as an amorphous solid when a concentrated alcoholic solution is poured, drop by drop, into a large volume of cold, low-boiling petroleic ether. When the temperature rises to about 20° , the precipitated cicutoxin melts into the original sirupy mass. It is not volatile with steam nor can it be distilled in any manner without decomposition, and consequent loss of toxicity. When pure it is neutral to litmus, phenolphthalein, congo red and sodium alizarinesulfonate, but if dissolved in alcohol and the solution allowed to stand at room temperature for a few hours, sufficient decomposition will take place to render the solution slightly acid. Cicutoxin is not an aldehyde, acid, ester, carbohydrate, anhydride, ketone or hydrocarbon, but by acetylation with acetic anhydride it shows weak alcoholic properties. When ignited it burns with a smoky flame leaving a carbonaceous residue. It unites with free bromine very energetically, with the liberation of gas, the reaction being strongly exothermic. When in solution it also takes up some bromine and iodine. It ignites spontaneously when a few drops of concentrated nitric acid are poured upon it. In contact with concentrated sulfuric acid and phosphorus trichloride it chars immediately.

Cicutoxin does not haemolize bovine, sheep or rabbit blood. It has a specific gravity of 0.9659 at 22° , and an index of refraction of 1.5885 at 25° . Its solutions exhibit no absorption bands in the visible spectrum but a general absorption is noticed in the violet. The ultraviolet was not examined.

Tests for Cicutoxin.—No satisfactory chemical test for the detection of this poison has heretofore been submitted. Takayama,¹ however, gives the following color test: a concentrated solution of cicutoxin in

¹ *Mitteil. Med. Ges. Tokyo*, 17, Heft. 6 (1903).

phenol, or a mixture of phenol and ether (3 : 1), exhibits a beautiful green color when a drop of concentrated sulfuric acid is brought in contact with it on a watch glass, changing to blue and violet by reflected light and finally to brown and reddish brown.

The author finds that this test is not entirely satisfactory because the given color changes are not only produced by the pure cicutoxin but by the polymerized and decomposed product which is no longer poisonous.

The following chemical test may be given as one not open to the above objection and, as far as the author's experience goes, is entirely characteristic for the pure cicutoxin: Add a 2% aqueous barium hydroxide solution, in small quantities, to a 5% alcoholic solution of the poison, until a voluminous precipitate appears and continue the addition till the color changes to a light green, then a few drops more, after which the solution is set aside. In from one to ten minutes the precipitate will have assumed a pea-green to olive-green color, which changes to a reddish brown (O—Shade I, Mulliken Color Standard, Sheet A), if an excess of barium hydrate has been added. On the addition of a dilute mineral acid in slight excess, the color changes to a darker red (OR—Shade I, Mulliken Color Standard, Sheet A).

For detection in stomach contents, an ethereal extraction is made and the residue tested by the above method. If the quantity allows, a subcutaneous injection of 0.05 g. of substance in dilute alcohol is given to a rabbit or guinea pig and observations made of the resulting symptoms. One-tenth this amount may be used for the production of characteristic symptoms in frogs.

Decomposition Products of Cicutoxin.—The dry distillation of cicutoxin yields a gas, between 125° and 148°, burning with a blue flame, which is not absorbed by solutions of bromine, potassium hydroxide or ammoniacal cuprous chloride. 4.7 g. material yielded 11.6 cc. of the gas, measured at 20° and 650 mm. pressure. Unsuccessful attempts were made to explode this gas with three and four volumes of oxygen. The material at hand could not be sacrificed for further attempts along this line. A previous distillation of cicutoxin (36.6 g.) had been carried out at diminished pressure, collecting the distillate in the following fractions:

Fraction.	Temp.	Pressure.	Grams distillate.	Sp. gr.	n.
1	45.5–52°	150–100 mm.	0.27	0.8316 _{24°}	1.363 _{24°}
2	52–85°	135–100 mm.	1.78	0.8874 _{20°}	1.370 _{24°}
3	110–168°	70–64 mm.	3.13	0.9360 _{20°}	$\left\{ \begin{array}{l} 1.4845_{12°} \\ 1.4812_{21.5} \\ 1.4766_{30°} \\ 1.4726_{40°} \end{array} \right.$
4	120–150°	160 mm.	3.82	0.9608 _{20°}
5	150–176°	180 mm.	0.80

The charred residue remaining in the flask weighed 19.37 g. Great

volumes of white and yellow fumes passed off during the distillation. These had hydrocarbon odors. Analyses made of the oil obtained in fraction 3, gave the following results:

(a) 0.3829 g. oil gave 1.0455 g. CO_2 and 0.3465 g. H_2O or C 74.47 and H 10.13;

(b) 0.4090 g. oil gave 1.1133 g. CO_2 and 0.3781 g. H_2O or C 74.24 and H 10.34.

Calc. for $\text{C}_{13}\text{H}_{21}\text{O}_2$: C, 74.58%; H, 10.12%.

The steam distillation of cicutoxin yields a colorless oil. It is only partially soluble in water, the major portion being found as a globule floating on the water in the receiver. This product has a pleasant essential-oil odor, and polymerizes in the course of a few weeks into a clear transparent semisolid resin. A combustion of this oil gave the following values:

0.2545 g. oil gave 0.7592 g. CO_2 and 0.2412 g. H_2O .

Calc. for $\text{C}_{14}\text{H}_{22}\text{O}$: C, 81.44%; H, 10.75%; found: C, 81.36; H 10.61.

Not enough material was at hand for molecular weight determinations.

When cicutoxin is treated with a fairly mild oxidizing agent such as potassium permanganate or nitric acid (1 : 3), it breaks up into various well-known substances. Pohl¹ detected oxalic acid as a decomposition product of cicutoxin, by using potassium permanganate. The correctness of his observation was confirmed by the work in this laboratory, where oxalic acid has been obtained with both permanganate and dilute nitric acid oxidations. Carbon dioxide is another product of this treatment.

In order to determine the amount of oxalic acid and carbon dioxide resulting from the oxidation, the following experiment was carried out: 0.7681 g. cicutoxin was heated in a flask on a water bath together with 50 cc. of water solution of nitric acid (1 : 2) for 24 hours, water being added from time to time, to maintain the approximate concentration of the acid. The vapors from the flask were aspirated through water, concentrated sulfuric acid and potassium hydroxide, respectively. At the end of the experiment the tubes containing the alkali gained 0.5639 g. in weight, which represented carbon dioxide. This amount, reduced to carbon, was 20.23% of the weight of the oxidized cicutoxin. There remained in the flask an unoxidized residue weighing 7.7 mg. This residue can be broken up by prolonging the oxidation. The oxalic acid was obtained from the nitric acid solution by neutralizing the latter with KOH, acidifying with acetic acid, treating with calcium chloride and titrating the oxalic acid liberated from its calcium salt, with standard potassium permanganate, giving 0.19297 g. $(\text{COOH})_2$. Assuming that the carbon atoms and one oxygen atom of the oxalic acid came from cicutoxin, it would mean that 11.27% of the cicutoxin went to oxalic acid. The ratio of $2\text{C} + \text{O}$ to $\text{C}_{13}\text{H}_{21}\text{O}_2$ is 13.23%.

Three additional products resulting from the oxidation were identified,

¹ *Loc. cit.*

namely, hydrocyanic acid, isobutyric acid and acetyl-2-cyclopentanone. The first of these was found in the wash water through which the carbon dioxide was aspirated. This acid, precipitated with silver nitrate, gave a white salt, not sensitive to light, and upon burning showed the cyanide composition. The nitrogen had been supplied by the nitric acid. When the nitric acid solution resulting from the cicutoxin oxidation was shaken with ether, the ethereal solution treated with metallic zinc to remove the dissolved nitric acid, and the filtrate from the zinc treatment allowed to evaporate at room temperature, a liquid remained, having acid properties and a decided isobutyric acid odor. This liquid was distilled, the distillate shaken out with ether and, after drying, the substance was recovered from the ether and burned, with results indicating the composition $C_4H_8O_2$.

In a subsequent oxidation of cicutoxin with nitric acid, the major portion of oxalic acid was removed by crystallization and the larger portion of nitric acid by evaporation over caustic soda. The resulting paste was extracted with ether, the ethereal solution treated with zinc as above and the resulting liquid distilled under a pressure of about 15 mm., giving a constant and sharp boiling point of 73.5° . It had a rather pleasant ethereal odor and yielded combustion values indicating the composition $C_7H_{10}O_2$. Blaise and Koehler¹ synthesized a substance with this composition, whose boiling point was 75° at 8 mm. and showed it to be acetyl-2-cyclopentanone.

Attempts at hydrolyzing the cicutoxin with dilute sulfuric and hydrochloric acids were unsuccessful, but as a result there was obtained a very inert polymerization product, which was labelled "K." The same product was evidently formed by both processes. Cicutoxin in contact with 50 times its weight of 20-25% sulfuric acid was at first heated on the water bath for a couple of hours and then subjected to steam distillation for three hours. The substance swelled, darkened and became porous like a sponge. After removal from the flask it hardened and became brittle. It was powdered and washed free of acid with boiling water, dried to constant weight and burned.

(a) 0.2021 g. "K" by H_2SO_4 gave 0.5497 g. CO_2 and 0.1414 g. H_2O .

(b) 0.1809 g. "K" by H_2SO_4 gave 0.4932 g. CO_2 and 0.1295 g. H_2O .

Mean composition from (a) and (b) C 74.27%, H 7.91%.

The same procedure was carried out with cicutoxin and 20% hydrochloric acid, yielding apparently the same "K."

0.2363 g. "K" by HCl gave 0.6474 g. CO_2 and 0.1734 g. H_2O .

Composition of "K" by HCl , C 74.75%, H 8.21%.

Calculated for $C_{17}H_{22}O_3$: C 74.40%, H 8.09%.

A similar treatment of cicutoxin with nitric acid yields a different substance, which indicates the introduction of oxygen into the polym-

"K" obtained by the first two processes, as well as that obtained by heating cicutoxin with water in a sealed bomb tube to 200°, is one of the most stable and chemically inert substances known to the author. It is very sparingly soluble in hot ethyl and amyl alcohol, amyl acetate, naphthalene and phenol, but wholly insoluble in water, chloroform, pyridine, methyl alcohol, turpentine, carbon disulfide, carbon tetrachloride, potassium hydroxide solution, formic and acetic acids. No reagent was found to dissolve it to any appreciable extent except concentrated nitric and sulfuric acids, which destroy its identity.

The decomposition of cicutoxin with hydriodic acid (sp. gr. 1.7) was attempted in the hope of determining the number of methoxyl groups present in the compound. Various alkyl determinations were made, both with the free cicutoxin and when dissolved in glacial acetic acid, rendering values between 1.50% and 1.75% CH₃. Judging from the molecular weight determinations and subsequent work, these values do not indicate the presence of a CH₃O- group in the molecule.

Combinations of Cicutoxin.—Besides being very unstable, cicutoxin is relatively inert and only a few combinations of definite character have been successfully made. After working with the substance for three years, Boehm¹ says he is unable to arrive at an understanding of its chemical nature. This was doubtless due to the fact that he did not recognize the great instability of the substance at temperatures above 50°, and also when dissolved in alcohol.

Cicutoxin is best precipitated from its alcoholic solution as a compound of lead or barium. The former is the more stable and definite. The barium salt seems to be a combination of the partly decomposed cicutoxin molecule, and is itself unstable. For precipitating the lead compound, a clear water or alcoholic solution of basic lead acetate is prepared, of about 10% strength, and added slowly to an alcoholic solution of cicutoxin at room temperature, producing immediately a light yellow precipitate. The reagent is added until no further precipitation results. The precipitate is first washed by decantation and then on a filter paper with 50% alcohol until the filtrate is free from lead. The compound

¹ *Loc. cit.*

does not melt, but begins to decompose and char at about 230° . It ignites spontaneously when concentrated nitric acid is added to it.

Calc. for C ₁₉ H ₂₇ O ₅ Pb.....					38.19	42.04	5.01

The barium salt is made by slowly adding a 5% aqueous barium hydroxide solution to a dilute solution of cicutoxin in alcohol, at room temperature, with constant stirring. A yellowish precipitate at first appears, which turns greenish to dark green after the point of saturation has been reached and the solution becomes slightly alkaline. This precipitate settles slowly and is stable towards alcohol and water so that the compound may be washed as in the case of the lead salt, but if the barium hydrate is added to excess the color of the precipitate changes to nearly that of Shade I, Yellow-Orange, in Mulliken's Color Standards. If an excess of acid is added to the barium salt, a reddish brown sirupy substance resembling the original material separates out. The above observations would indicate that the barium salt thus obtained is unstable and that great importance cannot be attached to the values obtained for its composition. With a little experience one may be able to interrupt the precipitation at the right moment, so that a compound of uniform composition can be obtained. When this barium salt is kept for some months in a desiccator, or in the open air, the green color gradually fades into a sandy brown.

The washed and dried barium salt yielded the following analytical values:

The barium salt behaves like the lead salt in the melting-point tube, charring above 200° .

According to preliminary tests, cicutoxin possesses alcoholic properties, therefore attempts were made to produce a pure acetyl product of the poison. Both acetic anhydride and acetyl chloride were used but it was found that the latter reagent was the more adaptable. A dilute solution of cicutoxin in glacial acetic acid was made and acetyl chloride added in excess. The solution turned from a ruby-red to a dark brown, with a faint tint of green, but yielded no precipitate. The reaction mixture

was evaporated to dryness at a low temperature. The brown residue was dissolved in a small amount of hot alcohol and precipitated from low-boiling petroleic ether. This was repeated and then the brown powder dried in a desiccator to constant weight and burned.

(a) 0.2016 and 0.2019 g. acetyl prod. gave 0.5012 and 0.5216 g. CO_2 ; 0.1266 and 0.1300 g. H_2O .

Calc. for $\text{C}_{14}\text{H}_{16}\text{O}_3(\text{OCCH}_3)_2$: C 67.89%, H 6.97%; found: C 67.80, 69.09 and H 7.03, 7.07.

The acetyl product also precipitates from the alcoholic solution upon cooling, and this might have been a better method for the purification of the substance.

The iodine value of cicutoxin was found according to Hübl, the mean of two determinations being 125.5. Assuming the molecular weight of the substance to be 302.21, three atoms of iodine entered the molecule. The number obtained by calculation, using the above iodine value, was 2.99.

The bromine and iodine derivatives of cicutoxin have been made but they are difficult to purify, and a good deal of variation in the halogen content of different lots have been found, so that too much weight should not be attached to these determinations. The iodine compound, which is the more satisfactory to work with, is made by adding a dilute solution of iodine in glacial acetic acid to a solution of cicutoxin in the same solvent. Almost immediately a brown precipitate settles out, which is washed free of iodine with carbon tetrachloride. The substance is further purified by extracting with ether, until the latter solvent remains colorless. The ether removes a small amount of a substance that contains iodine. The ether insoluble residue is then dried and subjected to analysis. The compound ignites spontaneously when heated to 100° .

Calc. for $\text{C}_{14}\text{H}_{17}\text{O}_3\text{I}$						46.66	4.76	35.25

The bromine compound was made similar to the iodine, but in this case a dark brown to black liquid separated. This was purified in a similar way to the one above, but it was difficult to wash free of bromine and almost impossible to dry. Carius' determinations on this product yielded 22.15% and 23.53% bromine. The percentage of bromine calculated for $\text{C}_{14}\text{H}_{17}\text{O}_3\text{Br}$ is 25.54, showing that the composition is not far remote from that suggested by the iodine product.

It was found that the halogen acids form addition products with cicu-

toxin, or, more correctly, with a modified form of the cicutoxin molecule. The hydrochloride of cicutoxin was made by passing dry hydrochloric acid gas into a solution of the substance in absolute alcohol until the solution became saturated at the temperature of an ice-salt mixture. After saturation the flask was kept in the freezing mixture for 24 hours, with the hope of getting a crystalline product to separate, but without success. The dark brown solution resulting was evaporated to dryness at about 50° , the residue taken up in ether and shaken free of hydrochloric acid with water. The ethereal solution was then dried with calcium chloride and evaporated to dryness, leaving a brown amorphous powder which was subjected to analysis.

The amine hydrochloride of cicutoxin was prepared by saturating the alcoholic solution with dry ammonia gas and heating to 165° in a sealed bomb for two hours. The resulting solution was treated with an excess of hydrochloric acid, evaporated to dryness and the residue taken up in ether, washed with water and the substance precipitated from a mixture of low-boiling petroleic ether and carbon tetrachloride (three to one, by volume). The resulting brown product was washed, dried and subjected to analysis with the following results:

0.1985 g. subs. gave 0.1061 g. AgCl which is 13.22% Cl.

0.4487 g. subs. gave by Dumas' method, 19.6 cc. N at 26° and 646.2 mm. pressure, equivalent to 4.07% N.

(a) 0.1642 g. subs. gave 0.3952 g. CO₂ and 0.1000 g. H₂O equals C 65.64 and H 6.82.

(b) 0.1871 g. subs. gave 0.4519 g. CO₂ and 0.1134 g. H₂O equals C 65.87 and H 6.78.

Structure of the Molecule.—Recognizing that no constitutional formula can be ascribed with certainty to a complex molecule upon purely analytical data, yet when a certain familiarity with a substance is gained, combined with a knowledge of a large number of transformations, it would seem justifiable to incorporate that knowledge into an expression best explaining the facts known. Besides the facts recorded in this paper the author has made countless observations upon cicutoxin and its chemical behavior. Four-fifths or more of the experiments undertaken with the substance

have been negative or inconclusive and therefore omitted from this discussion. Each observation, however, whether positive or negative, has contributed to its knowledge.

More and more as the facts accumulated the author was led to believe that in the molecule of cicutoxin he had a pyrone nucleus to deal with. γ -Pyrone has the constitution shown in (I), in which one or more hydrogen

atoms may be substituted by an element or group, retaining the double linkage between the two pairs of carbon atoms as in chelidonic acid (II). One side of the molecule may be saturated by another pair of elements or groups as in α -ethyl- β , β' -dimethylpyronone (III), which was synthesized by Wedekind.¹

According to the records of Brühl,² Willstätter and Pummerer,³ Hantzsch and Denstorff,⁴ Feist and Baum,⁵ Staudinger,⁶ Ruhemann⁷ and others, concerning pyrone and its derivatives, a marked similarity in properties exists between this class of substances and cicutoxin. Both classes polymerize and change color in the air and especially when heated, both oxidize and yield oxalic acid quite readily, both are unsaturated and have indefinite basicity, both have carbonyl oxygen without yielding an oxime or phenylhydrazone, both add halogen acids and salts, but not free halogens, both substitute halogens for hydrogen, their iodine substitution products being very stable, with high melting points. Both classes form colored salts with certain basic elements and both substitute oxygen for the nitrogen in ammonia. These, together with some other minor similarities, have led the author to believe that cicutoxin is a derivative of γ -pyrone.

The reason for not being able to isolate and determine this constituent may be found in the fact that unstable groups are attached to the pyrone nucleus, which break up and effect immediate polymerization when the molecule is subjected to higher temperatures or chemical treatment. This explanation becomes more plausible when one considers the character

¹ *Ann.*, **378**, 261 (1911).

² *Ber.*, **24**, 2450 (1891).

³ *Ibid.*, **37**, 3740 (1904).

⁴ *Ibid.*, **40**, 241 (1907).

⁵ *Ibid.*, **38**, 3562 (1905).

⁷ *J. Chem. Soc.*, **75**, 415 (1899).

of these groups and the extraordinary stability of the polymerization product "K."

We then have the following building material out of which to construct the graphic molecule: a pyrone nucleus, an acetyl-2-cyclopentanone group, an isobutyl group, which when oxidized away would yield either isobutyric aldehyde or isobutyric acid. In case the former resulted it would, according to Taipale,¹ be oxidized to isobutyric acid by the hydrocyanic acid shown to be present. Besides these, an unsaturated and unstable group must be introduced on purely empirical grounds, which is chosen only after careful consideration of its properties and the transformations it is likely to occasion. In view, therefore, of the facts adduced, the author feels justified to submit the following structural formula for the cicutoxin molecule (IV),

This expression corresponds to the empirical formula $\text{C}_{19}\text{H}_{26}\text{O}_8$ obtained by analysis. The lower left hand radical is cyclopentanone containing a labile hydrogen atom, making it tautomeric with cyclopentanol, in which condition the formation of the acetyl product and barium salt are rendered possible. The same condition of tautomerism is presumed for the β' -hydrogen atom of the pyrone ring, shifting to the γ -position under certain conditions. The decomposition product obtained from the nitric acid oxidation was acetyl-2-cyclopentanone, shown in (V), instead of the straight pentanone, shown as a radical in (IV).

Since the pyrone molecule is far less stable than the five-membered carbon ring it is obvious that, when the molecule is split up by the nitric acid, the break should occur at the most vulnerable place. We therefore have the isobutyl group liberated and oxidized to isobutyric aldehyde or acid, the pentanone group split off, taking with it the oxygen and α' -carbon atoms of the pyrone together with the attached methyl. The

¹ *J. Russ. Phys. Chem. Ges.*, 41, 815 (1909).

rest of the molecule is oxidized to oxalic acid and carbon dioxide, with the exception of a carbon-hydrogen group which forms hydrocyanic acid with the nitrogen from nitric acid, and one or more hydrocarbons that are undoubtedly liberated in the polymerization immediately preceding the oxidation.

The right hand isoprene group is the most unstable part of the entire molecule. Isoprene decomposes readily under certain circumstances and polymerizes under others, and these properties especially fit the conditions of the cicutoxin molecule. Suppose the isoprene radical should be split in two, liberating C_2H_4 , and the free bond of the isoprene carbon unite with the β -carbon of the pyrone ring, we should get the structure represented in (VI).

If this molecule should polymerize, which is not beyond the range of possibility, we would have a product whose composition would be that of "K," or $(C_{17}H_{22}O_3)_x$. On the other hand, if under certain conditions, particularly an acid medium, the entire isoprene group were to be removed and acetyl groups substituted for the two labile hydrogens, we should get the form represented in (VII), which has the same composition as the acetyl product isolated from cicutoxin.¹

The iodine product obtained may be represented by the same formula,

¹ NOTE.—An objection to this formula may be made on the ground that the introduction of a triple bond in the pyrone nucleus is unprecedented, but it is nevertheless within the range of possibility. It has already been noted that, although pyrone contains double bonds, it does not add halogen, and this property is apparently not changed by the introduction of a triple bond.

one iodine being substituted for the β' -hydrogen in the pyrone ring and the isoprene group eliminated as shown in (VIII).

The lead salt of cicutoxin may be considered as having been formed like the neutral salt combinations with pyrone itself in which oxonium compounds have resulted. In this case the PbO and OH groups from the basic lead acetate are in the same manner supposed to satisfy the quadrivalent oxygen of the pyrone nucleus making the formula for the lead salt $C_{19}H_{26}O_3 \cdot PbO \cdot OH$. Descriptions of somewhat similar organic lead oxide combinations may be found in the literature,¹ but too much credence should not be placed on either the lead or the barium salt for the reason that their purification could not be accomplished satisfactorily. The barium salt is not supposed to be an oxonium compound, like the lead salt and the hydrochloride, but a cyclopentanolate, obtained by the substitution of the cyclopentanol hydrogen in two molecules of cicutoxin. No doubt other alkali and alkaline earth salts of the same composition are formed although their isolation proved unsuccessful.

It has already been pointed out that in a mineral acid medium cicutoxin easily decomposes, with a recombination or polymerization of certain parts resulting from the decomposition. Consequently, it was not to be expected that a straight hydrochloride or amine hydrochloride of the substance could be made. However, the hydrochloride obtained bears a simple relation to certain decomposition products obtained from cicutoxin. The product "K," obtained from a mineral acid medium, is considered some multiple of $C_{17}H_{22}O_3$. If this group were to combine with the oil obtained by steam distillation ($C_{14}H_{22}O$), with the elimination of H_2O , and if this compound molecule should add two molecules of hydrochloric acid, we would get a compound corresponding to the analytical values obtained for the hydrochloride made from cicutoxin.

Not so simple a relation as this is disclosed by the composition of the amine hydrochloride, but the analytical values for this compound have been included without attempting to show what the relation is. It is

¹ *Jahresber. Chem.*, **16**, 566 (1863); *Ann.*, **255**, 195 (1890); *Deutsche Zucker Industrie*, **12**, 1367.

not improbable that this product is the hydrochloride of a modified imino cicutoxin corresponding to pyridone which is obtained from pyrone with ammonia, or oxypicolinic acid obtained from comanic acid.

It is interesting to note that chelidonic acid, a simple derivative of pyrone, has been isolated from the roots of the poisonous veratrum or white hellebore belonging to the lily family, a plant also growing in swamps and marshy ground.

Toxicological.¹

A fairly concordant literature is found on the physiological effects of this poison. With the exception of the frog, the symptoms are very similar in all the lower animals, as well as man. Cicutoxin may be classed as a narcotic cramp poison which attacks certain brain centers.

Three well-defined stages of symptoms are recognized in cicuta poisoning, namely, a prodromal, a paroxysmal and a paralytic stage. The first represents the time prior to the beginning of visible symptoms, and is usually not of more than forty minutes' duration.

When the poison is administered intravenously the animal at once passes into the second or paroxysmal stage, beginning with a strong salivation and tremors. The animal is then seized by convulsions at irregular intervals, characterized by violent chewing and frothing at the mouth. The tonic and clonic spasms, into which the animal is thrown, render it unconscious and irresponsive to stimulation. There is also dilation of the pupils, a more rapid and shallow respiration, as well as an increase in body temperature. This stage usually lasts from twenty minutes to six or eight hours.

The paralytic or final stage represents the time when the animal has relapsed into total paralysis and is no further responsive to stimulation. This stage is only of a few minutes' duration.

Wikszemski² has shown that cicutoxin attacks the cramp center of the brain, located at the base of the fourth ventricle. It also affects the pneumogastric centre so that a small dose stimulates and a larger one paralyzes the action of the lungs and heart. The animal dies from asphyxiation and exhaustion.

In regard to the toxicity of the poison it has been found that a root the size of a walnut is sufficient to kill a cow. 150-200 mg. cicutoxin kills the average rabbit and 200 mg. the average cat. Boehm² found that, per kilo body weight of dogs, 110 mg. per mouth and 21 mg. intravenously, was sufficient to kill; and that 50 mg. per kilo body weight of cats, when administered per mouth, was found sufficient to kill. From other in-

¹ A detailed account of the botanical and toxicological investigations of water hemlock will be published in *Bulletin* 81 of The Nevada Agricultural Experiment Station.

² *Loc. cit.*

vestigations, however, it would appear that the lethal dose of this poison cannot be correctly given in terms of milligrams per kilo body weight.

No abnormalities whatsoever are noticed after death, with the exception of a pronounced venous hyperemia of the brain and lungs, and in certain cases, a reddening of the inside lining of the stomach.

No antidote for cicutoxin is known. The most successful treatment, in human cases of poisoning, consists in producing vomiting and moderating the effects of the convulsions by means of a narcotic, such as morphine or opium.

The author wishes to acknowledge the assistance of Mr. August Holmes, during the major portion of this work.

Conclusion.

Water hemlock is an umbelliferous, poisonous plant, growing along the banks of streams and in marshy ground. It is recognized under at least three distinct species in this country, all three containing the same poisonous principle, cicutoxin, which is located primarily in the rhizome or root-stalk of the plant.

Cicutoxin is an unstable resin-like substance of the formula $C_{19}H_{26}O_3$, and is a complex derivative of pyrone. A tentative structural formula for the cicutoxin molecule has been proposed. It decomposes and polymerizes readily, especially at temperatures above 50° . It is extracted from the tubers by means of ether and enters violently into combination with free bromine.

It forms combinations with lead, barium, hydrochloric acid, ammonia, and yields the double acetyl derivative.

A reliable chemical test for its presence has been found.

Cicutoxin is a spasmotoxin, producing symptoms that may be separated into a prodromal, a paroxysmal and a paralytic stage. Death ordinarily results in from thirty minutes to eight hours. The lethal dose of cicutoxin for the average rabbit is 175 mg., and "50 mg. per kilo body weight" for cats, when administered per mouth. Cicutoxin attacks a nerve center in the calamus scriptorius and kills by asphyxiation and exhaustion.

It is not a constitutional poison and the lethal dose cannot properly be given in terms of milligrams per kilo body weight. No antidote is known for this poison, and the most reliable treatment at present consists in producing vomiting and allaying the convulsions by means of a narcotic.

RENO, NEV.

A NEW SYNTHESIS OF IMINOACETONITRILE AND ITS CONVERSION TO HYDRAZINODIACETIC ACID.

BY J. R. BAILEY AND D. F. SNYDER.

Received February 8, 1915.

Introduction.

From the work of various investigators¹ it appeared highly probable that methyleneaminoacetonitrile, $\text{CH}_2 = \text{NCH}_2\text{CN}$,² would readily add on prussic acid, and thus furnish an excellent method for the preparation of iminoacetonitrile, $\text{NH}(\text{CH}_2\text{CN})_2$.³ Our first experiment in this direction showed that the expected reaction proceeds normally at room temperature, when the above methyleneamino compound is subjected to the action of either absolute or an aqueous prussic acid. This method of preparing the nitrile of iminodiacetic acid, on account of the ease with which the starting substances can be obtained, and, because of the fact that the reaction proceeds quantitatively without the formation of other products, may supplement the method of Eschweiler, referred to above, where, in the treatment of hexamethylenetetramine with prussic acid under different conditions, aminoacetonitrile, iminoacetonitrile, and nitrilotriacetonitrile, $\text{N}(\text{CH}_2\text{CN})_3$, are formed in varying amounts. Strangely enough, M. Delépine states that methyleneaminoacetonitrile is indifferent to prussic acid.⁴ This investigator showed that ethylidene- α -propionitrile, $\text{CH}_3\text{CH} = \text{NCH}(\text{CH}_3)\text{CN}$, and numerous alkylidene amines add on prussic acid; but, after trying under modified conditions to effect the reaction that, according to our observation proceeds so smoothly between methyleneaminoacetonitrile and prussic acid, he reported as follows: "J'ai constaté que ce corps ($\text{CH}_2 = \text{NCH}_2\text{CN}$) restait absolument inaltéré sous l'influence de l'acide cyanhydrique à froid, en présence ou en l'absence de solvants." Delépine advances the supposed resistance of methyleneaminoacetonitrile towards prussic acid in support of the dimeric formula proposed by Klages for this substance.⁵ In case Klages' view of the molecular weight of methyleneaminoacetonitrile be correct, and we have no reason to doubt the correctness of his conclusion in this matter, we must ascribe to the prussic acid in the above reaction a depolymerizing action which probably precedes the additive action. A molecular weight determination showed conclusively that iminoacetonitrile is monomolecular. Granting that methyleneaminoacetonitrile is dimolecular, no insight into the constitution of the molecule is afforded by its chemical behavior be-

cause depolymerization always accompanies its chemical changes. Frequently the group $N = C$ in polymerized molecules takes up HCN with the resultant addition product monomolecular, as in the above case investigated by us. Von Miller with his co-workers¹ found that anhydroformaldehyde aniline, although trimolecular, and dimeric anhydrovaleraldehyde aniline showed the behavior toward prussic acid of simple monomolecular compounds, yielding anilidoacetonitrile and anilidovaleronitrile, respectively. Ethylideneaniline, on the other hand, proved indifferent to prussic acid. Furthermore, unpublished experiments conducted in this laboratory show that the complex insoluble reaction product of formaldehyde with hydrazine is not in any way altered by prussic acid.² Delépine observed that the polymeric condition of alkylidene amines at lower temperatures is not always of moment in their behavior toward HCN, as he found that "the polymerized molecules frequently react like the simple molecules."³

Attempts were made by us in the preparation of iminoacetonitrile to generate the prussic acid from KCN and HCl in the presence of the methyleneaminoacetonitrile, and thus simplify the process. However, as is frequently the case in the conversion of the complex $N = C$ to $NH-CCN$ by the addition of HCN, the desired result was not attained by this method.

Knoevenagel³ has shown that aldehyde bisulfite compounds condense with amines with the elimination of water, forming salts of substituted aminomethane sulfonic acids of the general formula $R_2NCH(R)SO_3Na$. These latter substances react readily with potassium cyanide, yielding substitution products of aminoacetonitrile of the general formula, $R_2NCH(R)CN$. It appeared probable that a like result might be attained by adding alkali bisulfite on to the $N = C$ complex in methyleneaminoacetonitrile, and then treating the reaction product with KCN. As shown in the experimental part of this article, iminoacetonitrile may be made in this way, but the conditions were not established under which a satisfactory yield could be obtained.

A very comprehensive investigation of iminoacetonitrile has been carried out by Jongkees.⁴ In the course of his work he converted the nitrile to ethyl hydantoino-1-acetate,

We have been able to improve on his rather complicated process in the preparation of this substance, in that, by treatment of iminoacetonitrile in glacial acetic acid with potassium cyanate, saponification of the ureido

¹ *Loc. cit.*

² Observation of L. A. Mikeska.

⁴ *Rec. trav. chim.*, **27**, 287 (1908).

derivative thus formed, and then esterification, we pass directly from iminoacetoneitrile to the above ethyl hydantoinoacetate with a 45% yield, and without the isolation of the intermediary products. This process can no doubt be employed in converting other imino acid nitriles into the corresponding hydantoino acid esters. The use of glacial acetic acid as a solvent in effecting the urea synthesis was first tried in this laboratory in an investigation of the action of cyanic acid on hydrazo-*i*-butyric acid, $(\text{CH}_3)_2\text{CNHNHC}(\text{CH}_3)_2$, the results of which work will

be published shortly. Experiments were tried without result to convert iminoacetoneitrile to its ureido derivative in the usual way, by the action of potassium cyanate on the hydrochloride of this amine in water solution.

The H in the NH group of iminoacetoneitrile, in contrast to the imino hydrogen in the corresponding acid, is very reactive, but, especially where an elevated temperature is required to replace this hydrogen, a disturbing factor enters in the case of the nitrile, owing to the ease with which this substance splits off HCN. Although iminodiacetic acid has been known a long time,¹ no investigator has announced the preparation of corresponding thiohydantoin from this imino acid and mustard oils. As Marckwald, Neumark, and Stelzner² have shown that, in the case of the aliphatic amino acids, it is necessary to salify the carboxyl before the NH_2 group will react readily with mustard oils, it appeared probable that salts of iminodiacetic acid, in contrast to the free acid, would condense with mustard oils. We find that by using the acid sodium salt of iminodiacetic acid, it is very easy to prepare thiohydantoin of the general formula

which can be readily isolated in the form of their ethyl esters.

Our work on the derivatives of iminodiacetic acid had its origin in the problem of working out a method of passing from imino diacids to hydrazinodiacids, corresponding to hydrazinodiacetic acid, $\text{NH}_2\text{N}(\text{CH}_2\text{COOH})_2$. This hydrazine, discovered by Curtius and Hussong,³ readily yields with nitrous acid iminodiacetic acid: $\text{NH}_2\text{N}(\text{CH}_2\text{COOH})_2 + \text{HNO}_2 = \text{NH}(\text{CH}_2\text{COOH})_2 + \text{N}_2\text{O} + \text{H}_2\text{O}$.⁴ From the work of Fischer,⁵ Renouf,⁶ and Harries⁷ on the reduction of nitrosamines, it appeared highly

probable that iminodiacetic acid could be reconverted to hydrazinodiacetic acid by reducing nitrosiminodiacetic acid. Working with methyl nitrosiminodiacetate, $\text{NON}(\text{CH}_2\text{COOCH}_3)_2$, we have obtained hydrazinodiacetic acid by reduction with sodium amalgam, and experiments are being carried out in this laboratory directed towards the extension of this process to the preparation of other hydrazino diacids. Although this method is of no preparative value in the above case, where it has been applied, it will doubtless prove of value in preparing some of the higher homologs in this series.

Experimental Part.

Preparation of Iminoacetonitrile from Methyleneaminoacetonitrile and Prussic Acid.—100 cc. of absolute prussic acid, containing 10 drops of concentrated hydrochloric acid, are poured on 100 g. of methyleneaminoacetonitrile in a thick-walled pressure flask. In about twenty-four hours complete solution is effected, and then later on the iminoacetonitrile begins to crystallize out in an interwoven mass of long prisms. At the end of forty-eight hours the excess of prussic acid is recovered by distilling it off below 50° , and finally a further small amount is removed from the nitrile by allowing it to stand *in vacuo*. The compound is then purified by recrystallization from acetic ether, and finally from benzene. Petrol ether is an excellent solvent for purification, where small amounts of the nitrile are to be identified, as even from smears it can be regained colorless in long, hair-like needles by the use of this solvent. Prepared in the above way, iminoacetonitrile melts sharply and undecomposed at 75° , as determined by Eschweiler. In working with this substance the fact should be borne in mind that on prolonged heating in solvents, it evolves prussic acid. As a further identification of the preparation obtained by the action of prussic acid on methyleneaminoacetonitrile, it was converted according to the directions of Eschweiler into the corresponding acid, and into the characteristic hydrochloride of the methyl ester described by Jongkees. The following analysis and molecular weight determinations were made on the nitrile prepared by the new process:

Calc. for $\text{C}_4\text{H}_6\text{N}_2$: C, 50.53; H, 5.26; N, 44.21; found: C, 50.67; H, 5.36; N, 44.39.

Three molecular weight determinations by the freezing point method with acetic acid as the solvent gave 105, 107, and 106. Calc. for $\text{C}_4\text{H}_6\text{N}_2$: 95.

The following modifications of making iminoacetonitrile as described above were tried in the hope of obviating the use of free prussic acid: One gram of methyleneaminoacetonitrile and 1 g. of KCN were dissolved in the least amount of water at 60° , and then 1 mol of HCl allowed to drop into the solution. Not a trace of iminoacetonitrile could be detected, but considerable unchanged methylene compound was recovered. In a second experiment 1 g. of methyleneaminoacetonitrile was stirred into a solution of sodium bisulfite, prepared from 0.8 g. of Na_2CO_3 and 2.7 g.

of water in the usual way. The methylene compound dissolved readily with an elevation of temperature of 15° , so that there is little doubt that in this process the bisulfite adds onto the $N = C$ complex. The new substance can be precipitated along with inorganic admixtures by the addition of alcohol, but, because of its ready solubility in water and its insolubility in organic solvents, a method of purification was not found. However, when the reaction mixture of bisulfite and the methylene compound was treated with one mol of KCN in water solution at 60° , the solution concentrated to a pasty consistency *in vacuo* on a water bath, and the residue extracted with petroleic ether, a considerable amount of iminoacetonitrile was obtained.

Salts of Iminoacetonitrile.—The only salt of iminoacetonitrile described in the literature is the hydrochloride, which, according to Eschweiler, precipitates on leading hydrochloric acid gas into an ether solution of the nitrile.¹ We found that a convenient way to prepare this salt is to dissolve the nitrile in 20% $CH_3OH-HCl$ by slightly warming. In a few minutes after solution, the nitrile separates as the hydrochloride in characteristic long prisms.

A more stable salt than the hydrochloride is the nitrate, which may be prepared as follows: 1 g. of the nitrile is dissolved in 4 cc. of concentrated nitric acid, and the precipitation of the salt effected by the addition of 4 cc. of absolute alcohol. For purification the nitrate is dissolved in boiling alcohol, and then precipitated by the addition of ether. It crystallizes from alcohol in very long slender needles, which melt at $134-135^{\circ}$, apparently undecomposed, but in a few seconds the liquid blackens with gas evolution. The nitrate, like the hydrochloride, hydrolyzes in water solution, from which, on shaking out with ether, the free iminoacetonitrile may be regained.

Calc. for $C_4H_4O_3N_4$: C, 30.38; H, 3.80; N, 35.44; found: C, 30.70; H, 3.98; N, 35.65.

Nitrosiminoacetonitrile, $NON(CH_2CN)_2$.—If to 1 g. of iminoacetonitrile in 10.5 cc. of $N H_2SO_4$ a concentrated solution of 0.75 g. of $NaNO_2$ be added, there separates immediately a light yellow oil, which on cooling and stirring solidifies. The nitrosamine thus obtained gives the Liebermann reaction. It is more difficultly soluble than the parent substance in all solvents. For analysis it was purified by precipitation from an acetic ether solution by the addition of petroleic ether, as well as by recrystallization from benzene. It crystallizes in the form of slender prisms of a faint yellow color, melting undecomposed at 38° . Snessarew gives $51-52^{\circ}$ as the melting point of nitroso- α -iminoisobutyronitrile,² while Passavant describes nitroso- α -iminopropionitrile as an oil.³ The melting point of

¹ *Ann.*, 278, 231 (1894).

² *J. prakt. Chem.*, [2] 89, 364 (1914).

³ *Ann.*, 200, 131 (1880).

iminopropionitrile lies between that of the corresponding iminonitriles of Eschweiler and Snessarew, so that in all probability the nitroso derivative of iminopropionitrile can be obtained as a solid like the above homologs. Our attempts to reduce nitrosiminoacetonitrile with sodium amalgam to hydrazinodiacetonitrile, and isolate the latter in the form of the corresponding difficultly soluble hydrazinodiacetic acid have thus far failed, because the nitroso compound is decomposed in the alkaline solution. However, further attempts will be made to establish conditions under which a reduction can be effected. Despite the fact that this nitrosamine appears perfectly stable, none of the analyses, which were made on three different preparations, agreed closely with the calculated percentages, and it may be that the melting point given above will be found too low, when carried out on a perfectly pure sample.

Calc. for $C_4H_4ON_4$: C, 38.71; H, 3.23; N, 45.16; found: C, 39.31; 39.19, 39.19; H, 3.32, 3.39, 3.31; N, 44.88, 44.45, 44.50.

Benzoyliminoacetonitrile, $C_6H_5CON(CH_2CN)_2$. — Jongkees obtained acetyliminoacetonitrile as a viscous oil, boiling at 227° under 16 mm. pressure, but was unable to make the substance crystallize. We find that the benzoyl derivative in contrast to the acetyl compound is a beautifully crystallizing substance, which can be readily prepared from iminoacetonitrile in benzene solution by heating it with one mol of benzoyl chloride. The benzoyl derivative thus prepared is readily soluble in alcohol, chloroform, acetic ether, and water, and difficultly soluble in ether and benzene. Recrystallized from alcohol, it is obtained in diamond shaped prisms, made up apparently of laminated plates, melting undecomposed at $131-132^\circ$.

Calc. for $C_{11}H_9ON_3$: C, 66.33; H, 4.52; N, 21.11; found: C, 66.08; H, 4.68; N, 21.25.

Ethyl Hydantoino-1-acetate,
$$\begin{array}{c} \text{CO}-\text{N}-\text{CH}_2\text{COOC}_2\text{H}_5 \\ | \quad | \\ \text{NH} \quad \text{CH}_2 \end{array}$$
—2 g. of finely pow-

CO

dered potassium cyanate are stirred into a solution of 2 g. of iminoacetonitrile in 20 cc. of glacial acetic acid, whereupon reaction proceeds with a temperature elevation of about 16° . After several hours' standing, the mixture is evaporated to dryness *in vacuo*, the residue saponified by boiling with 20 cc. of concentrated hydrochloric acid, the solution again evaporated to dryness, and finally the hydantoino acetic acid esterified by boiling for two hours with 50 cc. of 5% $C_2H_5OH-HCl$. After driving off the alcohol, the hydrochloride of the ester is dissolved in a little water, the solution made just alkaline with ammonia, and then the ester extracted with chloroform. The substance, purified by recrystallization from alcohol and benzene, corresponded in its properties with the prepara-

tion obtained by Jongkees with carboxymethyliminoacetonitrile, $\text{CH}_3\text{OCON}(\text{CH}_2\text{CN})_2$ as the starting substance.¹ Our yield of hydantoino ester by the above process was about 44% of the theoretical. The same substance was obtained by the action of sodium ethoxide on methyl ureidodiacetate in ethyl alcohol solution.² As a further confirmation of the constitution of the ethyl hydantoinoacetate prepared by us, a nitrogen determination was made.

Calc. for $\text{C}_7\text{H}_{10}\text{O}_4\text{N}_2$: N, 15.05; found: N, 15.35.

For the preparation of this hydantoin, 2 g. of iminoacetonitrile, dissolved in 2 mols of *N* NaOH, are allowed to stand 48 hours, and then the solution is boiled until there is no further escape of ammonia. One-half of the alkali is now neutralized with HCl, the solution evaporated to a small volume, 2.8 g. of phenyl mustard oil in 20 cc. of alcohol added, and the mixture boiled under a return condenser for 6 hours. The solution is next evaporated to dryness, and the residue containing the hydantoin esterified by boiling it with 50 cc. of 5% $\text{C}_2\text{H}_5\text{OH}-\text{HCl}$ for 2 hours, and then proceeding just as in the preparation of the above ethyl hydantoinoacetate. The yield obtained on the thiohydantoin was about 72% of the theoretical. It crystallizes from alcohol in long, slender prisms with dome-shaped end faces, which melt undecomposed at 134° . The compound is difficultly soluble in water and readily soluble in the common organic solvents, petroleic ether excepted.

Calc. for $\text{C}_{13}\text{H}_{14}\text{O}_3\text{N}_2\text{S}$: C, 56.12; H, 5.04; N, 10.07; S, 11.51; found: C, 56.27; H, 5.25; N, 10.28; S, 11.49.

Ethyl-3-Methyl-2-thiohydantoino-1-acetate.—This hydantoin, prepared by the use of methyl mustard oil similarly to the phenyl compound, can be recrystallized from petroleic ether in the form of slender needles, which melt undecomposed at 62° . The methyl hydantoin is readily soluble in all the common solvents.

Calc. for $\text{C}_8\text{H}_{12}\text{O}_3\text{N}_2\text{S}$: N, 12.92; found: N, 13.06.

Preparation of Hydrazinodiacetic Acid from Methyl Nitrosoimino-diacetate.—0.5 g. of $\text{HCl}-\text{NH}(\text{CH}_2\text{COOCH}_3)_2$, prepared according to the method of Jongkees¹ were dissolved in 10 cc. of water, and to this solution 1.75 g. of NaNO_2 in 2 cc. of water were added. 3.5 g. of methyl nitrosoiminodiacetate separated as a yellow oil, heavier than water. No analysis was made on this preparation, as it is described in an article by Curtius,

¹ *Loc. cit.*

² See the following article.

Darapsky and Mueller.¹ The 3.5 g. of crude nitroso compound, obtained in the above experiment, were dissolved in 29 cc. of 50% alcohol, and reduced at 10° by introducing 50 g. of 5° sodium amalgam in small portions, with constant shaking. After the amalgam had become exhausted, 10 cc. of water were added and the solution, poured off from the mercury, was boiled a few minutes. On making the solution just acid with HCl, 0.6 g. of almost pure hydrazinodiacetic acid crystallized out. Reduction of the aqueous solution, from which the 3.5 g. of nitroso compound separated, with 25 g. of amalgam yielded an additional 0.3 g. of the hydrazino acid. The substance proved identical in every respect with a sample of hydrazinodiacetic acid, made from hydrazine hydrate and monochloroacetic acid.² The following analysis was made on the sample obtained in the above reduction and purified by recrystallization from water:

Calc. for $C_4H_8O_4N_2$: N, 18.92; found: N, 18.88.

THE NITROSO DERIVATIVES OF SEMICARBAZINODIACETIC ACID ESTERS.

By J. R. BAILEY AND D. F. SNYDER.

Received February 8, 1915.

Introduction.

In studying the relation between the derivatives of hydrazinodiacetic acid and those of iminodiacetic acid, we had occasion to repeat the work of Bailey and Read³ on the action of nitrous acid on methyl semicarbazinodiacetate. They showed that in this reaction methyl iminodiacetate is formed, but did not succeed in isolating the intermediary nitroso compound, $NH_2CON(NO)N(CH_2COOCH_3)_2$. We find that this primary reaction product can be isolated and analyzed, but after a few hours standing undergoes spontaneous decomposition as follows:

The constitution of this new substance as methyl ureidodiacetate was established by its synthesis from the hydrochloride of methyl iminodiacetate⁴ and potassium cyanate, as well as by its conversion to esters of hydantoino-1-acetic acid.⁵ In the sodium alcoholate condensation of methyl ureidodiacetate to a hydantoin,⁶ it was found that the methyl

¹ *Ber.*, 41, 356 (1908).

² *J. prakt. Chem.*, [2] 83, 271 (1911); *THIS JOURNAL*, 36, 1747 (1914).

³ *THIS JOURNAL*, 36, 1747 (1914).

⁴ *Rec. trav. chim.*, 27, 287 (1908).

⁵ See foregoing article of Bailey and Snyder.

⁶ *Cf. Am. Chem. J.*, 28, 386 (1902).

ureido ester in ethyl alcohol with sodium ethoxide gave the *ethyl* ester of hydantoino-1-acetic acid, while sodium methoxide acted on the substance in methyl alcohol with the formation of the *methyl* ester of hydantoino-1-acetic acid. Bailey and Read observed a similar interchange of alkyls in the triazine condensation of methyl and ethyl semicarbazino-diacetate.¹

Fischer, in describing the spontaneous decomposition of nitrosodiethyl-semicarbazide, $\text{NH}_2\text{CON}(\text{NO})\text{N}(\text{C}_2\text{H}_5)_2$, states "these crystals can be filtered and washed, but not dried; after remaining a short time in a desiccator, they lose their yellow color and change with gas evolution to a colorless, strongly alkaline liquid."² It is probable that *unsym.*-diethyl-urea, $\text{NH}_2\text{CON}(\text{C}_2\text{H}_5)_2$ was formed in this decomposition, and that the alkaline reaction was due to small amounts of diethylamine and ammonia. Furthermore, in describing the nitroso derivative of methylphenylsemicarbazide, which he was able to analyze, Fischer states: "It melts at 77° with slight gas evolution and changes to a dark yellow oil, which was not further investigated."³ Here the decomposition would be expected to yield *unsym.*-methylphenylurea. Thiele⁴ has shown that α -nitroso-phenylhydrazine on heating in nitrobenzene solution decomposes quantitatively into nitrous oxide and aniline,

Darapsky and Prabhaker⁵ observed a similar decomposition on heating the esters of α -nitrosohydrazinoacetic acid *in vacuo*, in that nitrous oxide and esters of aminoacetic acid were formed,

Further investigation may show that, in conformity with the above uniform decomposition of nitroso hydrazino derivatives, it is possible in all such cases to eliminate nitrous oxide and unite the two rests joined to either side of the $=\text{NNO}$ complex.

The decomposition in water solution of the nitroso derivatives of all secondary semicarbazino derivatives thus far investigated proceeds with the hydrolysis of the ureido group and the evolution of nitrous oxide, as first observed by Fischer, *e. g.*,

In conformity with this reaction, Bailey and Read found that methyl nitrososemicarbazinodiacetate in water solution decomposes normally as follows:

¹ THIS JOURNAL, 36, 1754 (1914).

² *Ann.*, 199, 313 (1879).

³ *Ibid.*, 190, 165 (1878).

⁴ *Ber.*, 41, 2809 (1908).

⁵ *Ibid.*, 45, 1658 (1912).

Experimental Part.

Methyl Nitrososemicarbazinodiacetate,

$\text{NH}_2\text{CON}(\text{NO})\text{N}(\text{CH}_2\text{COOCH}_3)_2$.—Methyl semicarbazinodiacetate is dissolved in five times its weight of water, a concentrated solution of one mol. of NaNO_2 added, and to this mixture kept cool in ice water, one mol. of 3 *N* H_2SO_4 gradually added with constant shaking. The nitroso compound requires about one hour for complete separation. It is readily soluble in alcohol, chloroform, and benzene, and is best purified by recrystallization from acetic ether. In order that it may dry quickly, it is well to wash the nitroso compound with ether after filtering from the acetic ether. From acetic ether, it crystallizes in very characteristic tetragonal prisms of a deep yellow color, which melt with decomposition at $67\frac{1}{2}^\circ$. Even after careful purification, the substance must be kept in a cool place to preserve it sufficiently long for an analysis.

Calc. for $\text{C}_7\text{H}_{12}\text{O}_6\text{N}_4$: C, 33.87; H, 4.84; N, 22.58; found: C, 34.01; H, 4.99; N, 22.67.

Ethyl Nitrososemicarbazinodiacetate.—This nitroso derivative is prepared similarly to the above methyl ester, with the exception that here it is possible to work with the semicarbazide in an equal weight of water and, therefore, to obtain a better yield of the nitroso compound, about 1.4 g. from 2 g. of ethyl semicarbazinodiacetate. This compound possesses a remarkable difference in its solubilities in ether within a short range of temperature. It was found that a saturated solution of the nitroso compound in ether at 27° , on cooling to 5° , solidified so compactly that the test tube in which it was contained could be inverted without any loss of substance. The nitroso derivative was obtained in this way in a very pure state as a matted mass of hair-like needles, melting with decomposition at 60° .

Calc. for $\text{C}_9\text{H}_{16}\text{O}_6\text{N}_4$: N, 20.29; found: N, 20.25.

Methyl Ureidodiacetate from Methyl Nitrososemicarbazinodiacetate.

—Of the above nitroso compounds the methyl ester is the better suited for the isolation of the ureidodiacetate. For the preparation of methyl ureidodiacetate, methyl nitrososemicarbazinodiacetate is allowed to stand over sulfuric acid in a desiccator, slightly open to the air. After a short time, depending no doubt in a large measure on the temperature, gas evolution commences with a rise of temperature and the decomposition proceeds quickly to completion. The residue is then washed with a very little chloroform, which removes a small amount of smear and effects crystallization, and the ureido compound is then readily purified by crystallization from alcohol. Methyl ureidodiacetate is difficultly

soluble in ether and benzene, and readily soluble in the other common solvents with the exception of petroleic ether. From alcohol it crystallizes in prisms with dome-shaped end faces and melts at 145° with the elimination of alcohol and formation of methyl hydantoino-1-acetate.

Methyl Ureidodiacetate from the Hydrochloride of Methyl Iminodiacetate and Potassium Cyanate.—Potassium cyanate and the hydrochloride of methyl iminodiacetate react readily in concentrated aqueous solution. The ureido compound separates out in large part, and a further amount can be obtained by evaporating the solution to dryness and extracting with alcohol. This preparation proved identical with the decomposition product of methyl nitrososemicarbazinodiacetate.

Calc. for $C_7H_{12}O_6N_2$: C, 41.18; H, 5.88; N, 13.73; found: C, 41.20; H, 5.95; N, 13.91.

Conversion of Methyl Ureidodiacetate to the Methyl and Ethyl Esters to Hydantoino-1-acetic Acid.—One gram of methyl ureidodiacetate in 10 cc. of ethyl alcohol is treated with a solution of sodium ethoxide prepared from 0.12 g. of sodium. After the alcoholic solution has stood for one hour, it is neutralized with hydrochloric acid, the alcohol distilled off *in vacuo*, and the residue extracted with chloroform. The substance thus prepared and purified by recrystallization from benzene, proved identical with ethyl hydantoino-1-acetate, described in the foregoing article. Methyl ureidodiacetate in methyl alcohol gave with sodium methoxide the corresponding hydantoino methyl ester. However, a better method of preparing the latter substance is to heat methyl ureidodiacetate at 170° as long as alcohol is given off. The methyl hydantoino-1-acetate, purified by recrystallization from alcohol was obtained in prisms, melting at 114° . Jongkees, who first prepared this hydantoin, gave $107-108^{\circ}$ as its melting point. As a further confirmation of the constitution of the substance, as obtained by us, a complete analysis was made.

Calc. for $C_6H_8O_4N_2$: C, 41.86; H, 4.65; N, 16.28; found: C, 42.05; H, 4.72; N, 16.44.

Ethyl Ureidodiacetate.—The decomposition of ethyl nitrososemicarbazinodiacetate yielded a viscous residue, which on dissolving in benzene and precipitating with petroleic ether, separated as a smear. However, after this smear had stood several weeks, large irregular shaped crystals separated out. An attempt was made to identify this product, which was obtained in poor yield, as ethyl ureidodiacetate by synthesizing it in a way similar to that employed above for methyl ureidodiacetate. For this purpose the hydrochloride of ethyl iminodiacetate, made according to the method of Jongkees, was treated in aqueous solution with potassium cyanate and a substance extracted with chloroform from the solution, corresponding in solubilities and crystalline form to the decompo-

sition product of ethyl nitrososemicarbazinodiacetate. However, the latter substance melted at 80° and the ureido compound from the hydrochloride of ethyl iminodiacetate at 76° . On mixing the two preparations, dissolving the mixture in chloroform, and precipitating with petroleic ether, the substance obtained melted at 80° . It would, therefore, seem that ethyl ureidodiacetate can exist in two forms, but our available supply of ethyl semicarbazinodiacetate did not admit of the preparation of sufficient of the higher melting stable form to enable a further confirmation of this view by an analysis. Both preparations were found readily soluble in the common solvents with the exception of ether and petroleic ether and both separated from chloroform solution on addition of petroleic ether in characteristic flat prisms with dome-shaped end faces. The following analysis was made on the preparation from the hydrochloride of ethyl iminodiacetate and potassium cyanate:

[FROM THE INSTITUTE DOYEN, PARIS.]

A STUDY OF THE NINHYDRIN REACTION IN RELATION TO THE AGE AND HABITS OF INDIVIDUALS.

BY JOKICHI TAKAMINE, JR.

Received January 21, 1915.

According to Abderhalden, the blood contains a specific "Shutzferment,"¹ which lies latent in the blood but ever ready to be brought into activity when the proper conditions prevail. Such conditions are the numerous various diseases common to the human and animal kingdom. He has shown this by experiment—The ferment only being brought into mobility when a certain specific substratum was brought into contact with it and often no other.²

But it is not easy to conceive of the blood containing a vast number of ferments each labeled for a certain disease or group of diseases. Be that as it may, Abderhalden has shown that the blood contains a ferment only brought into activity by some special and extraneous agency. Following his method of procedure, I have determined that there is a ferment, the amount of which predominates in people of old age as compared to the amount of said ferment in young people. The amount of this ferment seems to be in direct ratio to the age of the person.

To incite the release of this ferment I have used human fibroma tissue with best results, but ordinary connective tissue will also cause similar action. I have also noted with interest that the habits of the persons whose serum was tested had a direct result upon the amount of ferment

¹ *Handbuch der Biochemischen Arbeitsmethoden*, 1912, Vol. 6, p. 223.

² *Z. physiol. Chem.*, 81, 90.

present or released. For example, drinkers gave tests more positive than persons of the same age with normal habits, again persons with syphilis—a disease most depletory—also gave relatively strong tests.

That this ferment is different from the "Shutzferment" is explained by its absolute absence in humans and animals (normal) of young age. Also that the "Shutzferment" cannot so greatly augment in old age—because it is at that time that we are less easily able to withstand the ravages of disease.

Therefore, for the above reasons, I have concluded that there is a ferment other than the "Shutzferment of Abderhalden" which is shown by the ninhydrin reaction to be in direct relation to the age and habits of individuals.

It is well to give here an example of one series of experiments showing the increasing amount of "ferment" with increase of age, and also the relatively great amount in the serum of a great drinker of intoxicants and a young man with syphilis.

Series No. 7.

1	M. B.....	17 yrs. old	No disease	No habits
2	Mme. J.....	27 yrs. old	No disease	Very healthy
3	M. P.....	21 yrs. old	Syphilis	Syphilis
4	Mme. V.....	36 yrs. old	No disease	No habits
5	Mme. I.....	49 yrs. old	No disease	Heavy drinker
6	M. V.....	50 yrs. old	No disease	No habits
7	Mme. N.....	73 yrs. old	No disease	No habits

The method¹ I will briefly state.

The serum, taken as sterile as possible, is allowed to stand in an ice chest until there is separation of the serum and clot. The former is twice centrifuged and 1.5 cc. is placed in a "Dialyser-Hülse" of Abderhalden, with about one gram of fibroma tissue. The fibroma tissue is prepared, by first washing free from blood, then boiling in distilled water. The water is changed and to the fresh water a little acetic acid is added and the solution boiled for one minute. If this water with the acetic acid gives no biuret reaction, the fibroma tissue is ready for use—placed in a sterile flask and covered with a layer of toluene. The dialyser, now containing the serum, fibroma and a little toluene is placed in a small reagent glass containing 20 cc. of distilled water and is allowed to stand at 39° for 10 hours. 10 cc. of the water solution is then boiled in a test tube with 0.2 cc. of a 1% solution of triketohydrindenhydrate for one minute.

A positive reaction means the binding of an amino group of the ferment to the ninhydrin in the X position to the carboxyl group. This combination forms a purple coloration.

¹ *Beitrage zur Klinik der Infektionskrankheiten und zur Immunitätsforschung*, 1913, p. 243.

RESULTS FROM SERIES NO. 7.

No.		Contents of dialyser.	With ninhydrin.
1.....	(a).....	1.5 cc. serum 1 g. fibroma tissue	—
	(b).....	1.5 cc. serum alone (control)	—
2.....		1.5 cc. serum alone (control)	—
3.....		1.5 cc. serum alone (control)	+++
4.....		1.5 cc. serum alone (control)	+
5.....		1.5 cc. serum alone (control)	+++
6.....		1.5 cc. serum alone (control)	++
7.....		1.5 cc. serum alone (control)	++++
++++ very strong test.		+++ strong test:	++ medium test:
+ weak test:		— no test.	

From the above series we find the following results:

1. That below the age of 27 years in healthy persons the ferment is not present or at least not sensible to tests.

2. That No. 3, aged 21, and syphilitic, gave a stronger test than a man and woman (normal) aged 36 and 49, respectively.

3. That No. 7 gave by far the strongest test, being alone due to the old age ferment.

4. That No. 6 of middle age gave a test of medium strength—he was a man of no habits.

5. That No. 5 of middle age gave an extraordinarily strong test—but she was a heavy drinker.

Experiments similar to the above were made on the serum of 68 persons with similar results.

Next it was interesting to note that the amount of the ferment was also in direct ratio to the age in animals.

An interesting series of experiments was tried with the blood of rats of different ages. Their blood serum was tested with rat sarcoma, tissue provided from the laboratories of Professors Ehrlich and Bashford, which was most active in giving a positive test with rat serum, with other albuminous matter such as human adenofibroma tissue and ordinary human connective tissue the results were generally negative. Very young rats of 85–100 grams gave no tests, rats of medium age, 115–130 grams, gave tests of medium strength, sometimes negative, and rats of old age gave strong tests.

1. The blood serum of 74 rats of 85–100 g.—always negative test.

2. The blood serum of 28 rats of 115 to 130 g.—weak positive.

3. The blood serum of 42 rats of 150–250—always strong positive test.

Note.—Controls of the serum alone and of the sarcoma tissue alone were always negative.

Experiments were tried on the blood of the horse and rabbit with similar results. The blood of a one month rabbit was tested in comparison to a rabbit of one year, the connective tissue of rabbits being used, with the

result that the blood of the young rabbit gave no test while that of the older gave an exceedingly strong test. Like results were obtained with the blood of a young and an old horse, the connective tissue of the horse being used.

Much speculation and many theories may be evolved to explain the significance of this ferment. But until it is isolated and its specific properties examined—work on which I am now engaged—nothing exact can be stated. Its connection with the fibrin ferment is doubtful, in that the coagulative power is greater in young and strong people than in people of older age—and since the coagulation is directly due to the fibrin ferment we see that this is in direct opposition to the action of the ferment.

Its presence may be due to the leucocytes and I have found that causing leucocytes in rabbits the blood gives stronger tests, but I have not yet determined the relative positivity of tests on young and old rabbits with leucocytes.

From my numerous experiments with the blood of human beings and animals I have found that there is a ferment in the blood shown by the ninhydrin reaction which is in direct quantitative relation to the age and habits of individuals.

Finally the test for this ferment is particularly interesting as a diagnosis of old age.

NEW BOOKS.

A Laboratory Manual for the Detection of Poisons and Powerful Drugs. By WILHELM AUTENRIETH. Authorized translation of the completely revised fourth German edition, by William H. Warren. Philadelphia: P. Blakiston's Son & Co. 320 pp., 25 illus. Price, \$2.00.

This well-known book comes to us in its fourth edition, entirely revised. The subject is divided into seven chapters, and there had been considerable rearrangement of the material. After discussing poisons volatile with steam, organic poisons, and metallic poisons, the author includes in Chap. IV, a number of substances, which seldom appear in toxicological investigations, but which have much theoretical importance. Such substances as cantharidin, ergot, santonin, sulfonal, saponin substances, and the toxalbumins have become of sufficient importance to warrant a discussion here.

Special methods of analysis both qualitative and quantitative, such as methods for the determination of arsenic and antimony, salicylic acid, and special alkaloids are discussed in the next chapter. The translator has here added the Gutzeit method for the detection of arsenic and antimony, as worked out in detail by Professor Sanger. Chapter VI will prove of special interest to Pharmacists and manufacturing chemists, as it contains a very satisfactory résumé of the methods in use for the quanti-

tative estimation of alkaloids and other powerful substances in raw materials. Since the toxicologist is often called upon to examine blood stains, the remaining chapter is devoted to this subject.

One valuable feature of the work for advanced students is the brief description of the synthesis of such organic drugs as acetanilide, anti-pyrine, phenacetine, pyramidone, salicylic acid, sulfonal, and veronal; substances that are continually coming into more common use.

It is suggested that in a future edition a more complete and detailed index would add to the value of the work. A student of medicine and toxicology will find this book an exceedingly valuable addition to his library.

E. H. S. BAILEY.

Kurzes Lehrbuch der Organischen Chemie. By A. BERNTHSEN, with A. DARAPSKY. 12 editions. Braunschweig: Friedrich Vieweg and Sohn, 1914. Pp. xix + 672. 8°. Price, unbound, M. 12; bound, M. 13.

The present volume forms the twelfth edition of this well-known and widely used text-book; the first edition appeared twenty-seven years ago. As a text-book, it is rapidly approaching the time when it will rival the *Course de Chemie* of Nicholas Lemery which appeared in 1675, passed through many editions, and served as a standard text-book for over fifty years.

To one familiar with the early editions of this book, the pages present an air of familiarity. Unlike many other German text-books, this one has not changed essentially in form, except to include recent discoveries and to make corrections in constants and data, and has not grown beyond the bounds which a self-respecting text-book should preserve. The fifth edition (1895) contained 572 pages; so that, in passing through seven editions, the book has accumulated only one hundred pages, and is still far from deserving the more pretentious title of *Handbuch*.

In the preface to the first edition, the author made the claim that the treatment "at least in the first half of the book" was "a purely inductive" one. Upon perusal of the pages of the text, however, it is hard to find any consistent application of this principle; in fact, it is probably true that no text-book of Organic Chemistry has ever been written in which the subject matter has been presented from an inductive point of view. The treatment throughout the book is especially characterized by a thorough-going formality, which, no doubt, has been the reason why this book has appealed particularly to students who have already completed an introductory course in Organic Chemistry, and to those who are compelled to review the subject with the purpose of familiarizing themselves as rapidly as possible with the systematic arrangement and typical reactions of the various classes and series of organic compounds. As might be expected, a few atavisms still cling to the pages of this most recent edition. Thus two (2) is chosen as the molecular weight of hydrogen, and as the

basis of molecular weights; the old nomenclature and formulas are used for substituted ammonium compounds, *e. g.*, "aniline hydrochloride, $C_6H_5NH_2$, HCl ," instead of phenylammonium chloride. Other illustrations of a similar character might be chosen.

Here and there throughout the book, the reader finds that the results of new and striking discoveries, recently made, have not been overlooked in revising the text. A few, chosen at random, will serve to illustrate this virtue: ozonides; isoprene and caoutchouc; the Walden inversion; desmotropism of acetoacetic ethyl ester; triphenylmethyl and tribiphenylmethyl; thioindigo; salvarsan and neosalvarsan, azomethane; univalent nitrogen in the Hofmann-Beckmann reactions; glycerol mononitrate and glycerol dinitrate, etc., etc.

In the chapter on carbohydrates, the author has taken great pains to simplify the subject matter to bring it within the scope of an elementary presentation. But, at the same time, he has been compelled to discuss relationships which are purely stereochemical in nature. It is hard to understand how these relations can be made clear to the student without the use of the formulas commonly employed to designate space-configurations, when at every turn in the discussion the language teems with phrases which become significant only when considered in conjunction with such formulas. But these formulas are not to be found within the confines of the book. A similar criticism may be applied to other sections of the book which appear to be too advanced for an elementary student and too elementary for an advanced student.

It is probably as unnecessary to say more in a review of this book as it would be to deliver a lengthy address in introducing a speaker well known to his audience.

LAUDER W. JONES.

An Introduction to the Study of Organic Chemistry. By H. F. CLARKE. London: Longmans, Green and Co., 1914. Pp. viii + 484-8°. Price, \$2.00 net.

The keynote of this new text has been sounded at the very beginning in the Preface. The author says:

"In the writing of text books of organic chemistry, there are two distinct and incompatible systems. In the one, it is the practical aspect of the science which is kept in chief view; in the other, the symmetry and homogeneity. The one constantly directs attention to details; the other approaches the subject with the desire of displaying its orderly principles and structural unity. The present writer adheres with conviction to the latter method." Again: "No real knowledge of organic chemistry can be acquired without laboratory work; and to supply in a small textbook, covering the entire field, these practical details so that they can be memorized without actual experience, is contrary to the best interest of students."

A prelude of this kind would lead one to expect a fairly straightforward

account of the salient features of the subject without unnecessary digressions, and, at the same time, facts enough to emphasize the "symmetry and homogeneity" of this branch of chemistry. This is exactly what one finds upon reading the book. At times the statements appear a little bold and dogmatic, unrelieved by amplification, but there is always chance for an argument on points of this kind. In an elementary text, is it not better to avoid too much amplifying of subject matter, always keeping as close to the whole truth as possible, rather than to set up entanglements that may thoroughly dishearten a beginner?

As a matter of fact, text-books of elementary Organic Chemistry serve chiefly as syllabi for quizzes and for courses of lectures in which teachers usually have the opportunity and privilege of introducing what they themselves may think desirable for the proper development of the subject. In view of this condition, this new text is suited admirably to serve as a foundation for science courses, and at the same time to give the student a sufficient array of facts to make the book serviceable as a reference book in connection with a laboratory course, which, I take it, the author believes should always accompany the courses of lectures, quizzes, or other formal methods.

THE REPRODUCIBILITY OF THE CADMIUM ELECTRODE.

By FREDERICK H. GETMAN AND VERNETTE L. GIBBONS.

Received February 22, 1915.

TABLE OF CONTENTS.—I. Introduction. II. Study of the e. m. f. of spongy cadmium and stick cadmium electrodes—(a) in concentration cells of methyl alcoholic solutions of cadmium iodide; (b) in concentration cells of aqueous solutions of cadmium iodide. III. Measurements of e. m. f. of stick electrodes against a standard electrode. IV. Consideration of the formation of hydriodic acid in the solution or of cadmium hydroxide on the electrodes as possible causes of the observed abnormalities. V. Consideration of allotropy as possible cause of the observed abnormalities. (a) Historical. (b) Evidence from e. m. f. measurements at different temperatures. VI. Formation of crystals on the electrodes and their analysis. VII. Study of other forms of cadmium electrodes. VIII. Evidence for allotropy of cadmium given by photomicrographic study of the various cadmium deposits.

The present work was undertaken to elucidate, if possible, some of the abnormalities observed by Getman¹ in the measurements of the potential of cadmium rods in alcoholic solutions of cadmium iodide. In a study of the reproducibility of the copper electrode, Getman² (in a paper read before a recent meeting of the American Electrochemical Society at Niagara Falls) showed that spongy copper, deposited electrolytically upon a loop of platinum wire, gave a constant and reproducible e. m. f. when measured in concentration cells of aqueous solutions of copper sulfate.

¹ *Am. Chem. J.*, 46, 117 (1911).

² *Trans. Am. Electrochem. Soc.*, 26, 67 (1914).

The attempt was first made to study cadmium in the same way. An apparatus was devised similar to the one described by Gibbons and Getman,¹ whereby the two solutions were kept separated from one another except during the time of actual measurement. The measurements were all made at 25°. The temperature was maintained constant to within $\pm 0.05^\circ$, in an electrically controlled thermostat. The purest obtainable methyl alcohol was dehydrated over pure lime for a week, then distilled into a dry receiver which was protected from the gases and moisture in the atmosphere by means of a soda-lime tube. The boiling point of this alcohol was 64.2° to 64.5° at 752 mm. of mercury. The solutions were made up by direct weighing of pure cadmium iodide and all volumetric apparatus used was carefully calibrated. The electrodes were either of spongy cadmium deposited on loops of platinum wire with high current density, or freshly cast rods of the purest cadmium obtainable. The Poggendorff compensation method was employed for measuring the electromotive forces of the different cells, and an enclosed type of Lippmann electrometer was the zero instrument.

The e. m. f. of the combination

with methyl alcohol as solvent was much higher when electrolytically deposited electrodes instead of when stick electrodes were used. The greatest value obtained for any pair of stick electrodes was 0.048 volt, after about five hours' standing in the cell, whereas the greatest value obtained for any pair of electrolytically deposited electrodes was 0.1049 volt, after twenty-four hours' standing. No constant values could be obtained, as in every case there seemed to be an increase in e. m. f. with the time, although there was no regularity in this increase. The cell stood in the thermostat for twenty minutes to acquire a uniform temperature, then the solutions were brought into contact with each other and the first measurement was made as quickly as possible.

It was thought possible that the greater e. m. f. shown with the electrolytically deposited electrodes might be due to the contact of the finely divided metal with the solution. Therefore, each solution was shaken in a shaking machine for one-half hour in contact with some of the electrolytically deposited metal. The e. m. f. measurements obtained when these solutions were put in the cell were much smaller than before, but quite a deposit of cadmium hydroxide was produced during the shaking. The formation of the hydroxide indicated that the action between the finely divided metal and the methyl alcoholic solution of cadmium iodide was a complex one. It, therefore, seemed inadvisable to consider further the reproducibility of an electrode of cadmium deposited electrolytically with high current density.

¹ THIS JOURNAL, 36, 1645 (1914).

A study of the behavior of stick cadmium electrodes in aqueous solutions of cadmium iodide was then undertaken. The following combination was used:

Three pairs of electrodes were so tested and in each case the e. m. f., at first very small, increased with the time. The electrodes did not seem to be coated with white hydroxide, but, on the contrary, the one in the more concentrated solution became gray in color and appeared coated over with a multitude of tiny crystals; and the electrode in the more dilute solution did not so appear. Evidently the cadmium was deposited upon the positive electrode in a different form from that which dissolved from the negative electrode.

To test this assumption the electrodes were each in turn measured against a standard electrode similar to a calomel electrode, only instead of calomel and 0.1 N potassium chloride, mercurous sulfate and 0.1 N

¹ After standing over night.

² After making a fresh boundary between the solutions.

cadmium sulfate were used. The standard electrode in each case proved to be the positive electrode of the combination:

1 30	0 2	1.1254	22 40	0 30	1.1308
1 55	0 25	1.1258	23 10	0 30	1.1309
4 30	2 35	1.1280	24 40	1 30	1.1308
5 55	1 25	1.1292	25 15	0 35	1.1310
6 15	0 20	1.1297	26 15	1 00	1.1310

The results are given in Table II. Electrodes which had been used previously as positive electrodes are designated as I₁, II₁, etc., while those used previously as negative electrodes are designated as I₂, II₂, etc.

Another freshly cast electrode gave, when first placed in the cell, an e. m. f. of 1.1237 volts and after 2 hrs. and 40 min. an e. m. f. of 1.1286 volts. This agrees fairly well with the values for corresponding times given in Table II, *d*.

Table II shows clearly that the electrode upon which the gray crystalline layer had been deposited was the stable one and that the electrodes previously used as negative electrodes gradually assumed the constant value of the gray electrodes. The e. m. f. of the cadmium electrode opposed to the standard electrode is seen to be 1.1324 volts (the average of the final values given in Table II, *a*, *b*, *c* and *d*). The difference between this value and the initial value for the freshly cast electrode amounts to 0.0093 volt.

When a solution of cadmium iodide in contact with a cadmium rod was exposed to the air for some time, it became slightly yellowish and, when it was tested with starch paste, a faint blue color confirmed the suspicion that a trace of iodine had been set free.

It was thought possible that the change in the metal and in the solutions might have been caused by small amounts of hydriodic acid, formed as follows:

If such were the case, the solution should show increased conductance, because of the hydrogen ions present, and a coating of cadmium hydroxide upon the metal should be detected by its solubility in ammonium hydroxide.

To decide the question of the formation of hydriodic acid, a highly polished button of cadmium was etched with nitric acid, thoroughly washed and dried. The conductance of 0.2 *N* aqueous cadmium iodide in contact with this button was measured at 25° at intervals over a period of eleven days. There was no increase in conductance and no change in the color of the solution, but there was a marked change in the appearance of the button. The bright crystalline surface became first dull, then black and at last could be seen to have a beautiful growth of shiny black crystals over its entire surface. At the end of two weeks the button was removed, washed, dried and examined microscopically (see page 969).

The buttons of cadmium which had become gray by standing in cadmium iodide or cadmium sulfate solution were tested with ammonium hydroxide solution, but there was no evidence to the eye or under the microscope, that any of the gray substance had been dissolved. An electrode which had stood for three days in 0.2 *N* cadmium iodide solu-

tion, was washed and treated with ammonium hydroxide. The coating apparently did not dissolve and after thorough washing, the electromotive force measurements showed only slight change. Hence the deposit upon the metal was proven not to be cadmium hydroxide.

Samples of the cadmium iodide solution in contact with cadmium did not, however, show the presence of free iodine when air was excluded, although the buttons and rods became gray. The formation of iodine in the solution may, therefore, have been due to oxidation by the air.

The above experiments seemed to indicate that some, if not all, of the abnormalities observed in the measurements of the concentration cells of metallic cadmium in cadmium salt solutions were, most probably, caused by an allotropic change in the metal and that this change was produced when the metal and the salt solution were in contact with each other.

In 1862, Matthiessen and v. Bose¹ mentioned the fact, that cadmium wires became brittle and easily pulverized, when heated several days at 100°. To hold the wires together it was necessary to coat them with varnish. They did not, however, notice any change in the conductivity of the wires.

Cohen and Helderman² have made an extensive investigation of the allotropy of cadmium. Their results are published in three papers and they have shown that cadmium exists in *at least two allotropic modifications and probably more*. One transition point at $64.9^\circ \pm 0.1^\circ$ has been measured by both pycnometric and dilatometric methods. The former method they consider less reliable, because the density is so easily modified by small amounts of inclusions in the metal. Their study of cadmium amalgams also indicates that there are several modifications of the metal. Cohen and Helderman hold that the electrodes made of cadmium amalgam are in a metastable equilibrium, which may be maintained for years, yet can be changed into stable equilibrium. The explanation given by Cohen for the analogous change from white to gray tin is stated³ as follows:

"Die Erklärung dieser Wirkung dürfte darauf zurückzuführen sein, dass der grauen Form, welche dann die stabile ist, unterhalb des Umwandlungspunktes eine geringere Lösungstension zukommt als der weissen. Infolge der höheren Lösungstension der letzteren wird diese bestrebt sein, in die stabile Form überzugehen; haben sich einmal Spuren von ihr gebildet, so wirken sie beschleunigend auf die weitere Umwandlung."

³ *Abegg's Handbuch der Anorg. Chem.*, 3, 550.

Smits,¹ in a paper entitled "Theory of Allotropy as Applied to Electromotive Equilibria," states that the different allotropic modifications give different kinds of ions and the separated metal may be of a different form from that dissolved. He also assumes that salt solutions have an accelerating influence in bringing about a state of equilibrium.

If the salt solution does have an accelerating effect upon the change taking place in the metal, the action of the iodide should be more marked than that of the sulfate. This was found to be the case, for a rod of cadmium became gray much more quickly in a solution of cadmium iodide than in a solution of cadmium sulfate of the same strength. That the temperature also has an effect upon this change was shown, since at a temperature of about 0° the change was more pronounced in a given period of time than it was at room temperature.

If the abnormalities observed in the cadmium concentration cells are due to a transition from one allotropic modification of the metal to another, there should be an electromotive force developed, when a gray cadmium rod and a polished freshly cast cadmium rod are immersed in a solution of a cadmium salt. This electromotive force should be greater the greater the temperature interval above or below the transition point and should undergo a reversal of sign when this temperature is passed, if no other reaction enters in to cause complications. The electromotive force at 25° in a 0.1 *N* cadmium sulfate solution should equal the difference between the electromotive forces of the two electrodes measured against the standard, *i. e.*, 0.0093 volt, and the gray electrode should be the negative terminal of the cell, because of its lower solution tension (see page 958).

To decide these questions, measurements of the electromotive force of the following combination were made at different temperatures:

The gray rods were the ones that had been measured against the standard electrode and had been shown to have a constant electromotive force. The freshly cast rods were polished with emery cloth, thoroughly washed and dried. In every series of measurements the cell was filled with the solution, corked tightly, placed in the thermostat and allowed to stand for one-half hour. At the higher temperatures the cell was opened occasionally to allow for expansion. The solutions were brought into contact with each other, the electrodes inserted in the cell and the first measurement made as quickly as possible. The results of several series of measurements at a given temperature agreed fairly well. The mean values are given in Table III and plotted in Fig. 1.

From Table III and Fig. 1 it is seen (1) that there is a progressive change in the e. m. f. of the concentration cells with the time, each curve tending toward a minimum, (2) that the e. m. f. diminishes with increase of temperature, (3) that at 25°, one-half hour after the electrodes are inserted in the cell, the e. m. f. is 0.0093 volt as calculated on page 957, (4) that the gray electrode is the negative terminal of the cell as was to be expected, and (5) that at 79.5°, a temperature above the transition point (64.9°)

¹ From one series of measurements only.

² Interpolated from the curves of the three series.

there is a reversal of the sign of the e. m. f. In the experiments at 79.5° the positive electrode was found to be coated over with white hydroxide of cadmium, which might easily account for the change from a negative

Fig. 1.

to a positive e. m. f. at the close of the series. An attempt was made to carry out a series of measurements of the e. m. f. of the combination at 98° , but the formation of the hydroxide took place so quickly that it was found quite impossible to obtain any reliable values.

Two freshly cast and polished electrodes were then measured against each other in a 0.1 *N* cadmium sulfate solution. The e. m. f. was appreciable, but fluctuated and the value seemed in some way to depend upon the degree of polishing of the electrode. This behavior might have been expected for the anomalous changes in the potential of cadmium are well known. Thus, Desch¹ makes the following statement: "Cadmium is so sensitive that merely rubbing the surface with emery paper is sufficient to make that specimen the anode when compared with an untreated specimen." The electrodes were washed, dried and left standing over night. They were then polished, washed and dried and placed in fresh 0.1 *N* cadmium sulfate solution and the e. m. f. of the combination was again determined with the same result as before.

¹ Desch's *Metallography*, p. 287.

The electrodes were then polished and placed in 0.2 *N* cadmium iodide solution and left to stand twenty-two hours in the ice chest, then two hours in the air at about -9° , when the solution solidified. The frozen solution was allowed to melt at room temperature and to stand for two and three-quarters hours before the electrodes were removed, washed and dried. They then appeared grayish and when placed in 0.1 *N* cadmium sulfate solution gave no measurable e. m. f. even after 40 mins. standing. The electrodes were again placed in 0.2 *N* cadmium iodide solution and, after twenty-four hours at room temperature, beautiful metallic crystals were found to be scattered over the gray background. The crystals were examined under the microscope and photographed (see page 966).

Some of the crystals were carefully removed from the electrode with a scalpel. They were found to be very slowly soluble in hydrochloric acid but readily and completely soluble in nitric acid. A few of the crystals were transferred to an evaporating dish, dissolved in a small amount of dilute nitric acid and the solution evaporated to dryness. The residue was dissolved in a small amount of distilled water and analyzed qualitatively. The crystals were found to be pure cadmium.

It seemed advisable to examine the crystalline deposit of cadmium formed upon cadmium or platinum by electrolysis of a cadmium sulfate solution with low current density. The solution employed was made up by diluting 10 cc. of saturated cadmium sulfate solution with 75 cc. of distilled water and 2 drops of dilute sulfuric acid. A current of $N.D._{100} = 0.15$ amperes (approx.) and at an e. m. f. of 2 volts was passed for about 5 hours. The cathode was either a polished, freshly cast rod of cadmium, or a platinum plate sealed into a glass tube. Three crystalline cadmium rod electrodes and one crystalline cadmium plated platinum electrode were so prepared and the e. m. f. of each measured against the standard electrode. The plated cadmium rods gave constant e. m. f. in each case after about 30 minutes in the cell and remained practically constant for at least 22 hours. The values agreed fairly well and were as follows: (1) 1.1343 volts, (2) 1.1336 volts, (3) 1.1340 volts. The cadmium plated platinum electrode showed greater fluctuations between the limits 1.1333 volts and 1.1348 volts over a period of 23 hours.

From the above it is seen that the e. m. f. of these crystalline electrodes is from 1 to 2 millivolts higher than the e. m. f. (1.1324 volts) of the gray crystalline electrodes formed by immersing the freshly cast rods in a solution of cadmium iodide.

The crystalline deposits were examined under the microscope and the crystal forms were in all cases similar to those shown in Fig. 11.

A gray deposit was formed upon the cadmium rod by electrolysis with high current density and its e. m. f. was measured against the standard

electrode. The measurement showed fluctuations between the limits 1.1341 volts and 1.1364 volts over a period of 24 hours.

The effect of amalgamation of a cadmium electrode was studied by measuring its e. m. f. against the standard electrode. There was much variation in the results, no two electrodes gave even approximately the same results in a given time and the values were in all cases much smaller than the similar measurements of the e. m. f. of the crystalline electrodes.

It seems, therefore, that cadmium electrodes reproducible to within 1 or 2 millivolts, when measured against the standard electrode, may be obtained either by allowing a polished cadmium rod to stand in a cadmium salt solution until it has acquired a uniform gray coating, or by electrolytically depositing crystalline cadmium upon a polished cadmium rod with a low current density. The electromotive behavior of cadmium in alcoholic solution of cadmium salts is now being investigated in this laboratory.

Frequent examination of the electrodes with a pocket lens made it apparent that valuable information as to the nature of the change which occurs when cadmium is immersed in solutions of its salts could be obtained by systematic microscopic observations.

Soon after entering upon the microscopic study of the surfaces of the electrode, it became evident that the cylindrical form of these electrodes was not suited to examination with high power objectives. To overcome this difficulty a cylinder of pure cadmium $1\frac{1}{2}$ cm. in diameter and about 3 cm. in length was prepared by casting the metal in a suitable mould. The cylinder was then cut into transverse sections about 4 mm. thick and one surface of each of the resulting buttons was polished. The polishing of the buttons was carried out in the following manner: After smoothing both surfaces of the button with a file, it was mounted with sealing wax in a shallow hole cut in a wooden block and then rubbed on blocks covered with emery paper of regularly graded fineness. Care was taken in changing from one paper to the next finer to rub in a direction at right angles to that previously followed, thus gradually reducing the size of the scratches. After a final abrasion with "cuttle-fish bone paper," the button was rubbed on a piece of velveteen with a jewelry polish to which had been added a few drops of xylol. A final brisk rubbing on a dry piece of velveteen developed a mirror-like surface.

After taking a photomicrograph of the surface of one of these buttons (as shown in Fig. 2) it was immersed in 0.2 *N* solution of cadmium iodide and maintained at a temperature of about 5° by placing in the ice chest. After 15 minutes immersion the button was removed from the solution, successively washed in water, alcohol and ether and then re-examined under the microscope. Unmistakable evidence of a distinct change in the character of the surface was obtained. The button was then replaced

Fig. 2.—Magnification 100.

in the cadmium iodide solution and after 3 hours' immersion was again re-examined microscopically. The small initial nuclei observed after 15 minutes immersion were found to have developed into the well de-

Fig. 3.—Magnification 100.

finer spots shown in Fig. 3. The button was regularly examined at 3 hour intervals, until after 18 hours' immersion the surface had assumed the appearance shown in Fig. 4. In order to determine whether this change

Fig. 4.—Magnification 100.

might be due to a deposition of cadmium hydroxide, the button was immersed for 10 minutes in dilute ammonium hydroxide, and then, after washing with water, alcohol and ether, it was re-examined under the microscope. The appearance of the surface remained unaltered and it was assumed that the deposit was not due to a film of cadmium hydroxide. After two weeks' immersion in 0.2 *N* cadmium iodide solution, the deposit

Fig. 5.—Magnification 200.

Fig. 6.—Magnification 100.

on the button had assumed a distinctly crystalline appearance as shown in Fig. 5. It has already been mentioned (page 962) that well developed crystals visible to the naked eye appeared on two of the electrodes used in the experimental cell, and it seemed of interest to compare these crystals with those observed on the button shown in the preceding illustration. Accordingly, photomicrographs were made of some typical crystals found on the electrodes as shown in Figs. 6 and 7. It was impossible

Fig. 7.—Magnification 100.

to bring more than a very limited portion of the field into sharp focus because of the cylindrical form of the electrodes and on account of the thickness of the crystals. However, a careful examination under the microscope in which various portions of the crystals were successively brought into focus, revealed the fact that they belonged to the isometric system, pentagonal dodecahedra and truncated octohedra being the prevailing forms.

Since* freshly cast cadmium is known to crystallize in the hexagonal system,¹ the foregoing observations seem to justify the conclusion that prolonged standing in a solution of cadmium iodide involves a change in crystalline form. Furthermore, the change in form being from a system of lower to one of higher symmetry confirms the conclusion drawn from the measurements of electromotive force (page 957) that the freshly cast cadmium electrodes are unstable. In his metallography, Desch² (*Loc.*

¹ Gmelin-Kraut's *Handbuch der Anorg. Chem.*, 4, 109.

² Desch's *Metallography*, "Text-Books of Physical Chemistry," Longmans, Green & Co.

cit) says, "Several metals exist in more than one crystalline modification, in which case the forms stable at high temperatures are of a lower degree of symmetry than those at low temperatures." It has already been pointed out that lowering the temperature favors the formation of a stable cadmium electrode when the metal is immersed in a solution of cadmium iodide.

If the crystalline deposit on the electrode is the stable form of cadmium then it should be possible to inoculate the polished surface of a freshly cast cadmium button with some of these crystals and accelerate the transformation to this modification. In his investigation of the change of white into gray tin, Cohen¹ found that almost complete transformation was effected in 16 days by immersing a specimen of white tin, inoculated with the gray modification, in an alcoholic solution of stannic ammonium chloride. A similar experiment was carried out with a button of cadmium. After making a photomicrograph of the freshly polished surface of the button (Fig. 8) the button was inoculated with several isometric crystals

Fig. 8.—Magnification 200.

Fig. 9.—Magnification 200.

detached from one of the electrodes and allowed to stand for four weeks in a 0.2 *N* solution of cadmium iodide in ethyl alcohol at about 0°. That a distinct change had occurred is shown in Fig. 9 and that the transformation was more extensive than it would have been had the surface not been inoculated with the stable form of the metal is shown by the photomicrograph (Fig. 10) of an uninoculated polished button treated in exactly the same manner as that shown in Fig. 9. It is evident from this experiment that the transformation from one modification of cadmium to the other is much slower than in the corresponding case of tin.

A microscopic examination of a cadmium electrode upon which cadmium was deposited electrolytically revealed the same general type of crystals as was obtained by prolonged immersion of cadmium rods in a

¹ Abegg's *Handbuch der Anorg. Chem.*, 3, 550.

solution of cadmium iodide, although the potential of the former was about 2 millivolts higher than that of the latter. An experiment was then performed to determine, if possible, whether electrolytically deposited cadmium crystals might not serve as nuclei from which the crystallization would spread to a polished cadmium surface. A polished cadmium

Fig. 10.—Magnification 200.

Fig. 11.—Magnification 100.

button was suspended in a dilute solution of cadmium sulfate acidified with sulfuric acid and one-half of the surface of the button coated with a crystalline deposit of electrolytic cadmium ($N.D._{100} = 0.15$ amp., 2 volts). A photomicrograph of the deposit revealed the presence of the crystals shown in Fig. 11. The button was then immersed in 0.2 *N*

Fig. 12.—Magnification 100.

Fig. 13.—Magnification 100.

cadmium iodide solution and allowed to stand for two weeks at room temperature. At the end of this period the electrolytic deposit and the polished half of the button had acquired a dull gray color. The microscopic appearance of the polished half of the button is shown in Fig. 12, the line of demarcation between the polished portions and that upon

which the cadmium was deposited electrolytically being shown at AA. While a marked crystalline growth is apparent upon the polished half of the button, it is doubtful whether this was accelerated by the presence of the electrolytic deposit.

The etched cadmium button used in the conductance experiments (page 957) was examined microscopically before and after immersion in the cadmium iodide solution. The initial appearance of the button is shown in Fig. 13 and that at the end of two weeks in Fig. 14. These shiny, black crystals appear to belong to the isometric system but the cubic form is apparently predominant. A similar black deposit was obtained upon two cadmium rods, in one case the deposit being distinctly nodular. It seems probable that this is another allotropic modification of cadmium.

Fig. 14.—Magnification 200.

Newbery¹ considers the dulling or blackening of the surface of metallic electrodes during the passage of a current as due to extremely minute pittings in the metal, as if caused by explosive separation of gas from the interior of the metal. Such, however, was not the case in the present experiments. In every sample of the metal observed under the microscope the change of surface was clearly due to a deposit or growth upon the surface.

The gray form and the bright crystalline forms of cadmium described in this paper have doubtless been obtained by others working on the electrodeposition of cadmium,² but, as far as the authors can learn, the black crystalline form has never been obtained nor have the gray and bright crystalline forms been studied microscopically.

Summary.

1. The measurements of the e. m. f. of concentration cells of methyl alcoholic solutions of cadmium iodide show that neither freshly cast rods of cadmium nor spongy cadmium deposited electrolytically are reproducible.
2. Similarly freshly cast rods of cadmium are shown not to give a reproducible e. m. f. when used as electrodes in aqueous solutions of cadmium iodide.
3. Rods of cadmium which have become gray by standing in cadmium

¹ *J. Chem. Soc.*, 105-106, 2427 (1914).

² "Electrodeposition of Cadmium I," Historical Review, by Mathers and Marble, *Trans. Am. Electrochem. Soc.*, 25, 297 (1914).

iodide solution are shown to give a constant e. m. f. when measured against an unpolarizable electrode. Freshly cast rods of cadmium are shown to attain this value with time.

4. The behavior of cadmium electrodes in concentration cells is explained as due to an allotropic change.

5. Crystalline electrolytic deposits of cadmium on cadmium rods or platinum are shown to give a reproducible e. m. f. when measured against an unpolarizable electrode. This e. m. f. is, however, slightly higher than that given by the gray cadmium electrodes. Amalgamated electrodes are not reproducible.

6. Photomicrographs indicate a change in crystalline form and confirm the conclusions drawn from the e. m. f. measurements.

7. Attempts to inoculate the surface of the freshly cast cadmium with the stable modification indicate that the action is extremely slow.

8. Photomicrographs indicate that in all cases the change is due to a deposit upon the surface instead of to a pitting of the surface.

THE ENTROPY OF VAPORIZATION AS A MEANS OF DISTINGUISHING NORMAL LIQUIDS.

BY JOEL H. HILDEBRAND.

Received February 23, 1915.

In a series of studies which we are making on the theory of solutions, it has become necessary to distinguish between deviations from Raoult's Law, whose cause may be considered physical, and those due to chemical changes. As has been pointed out in a previous paper,¹ the choice between the alternatives in a given case is possible if we know whether or not the pure liquids are associated. For example, the occurrence of vapor pressures greater than those calculated by Raoult's Law in a mixture of benzene and stannic chloride, is explained by Schulze and Hock² on the assumption that the stannic chloride is associated, to a degree depending on the concentration. A great many deviations from Raoult's Law may be explained in this way, as the writer himself has done in the case of a number of amalgams.³ Such an assumption would be unjustifiable if we were sure that both liquids were themselves normal, that is, unassociated, for the presence of another component must tend to diminish such association rather than to increase it. In fact, in the case of benzene

¹ Ermon D. Eastman and Joel H. Hildebrand, "The Vapor Pressure of Gold, Silver and Bismuth Amalgams," *THIS JOURNAL*, **36**, 2020 (1914).

² *Z. physik. Chem.*, **86**, 445 (1914).

³ *Trans. Am. Electrochem. Soc.* **22**, 319, 335 (1912); *THIS JOURNAL*, **35**, 501 (1913); **36**, 2020 (1914).

and stannic chloride, just mentioned, all of the criteria we are able to apply show stannic chloride to be a normal liquid, so that its failure to lower the vapor pressure of benzene to the extent demanded by Raoult's Law is to be explained, not by a reduction in the number of mols of stannic chloride added, but rather to a physical effect such as would result from a change in the internal pressure, tending to increase the escaping tendency of the benzene.

In order to judge similarly of the correctness of the assumptions made in the calculations with amalgams, it is necessary to know whether the liquid metals are normal or associated. Unfortunately, however, most of the relations used to distinguish between normal and associated liquids are applicable only to organic liquids; being additive properties depending upon atomic values determinable only for such elements as form a number of compounds in various proportions. The only relations that are applicable to liquid metals are the surface tension law of Eötvös,¹ and Trouton's rule,² either in its original form or in one of the various modifications that have been proposed.

The application of the former relation to liquid metals has led to the conclusion that they are more or less associated. The value of this testimony will be considered in a future communication, this one being reserved for a discussion of the evidence furnished by the heat of vaporization.

The original Trouton rule states that the heat of vaporization of a liquid, divided by its absolute boiling point, is a constant for all normal liquids. This relation holds very well for normal liquids boiling in the neighborhood of 100° to 300°. It has been derived theoretically from the theorem of corresponding states;³ however, it must hold more closely than this theorem.⁴ As an extreme instance, mercury, for which Trouton's rule holds very well, shows wide deviation from the "law" of corresponding states. Moreover, its critical temperature, though not known, is certainly above 1000°,⁵ so that its boiling point, 632° A, is far from being 0.66 of its critical temperature on the absolute scale, as would be required to give any validity to this proof of Trouton's rule for mercury.

For associated liquids, such as water, alcohol, and liquid ammonia, the ratio is larger, which is explained by assuming that when a liquid is associated and its vapor is not associated, a certain amount of heat is required to dissociate the molecules of the liquid, hence the normal heat of vaporization is increased. The effect on the boiling point is doubtless

not very large, so that when abnormally high values are obtained the evidence of dissociation seems fairly satisfactory. Since the quotient of the heat of vaporization by the absolute boiling point represents the increase in entropy of the substance during vaporization, and since we wish to refer to this ratio at temperatures other than the boiling point, we will use the less cumbersome term entropy of vaporization.

A rule essentially the same as that of Trouton has been given by Le-Chatelier and Forcrand¹ whereby the entropy of dissociation of certain solid compounds at one atmosphere pressure is approximately 33 calories per degree.

As Trouton's rule has become more completely tested, especially at extreme temperatures, it has become evident that the entropy of vaporization to one atmosphere is by no means constant for all normal substances, but that it increases with the boiling temperature. Various modifications have accordingly been suggested. Two of these have been proposed by Nernst,² *i. e.*, $L/T_b = 8.5 \log T_b$, and $L/T_b = 9.5 \log T_b - 0.007T_b$, where L is the molecular heat of vaporization at constant pressure; and T_b the absolute boiling point. It is impossible to determine from what Nernst says, whether they have any other than an empirical foundation. They seem to be intended chiefly to take into account the low boiling gases. Another formula has been proposed by Bingham,³ $L/T_b = 17 + 0.011 T_b$. This formula is also empirical, and has been constructed without much reference to liquids boiling at very high or very low temperatures. More recently Forcrand⁴ has published a formula, also empirical, but which has attempted to include liquids with very high, as well as those with very low boiling points: $L/T_b = 10.1 \log T_b - 1.5 - 0.009T_b + 0.0000026T_b^2$. The course of this equation at high temperatures was determined by using data for the boiling points of silver and copper. It should be mentioned that the values at high temperatures would be considerably different if the data for zinc, bismuth, lead and tin, apparently as trustworthy as those for silver and copper, had been taken into account. For this reason the use of the formula by Forcrand for extrapolation to still higher temperatures, to get the boiling point of carbon, cannot be regarded as very significant.

Except for zinc and cadmium, the only values for the vapor pressures of metals at high temperatures are those of Greenwood,⁵ who determined the boiling points at three different pressures. Unfortunately, it is not possible to decide how much weight to give to these measurements. The

heat of vaporization calculated from one pair of values is widely different from that calculated from another pair in the case of each element. The simplest way to test vapor pressure measurements is to plot $\log p$ against $1/T$, which should give almost a straight line. The measurements of Barus¹ on cadmium and zinc when plotted in this way seem to be very satisfactory, a number of values being given in each case. On the same basis, however, the data of Greenwood for the other metals can hardly have much weight, either for or against any generalization on the entropy of vaporization. We hardly feel justified, therefore, in using the formula of Forcrand, gotten by using arbitrarily the data for two metals, to decide whether or not several others are normal or associated in the liquid state. It becomes necessary, therefore, to have some more justifiable basis for extrapolation from ordinary to high temperatures.

A formula has been published recently by Cederberg,² but it cannot be applied to the metals, as it requires a knowledge of the critical pressure and temperature.

It must be noted, first of all, that the boiling point at one atmosphere pressure has no special significance. We may, if it is desired, select any pressure or function of the pressure and temperature for comparing the entropy of vaporization of different substances. In order to represent the entropy of vaporization graph-

¹ *Phil. Mag.*, [5] 29, 141 (1890).

² *Z. physik. Chem.*, 77, 498 (1911).

ically we may put the Clapeyron-Clausius equation, $d \ln p / dT = L / RT^2$, into the form: $d \log p / d \log T = L / RT$. If, then, $\log p$ is plotted against $\log T$, the tangent to the resulting curve at any point represents the entropy of vaporization at that temperature divided by R . The appearance of such curves is shown in the accompanying figure, the original scale being greatly reduced in order to represent a number on the same plot. Now, if Trouton's rule in the original form were true, then the tangents to all of these curves should have the same slope at a value of $\log p$ corresponding to one atmosphere. It is evident, however, that this is not the case, but that the slope of the curves, at equal values of $\log p$, increases regularly with the logarithm of the temperature. Therefore, the entropy of vaporization for different substances cannot be the same at equal pressures, but rather at pressures that increase in some way, with the temperature. It was found that the tangents to the curves at points cut by any line of unit slope have the same slope, with a remarkable degree of precision. For accurate comparison the curves can be plotted on different sheets of transparent paper, and a line drawn on each whose equation is $\log p = \log T + K$, where K is a constant. By sliding one plot over the other, keeping this straight line superimposed on the two plots, it is possible to superimpose the curves with surprising accuracy, from the curves for nitrogen and oxygen up to those for cadmium and zinc.

The significance of the line of unit slope is this: since, for any vapor, at pressures low enough for it to obey the gas laws sufficiently accurately, we have the equation $p = RTc$, where c denotes concentration, and therefore $\log p = \log T + \log Rc$, the constant, K , in the above equation must equal $\log Rc$, and therefore along such a line c is constant. Our conclusion may be stated in words as follows: the entropy of vaporization for normal liquids is the same when evaporated to the same concentration, *i. e.*, when the final mean distance between the molecules of vapor is the same.

In Table I are given values of L/RT which make possible a numerical comparison of the new rule with that of Trouton, or its equivalent. The first column of figures contains the values of L/RT_c according to the new rule, the subscript denoting equal concentration of vapor. These values were obtained by plotting $\log p$ (in mm. of mercury) against $\log T$ very carefully on a large scale, and determining the slope of the tangents to the curves when $\log p = \log T - 0.5$, corresponding to a value of c of 0.00507 mols of vapor per liter. The selection of this concentration was entirely arbitrary, there being no apparent reason for choosing any particular concentration except the desirability of avoiding any extrapolation of the experimental data, that is, using a line that would cut all of the curves so plotted. In the second column are the values of L/RT_p , taken from the same curves but at equal values for the pressure, so as to correspond to Trouton's rule. However, instead of comparing the values when the

pressure of the vapor is one atmosphere, and when it may deviate considerably from the gas laws, it was thought fairer to choose a somewhat lower pressure. Accordingly the values in the table are for $\log p = 2.0$, corresponding to a pressure of 100 mm. of mercury. If Trouton's rule holds for one pressure it must hold for any other pressure. In the third and fourth columns are the temperatures at which the values in the first two columns were determined, respectively.¹

The values of L/RT_c are also given for ammonia, water and alcohol, typical associated liquids, in order that the magnitude of the deviation from that cause may be evident.

It will be seen that the deviation of L/RT_c from the mean is scarcely greater than the limit of error except for the metals, for which it is several per cent. less. There is no systematic change with the temperature. On the other hand, the values of L/RT_p at equal vapor pressures, corresponding to Trouton's rule, show a systematic increase from 11.0, for nitrogen, to 15.1, for zinc.

There are two principal deviations from the new relation that should be pointed out. The difference between L/RT_c for the metals and the values for the other substances in the table, while not great, is distinctly

¹ The sources of the vapor pressure data used were as follows: nitrogen, Fischer and Alt, *Ann. Phys.*, [4] 9, 1149 (1902); oxygen, Estreicher and Olszewski, *Phil. Mag.*, [5] 40, 454 (1895); chlorine, Johnson and McIntosh, *THIS JOURNAL*, 31, 1138 (1905); pentane to octane, Young, *Sci. Proc. Roy. Dublin Soc.*, 12, 374 (1910); bromonaphthalene Kahlbaum, *Z. physik. Chem.*, 26, 603 (1898); mercury, Smith and Menzies, *THIS JOURNAL*, 32, 1447 (1910); cadmium and zinc, Barus, *Loc. cit.*

more than the difference due to any uncertainty in the experimental data. It may be suggested that this deviation is due to a difference in molecular complexity. When a molecule escapes from the liquid to the vapor it is relieved of a very high internal pressure which exists in the liquid, and may, conceivably, expand with an absorption of energy. The amount of energy so absorbed we should expect to be greater in the case of molecules containing many atoms than with those containing but few. The expression for the entropy of vaporization might be written, therefore, $(L + e) / RT$, where e denotes the energy absorbed within the molecules on expansion from the high pressures existing within the liquid to the low pressure existing in the vapor. The quantity e is doubtless small compared with L , that is, most of the energy is required to overcome the attraction between the molecules, and but little in the expansion of the molecule itself. It is possibly safe to say, in the light of our rule, that in so far as it concerns the overcoming of attraction between the molecules, the entropy of vaporization to the same concentration is the same for all normal liquids. If a liquid is associated, a third, and much larger quantity of energy is involved in the dissociation of the complex molecules into simpler ones. In such cases the total entropy of vaporization is distinctly greater than the normal value for the given concentration, as is seen in the last three instances in the table.

Another deviation is found in the cases of hydrogen and helium. If the vapor pressure data¹ at these low temperatures can be trusted, then the entropy of vaporization is less than our rule would require, although the agreement is very much better than it is on the basis of the original Trouton rule. The values could not be included in Table I without a wide, and hence uncertain, extrapolation to lower pressures in order to use the same concentration as was used in the table. The direct comparison can be made however, at higher pressures. On putting $\log p = \log T + 0.444$, corresponding to a concentration of 1 mol in 22.4 liters, we obtain the values in the first row of Table II. In the second row are given for comparison the values of L/RT_p , when $\log p = 2.00$, as before.

TABLE II.

Substance.....	Helium	Hydrogen	Nitrogen	Oxygen
L/RT_c	7.0	9.8	10.5	10.4
L/RT_p	5.0	8.6	11.0	11.4

In view of the rapid change in the specific heats of solids, and presumably also of liquids, in the neighborhood of the absolute zero, and the consequent effect on the heat of vaporization, the deviation from our rule at these low temperatures might perhaps be expected. A further con-

¹ Data for hydrogen, Travers and Jacquerod, *Proc. Roy. Soc.*, 70, 490 (1902); *Z. physik. Chem.*, 45, 416 (1905); data for helium, Onnes, *Versl. K. Akad. Wet. Amst.*, 19, 1194 (1911) *Comm. Physik. Lab. Leid.*, 119.

sideration of the possibility of introducing the specific heats so as to make the necessary correction will be postponed till later.

It is possible to express the rule here given in the form of an equation which gives the vapor pressure of any normal liquid at any temperature in terms of some other such liquid chosen as standard. Let us consider the vapor pressures of two normal liquids, one of which we will take as a standard for the reference of all others. We may integrate the Clausius equation for each of these liquids, assuming, for the moment, for the sake of simplicity, that the heat of vaporization does not vary with the temperature. The resulting equations for the two substances are then:

$$\ln p = -L/RT + I \quad (1)$$

$$\ln p_s = -L_s/RT + I_s \quad (2)$$

the subscript referring to the one chosen as standard. Since $p = RTc$, we can write

$$\ln c + \ln R + \ln T = -L/RT + I \quad (3)$$

$$\ln c_s + \ln R + \ln T = -L_s/RT + I_s \quad (4)$$

Let us now select temperatures, T_c and $T_{c,s}$, at which the concentration of the vapor will be the same for the two substances, *i. e.*, $c = c_s$, when, according to our principle,

$$L/RT_c = L_s/RT_{c,s} \quad (5)$$

We may then subtract Equation 4 from Equation 3, obtaining

$$\ln T_c - \ln T_{c,s} = I - I_s \quad (6)$$

Let us call

$$T_c/T_{c,s} = a, \quad (7)$$

whence

$$L = aL_s \quad (8)$$

and

$$I - I_s = \ln a. \quad (9)$$

We are thus able to calculate L and I for any substance from the corresponding values for the standard substance using a single constant, a , so that this constant becomes the sole characteristic of a normal liquid necessary to define its vapor pressure with considerable accuracy. We may write, then, a universal vapor pressure law for such liquids by substituting for L and I , in Equation 1, the values given by Equations 8 and 9, obtaining the equation

$$\ln p = -aL_s/RT + I_s + \ln a. \quad (10)$$

It must be recognized, of course, that this equation does not take account of the change of the heat of vaporization with the temperature, and hence cannot be an exact equation. However, the change in the heat of vaporization depending on the difference between the specific heats of vapor and liquid, is not large, and is not very different for various liquids, so that Equation 10 becomes more exact if written

$$\ln p = -a/R \int L_s/T \, dT + I_s + \ln a, \quad (11)$$

where L_s is a function of the temperature.

This equation gives another method of plotting vapor pressure data so as to distinguish normal from associated liquids. Equation 11 may be put in the form

$$\frac{\log p/a}{T/a} = \frac{1}{2.3 R} \int L_s dT + I_s. \quad (12)$$

The right hand member of this equation is common to all normal liquids, so that the curves for all normal liquids can be superimposed by plotting $\log bp$ against bT , where $b = 1/a$. These curves are nearly straight lines, so that they are convenient for testing the accuracy of the experimental data and for comparing different substances with each other. The curves for associated liquids cannot be made to coincide with those for unassociated liquids by this means, but will be steeper, due to higher values for the heat of vaporization.

It should be noted that Equation 9, $I - I_s = \ln a$, gives the relation between the integration constants of the Clausius equation for all normal liquids, the "chemical constants" of Nernst, which have received considerable attention from him and others.

The question mentioned at the beginning of this paper, and which suggested the present study, regarding the association of liquid metals, cannot be answered very fully from the experimental data at hand. Mercury appears in the light of a perfectly normal liquid, the slight deviation being opposite in direction to that which indicates association, and being explainable on the basis of a smaller latent heat of expansion of the molecules themselves. Zinc and cadmium likewise appear normal at the temperatures in question. They might, however, be associated at much lower temperatures, such as were used in the amalgam measurements. This possibility could be excluded only by careful measurements at very low vapor pressures.

Summary.

It has been found that the entropy of vaporization (*i. e.*, the molecular heat of vaporization divided by the absolute temperature at which vaporization takes place) is the same for all normal liquids, not, as in Trouton's rule, where the vaporization takes place at the same pressure (one atmosphere), but when it takes place at the same concentration of vapor.

This fact may be expressed in the form of a vapor pressure equation containing a single constant characteristic of the liquid, this constant being determined from the temperatures necessary to give the same concentration of vapor in the different cases.

[FROM THE CHEMICAL LABORATORIES OF THE UNIVERSITY OF LIVERPOOL.]

A THEORY OF CHEMICAL REACTION AND REACTIVITY.

By E. C. C. BALY.

Received February 12, 1915.

During the last ten years a great number of papers have been published describing the absorption spectra of organic compounds, and the majority of these publications have dealt with the constitution of these compounds, the assumption being made that there exists a definite correlation between the primary structure of the molecule and the type of light absorption which it exerts. One of the oldest theories of constitution is the quinonoid theory, which categorically attributes visible color to compounds which possess a constitution analogous to that of ordinary benzoquinone. It is hardly necessary to point out the danger that attends the use of a physiological sensation of color as a criterion of constitution in this connection. There often exist pairs of compounds which to the eye have exactly the same color and yet when their absorptive power towards light is spectroscopically examined it is found that the compounds are materially different. As a matter of fact the application of accurate spectroscopic methods to the problem very soon revealed considerable difficulties and proved that the quinonoid theory is by no means as secure on its foundations as had previously been supposed. Some of these difficulties have been recognized by Hantzsch, who has put forward theories which differ to a certain extent from the old quinonoid theory. Hantzsch, however, still maintains that there is a definite correlation between light absorption and structure, and when he succeeded in preparing five differently colored alkali metal salts from one colorless acid he attributed essentially different formulas to them all.¹ But it was not long before Hantzsch also found himself in difficulties, because after he had obtained a number of different modifications of *m*-nitroaniline he was obliged to confess that there are not enough different formulas to go round.² It is not necessary here to specify the essential points of Hantzsch's theories and sufficient has already been said to indicate that the fundamental basis of them, and the older (quinonoid) theory, is the assumption of the existence of an absorption structure correlation. It may be pointed out, however, that there is not one particle of evidence to show why any one of the structural formulas devised by Hantzsch should possess a color different from that of any other. Indeed, recent investigations into the problem of light absorption by organic compounds by no means favor the view that there is any direct relation between absorption and constitution, if such relation is held to mean that when a colored salt is obtained from a colorless acid or base the parent substance

¹ Hantzsch, *Ber.*, 42, 966 (1909); Hantzsch and Robison, *Ibid.*, 43, 45 (1910).

² *Ber.*, 43, 1662 (1910).

has changed its constitution in the salt. The principal outcome of this work is the establishment of a definite relation between light absorption and chemical reactivity. The evidence obtained is so strong that it is necessary to formulate a new theory to account for the observed phenomena, a theory which must at the same time embrace all those experimental facts which appear to support the color constitution relation. It is proposed in this paper to develop this theory from the chemical side, and only briefly to indicate its bearing upon the problems of light absorption.

It follows from the Zeeman effect, that is to say, the resolution of spectrum lines into doublets, triplets, etc., in a powerful magnetic field, that the particles or atoms producing these lines must possess magnetic fields of their own. In a paper dealing with the pressure shift of spectrum lines, Humphreys¹ discusses these atomic fields and shows that they are capable of explaining the phenomena of the Zeeman effect and also of the shift of spectrum lines under the influence of pressure. While these atomic fields have been taken into consideration in explaining such physical phenomena as the above, their influence upon the properties of molecules does not seem to have received notice. These fields must possess both a polar and a quantity factor, and it would follow that atoms which are markedly different in their chemical properties must differ markedly in the polar factor of their force fields. When two such atoms approach one another sufficiently closely, the force lines due to their respective force fields will tend to condense together with loss of energy and with the formation of a condensed field. A potential gradient will thus be set up and it seems possible that if this gradient be sufficiently steep a transference of one or more electrons will take place from one atom to the other, whereby a true chemical compound of the two will be established. Primary valency would thus only mean the transference of one or more electrons along the potential gradient which is set up by the condensing together of the force lines arising from the electromagnetic fields of two atoms of opposite type that are brought close together. On these lines, therefore, it may be said that the chemical reaction or combination between the two atoms is due in the first instance to the force fields appertaining to the two atoms.

Turning now to the compound that is produced, it is evident that the general stability will depend upon the condensed force field between the two atoms. Before such a compound can be decomposed or resolved into its elements this force field must be opened up, and, therefore, the greater the number of force lines that are condensed within the field the more stable will be the compound and the greater the amount of energy required to decompose it.

¹ *Astrophys. J.*, 23, 233 (1906).

In the general case of any molecule it is clear that the independent existence of the several force fields due to the atoms composing the molecule must represent a metastable condition. A certain amount of condensation of the force lines of the various force fields must take place with the escape of energy and the establishment of a closed molecular force field which will determine the properties of the molecule. If a molecule of one compound reacts with a molecule of another compound such reaction takes place by virtue of their respective force fields. If these fields are of opposite type the force lines of the two will condense together with the result that an addition compound of the two is formed. Just as in the case of the two atoms dealt with above, this addition compound will possess potential gradients and if these be sufficiently steep there will follow a transference of one or more electrons between the constituent atoms with the formation of new chemical individuals.

Perhaps an example will make this more clear, but in quoting such an example it must be remembered that reactions which take place by means of ions are for the moment excluded for reasons that will presently be made clear. We may take a perfectly general case of an acid HX and a base YOH . According to the present theory the first stage of the reaction will be the formation of the addition compound YOH, HX , arising from the condensing together of the force lines of the molecular fields of YOH and HX . Within this complex a potential gradient will exist and if this is steep enough the electrons will rearrange themselves with the formation of XY, H_2O . Another way of stating the same fact is to say that the change within the complex will take place if the system XY, H_2O has less energy than the system YOH, HX . If it has less energy, then a new chemical individual XY is formed and we say that a chemical reaction has taken place.

A very important fact may be noticed here in passing, namely, that a chemical reaction will only occur when the gradient within the complex first formed is sufficiently steep to cause the electrons to migrate. The complex between the two original molecules will of course be formed whether or no a true chemical reaction occurs, for the formation of the complex depends only upon the force fields of the two molecules that are brought together. In this way we are enabled to recognize a very large gradation between the condition when a chemical reaction occurs between two molecules and the condition when, owing to their force fields being exactly the same, the molecules have no mutual influence whatsoever. This recognition of mutual influence between two molecules when no specific chemical reaction occurs is of great importance both in pure chemistry and in the phenomenon of light absorption.

According to the above view the reaction between molecules depends upon their force fields. But it has been already shown that these force

fields normally must be more or less closed, according to the measure of the polar and quantity factors of the several fields of the constituent atoms. The reactivity of any molecule must vary inversely as its force field is closed. If, owing to the inherent properties of the atomic fields, the force lines can form a completely closed system, then the molecule will possess no reactivity. If two such molecules with completely closed fields are brought together it is evident that they can have no influence upon one another, and, further, this absence of influence will be entirely independent of what their chemical properties in solution would lead us to expect. It would seem that in this fact is to be found the explanation of the absence of any reaction between HCl and NH_3 , 2H_2 and O_2 , 2CO and O_2 , etc., in the complete absence of water. The first case is peculiarly interesting since the known acidic and basic properties of these two gases would at once lead us to expect that they should immediately combine to form NH_4Cl . The other cases mentioned might be criticised from the point of view that in each of them the molecules of at least one diatomic gas have to be resolved into atoms before the chemical reaction can proceed. The HCl and NH_3 reaction is free from that possible objection, for it is purely one of addition, and yet it does not take place if the gases are dry. According to the present theory the reason why these two gases do not combine together lies in the fact that the molecules of both possess completely closed force fields and, therefore, they can have no influence upon one another. An exactly similar explanation holds good for the converse case, namely, that NH_4Cl vapor does not, when dry, dissociate into HCl and NH_3 . The molecules of NH_4Cl must possess a completely closed field which is not readily opened up and, therefore, when the substance is converted into vapor the molecules do not dissociate.

On the other hand, although a certain amount of condensing together of the force lines due to the atomic fields must occur *ex hypothesi*, yet by no means must the resulting force fields always be entirely closed. When the maximum possible condensing together of the force lines has occurred with the maximum possible escape of energy, there may be left over an uncompensated balance of force lines. This residuum will determine the properties of the given molecules and will give rise to what has long been recognized by chemists as residual affinity. Although this residual affinity has proved itself a very useful friend to chemists, yet it has always been of a somewhat mysterious, not to say mystic, nature which in moments of doubt as to the true dogma has from time to time been invoked to play the role of a *deus ex machina* and relieve the exigencies of the situation.

On the present theory, the whole of the reactivity and chemical properties of atoms and molecules is due to the force fields which have been proved to exist in the immediate neighborhood of the atoms. Chemical union

between atoms, chemical reaction between molecules, both are due to these force fields, and valency itself would seem not to be the *causa causans* of such reactions but to be a resultant effect. Valency in its stoichiometrical meaning is due to the interatomic rearrangement of the electrons when the potential gradients within the addition complexes first formed are sufficiently steep and the electronic transference results in a smaller energy content of the product. The so-called residual affinity is the uncompensated residuum when the maximum possible condensation of the force lines of the molecule has taken place. When this residuum is vanishingly small the given molecule exhibits no evidences of chemical reactivity, but when, as is more usually the case, the residuum has a finite value the molecule does possess an observable and measurable reactivity.

Among chemical compounds which possess a balance of uncompensated force lines or residual affinity water may be mentioned as a very typical example. The extraordinary power possessed by water of forming addition complexes with other molecules is too well known to need emphasizing here, but one or two points in connection with the hydrating power of water may be described. In the first place Humphreys, in his paper referred to above, showed that one of the results of the existence of the electromagnetic fields is the tendency of the mutually attracting faces of the atoms to be brought near together, and of the mutually repelling faces to be kept comparatively far apart. When, therefore, a molecule of a salt hydrates itself, owing to the formation of a closed force field between water and salt molecules, it is obvious that the distribution of the molecules must be symmetrical. Barlow and Pope¹ have shown that in such cases as $\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$ and $\text{Na}_2\text{CO}_3 \cdot 7\text{H}_2\text{O}$, $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$ and $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$ the addition of the water molecules takes place entirely along one axial direction of the crystal, that is to say, only one axis of the crystal grows on hydration. This, as readily can be seen, is an absolutely necessary sequitur from Humphreys' deduction. Indeed, it would seem that the conception of electromagnetic force fields gives a complete and rational explanation of all Barlow and Pope's observations, but this cannot be entered into here.

Again, the question of the hydrolysis of salts may be considered in connection with the present theory. When a salt hydrates itself there is formed a complex field due to the condensing together of the force lines of the two components, salt and water. In this complex there are two gradients to be considered, one between the component atoms of the salt and the other between the salt and the water. As long as the former is very steep, as it is in the case of the salts of strong acids and bases, then the tendency to hydrolyze will be a minimum. If, how-

¹ *J. Chem. Soc.*, 89, 1675 (1906).

ever, the former gradient is shallow, the gradients between the salt and water become relatively steeper. In such a case a rearrangement of the electrons will occur with the formation of acid and base from salt and water. The hydrolysis of a salt has been taken as a typical example of a chemical reaction, for it shows the rationale of the phenomena on the lines of the present theory.

From what has already been said, it is obvious that if the closed force field of a molecule be opened or unlocked its reactivity will be enhanced. This unlocking may be brought about in two ways, namely, by the use of a substance possessing residual affinity or by the action of light. If the molecules of a compound, the force fields of which are closed, be brought into the neighborhood of the molecules of another compound possessing residual affinity the force lines of the latter will interpenetrate the closed fields of the former, with the result that they will be opened and endowed with enhanced reactivity. The simplest case to consider is that of the solution of the closed force-field molecules in a solvent possessing residual affinity. The free force lines of the solvent molecules will interpenetrate the closed fields of the solute molecules, with the result that these will now be capable of reacting with any other suitable substance dissolved in the same solvent. Clearly, however, the case is an absolutely general one. The tendency of molecules possessing residual affinity will always be to open up the closed fields of other molecules whenever the two molecular types are brought together, whether an actual solution is formed or not, with the result that the previously closed fields become endowed with reactivity. The bearing of this upon chemical phenomena may be considered from three points of view.

In the first place the enhancement of the reactivity of the substance brings us at once to catalysis and indeed gives us an explanation of this phenomenon. Catalysis may be looked upon as the enhancement of the reactivity of one or more of the components of a reaction and a catalytic agent is a substance which, from the nature of its residual affinity, has the power of opening up the closed fields of the reactant molecules to a greater extent than they otherwise would be under the prevailing conditions. Conversely a negative catalyst is an agent which has the power of closing the force fields to a greater extent than they otherwise would be. Some advantage is held by this theory of catalysis because it gives a rational explanation of the positive and negative effects without the somewhat cumbersome conception involved in the ordinary theory of negative catalysis, namely, that a negative catalyst is one which destroys a positive catalyst assumed previously to be present.

A second point arises when the difference in type is considered of the force fields of the two groups of molecules, solute and solvent. It is clear that if the solute possesses basic characteristics the most suitable

solvent for the purpose of opening it up will be one the residual affinity of which is acid in type, and, conversely, a solute of acid type will most readily be opened up by a basic solvent. On the other hand, a solute the force field of which is not pronouncedly basic or acid will tend to be opened both by an acid and by a basic solvent, but the manner in which the opening up takes place will be different in the two cases. The potential gradients existing within the closed system of the solute will be attacked differently by the force lines of a basic and of an acid solvent. This will result in a difference between the reactivity of the solute in the two cases and, indeed, the solute will present amphoteric properties. An amphoteric substance, on the present theory, is to be defined as one the closed field of which is opened in a different manner by a basic and an acid solvent. A typical example of an inorganic amphoteric compound is aluminium hydroxide, the reactivity of which is different in acid and basic solvents, while an example of an organic amphoteric compound is nitrobenzene, the force field of which is opened quite differently by sulfuric acid and by dimethylaniline.

A third aspect of the opening-up process concerns the case when the solute possesses at least one steep potential gradient, and the residual affinity of the solvent differs markedly from that of the two atoms of the solute between which the potential gradient exists. Such cases as this occur more particularly in inorganic chemistry with the acids, bases, and salts. If the opening-up process be carried to the farthest possible extent the logical consequence will be the complete resolution of the solute molecule into two entities, each of which will be fully solvated owing to the new conditions under which the force lines have formed condensed systems with those of the solvent. As a result of the existence of the potential gradient in the original molecule one or more electrons will have migrated from one atom to the other, and, therefore, the two entities formed by the complete resolution of the closed field of the solute molecule will carry equal and opposite charges of electricity. Ionic dissociation, therefore, is a logical sequence of the force-field theory. The theory, however, gives a different perspective of chemical reaction and reactivity from that presented by the ionic dissociation hypothesis. Whereas the latter attributes all chemical reactions between dissociated salts to the ions, as if herein were to be found the driving force of such reaction, the electromagnetic force-field theory attributes all reactions and reactivities to the opened-up systems of the molecules independently of whether ions are formed or not. The formation of ions according to this theory is a secondary phenomenon running concurrently with the primary cause of reaction.

The second method of opening up the closed fields is by the influence of light. Due as they are in the first place to the rotation of the electrons

of the constituent atoms, it follows that the force fields must be capable of absorbing those rays of light which have the same vibration frequency as that of the electrons. The light in being absorbed does work upon the closed fields and opens them, and this gives a rational explanation of the selective absorption of light. An example of the opening up of the closed molecular force field by means of light is found in the union of hydrogen and chlorine. When in the dark and at ordinary temperatures, the force fields of these gases are closed and they have no action upon one another. Under the influence of ultraviolet light the reaction to form HCl proceeds owing to the opening of the closed fields by the light, and the amount of combination is a function of the amount of the light energy that is absorbed.

In considering the work done by the light upon the molecules by which it is being absorbed, it was pointed out that the effect produced is to open up the closed fields of these molecules. When a substance is dissolved in a solvent it is clear that there must be set up generally an equilibrium condition. Some of the molecules will have their closed fields opened while others will not, and so an equilibrium is established, and upon this equilibrium the reactivity of the system depends. When such a system absorbs light the tendency will be for the light to increase the number of molecules having their fields open. The equilibrium previously existing is, therefore, shifted towards the reactive side, a new photodynamic equilibrium being established. The whole of the phenomena of photocatalysis can thus be explained on these lines.

The mechanism of the opening up of a closed force field may now be dealt with in greater detail. The general statement has been made that a given closed field may be opened by the influence of a solvent or by the influence of light, the action of the light being evidenced by the selective absorption of definite rays. If now the case be considered of a complex molecule, it is clear that the force field of that molecule will be complex. There must exist in such a complex field a network of potential gradients and the influence of the solvent in opening up the field will depend upon the nature of that solvent. It would be expected that the influence of a solvent upon a complex force field would be progressive, and that it would attack various portions of the field in turn. It indeed follows that the opening up of a complex field must take place in definite stages, the number of stages depending upon the complexity of the field. Each of these stages will be influenced by light so that each stage must be characterized by its power of absorbing definite light rays and may be differentiated in this way because the light waves absorbed by the various stages will be different. Each of these different stages mark steps in the opening up of a given force field and, therefore, are functions of a given molecule with a definite primary structure. The number of possible stages

will depend upon the complexity of the force field and these stages in turn may be called into play by the use of suitable solvents. Very typical examples of compounds which are opened up in stages are the β -substituted naphthalene compounds, which as a rule in alcoholic solution show three absorption bands. Three stages in the opening up of the force fields must, therefore, coexist in the solvent, each one characterized by its power of absorbing definite rays of light. In concentrated sulfuric acid solution the absorption spectrum is very different, since other stages are called into play, but usually one of these stages at least is common to the two solvents.

Certain experimental evidence may now be presented which gives very clear and decisive support to the theory. Since the opening-up process takes place in stages, and since each stage is characterized by its light absorptive power, it should be possible to follow the course of a chemical reaction and to trace the appearance of the stages by optical methods. Each opened-up stage must possess a definite reactive power towards other molecules. It is probable that a particular and definite stage must be reached before any specific reaction can occur. By this it is meant that if it be desired to induce a definite reaction towards a definite reagent it is necessary in all probability to open up the closed force field to one definite stage. Any earlier stage in the opening up will not endow the system with the required reactivity. In short, it may certainly be assumed that while each stage in the opening up possesses a definite reactivity, a certain limiting stage must be reached before any particular reaction can proceed.

Some years ago Miss Marsden and I investigated the absorption spectra of certain aromatic amino-aldehydes and ketones and we have found that the alcoholic solutions of these compounds exhibit a well-marked absorption band.¹ The addition of a small quantity of alcoholic HCl to any one of these solutions causes the development of a yellow or red color which disappears when more of the acid is added. This color is due to the appearance of a new absorption band nearer to the red than that shown by the parent compound. On the addition of the excess of acid the absorption spectrum changes to that of the hydrochloride of the amino base, which somewhat resembles that of the free base itself. It is clear from these results that the conversion of the amino bases to their hydrochlorides is not simply an addition reaction. There is no doubt that it is not the amino compound such as exists in alcoholic solution which forms the salt, but that the first quantity of acid converts the base into an intermediate form and *it is this intermediate form which reacts with more acid to give the salt*. These results at once extend our view of chemical reaction, in that they undoubtedly prove the existence of a hitherto unrecognized

¹ *J. Chem. Soc.*, 93, 2108 (1908).

intermediate stage; they also afford a definite proof of the force-field theory, for it was exactly this phenomenon which was shown above to be the direct result of the application of the theory to chemical reaction. The addition of the first quantity of HCl opens the closed fields to a higher stage, which is evidenced by its characteristic light absorptive power, and the field must be opened to this stage before the molecule can react to give the salt. These results also have a bearing on the application of the theory to catalysis. When the above amino compounds are treated with methyl iodide they tend to give their methyl derivatives. The velocity of this reaction is known to be materially increased when some acid is added. The acid has been shown to open up the closed systems to a higher stage with a greater reactivity, and, therefore, it acts as a positive catalyst in the methylation of these compounds.

Exactly analogous results have been obtained by Mr. Rice and myself in the sulfonation of aromatic phenol ethers.¹ In this case it was found possible to convert the whole of the reacting substance into the intermediate form and to observe its change into the sulfonic acid. In the former case we succeeded only in obtaining a small quantity of the amino base in the intermediate and more reactive form owing to the affinity between this form and the acid. In fact the maximum amount of this stage is obtained when only about 0.2 equivalent of HCl is added. In the sulfonation reaction, when the compounds are dissolved in cold concentrated sulfuric acid they are in many cases entirely converted into the intermediate stage, which frequently is characterized by its absorption of visible light so that the solution is visibly colored. On standing, the system is slowly changed to the sulfonic acid and the progress of the reaction can be followed with the spectroscope. The absorption spectrum of the sulfonic acid differs entirely from that of the intermediate stage, and somewhat resembles that of the original substance in alcoholic solution. It is, perhaps, worth mentioning that if the sulfuric acid solution, before the sulfonation has taken place, is poured onto ice the original compound is recovered in a pure state. These two investigations establish beyond any doubt the existence of the intermediate stage in a chemical reaction such as was deduced from the force-field theory.

The fact that the existence of the various stages in the opening up can be recognized by their characteristic light absorption enables us to interpret absorption observations with considerable certainty. These phenomena and their explanation will be fully dealt with in a subsequent paper, but reference may be made to one statement given above, namely, that nitrobenzene is an amphoteric substance. Mr Rice and I have found that the nitro derivatives of benzene tend to exist with their force fields

¹ *J. Chem. Soc.*, 101, 1475 (1912).

very definitely closed.¹ This results from the difference between the affinities of the phenyl nucleus and the nitro group. Such a compound would naturally tend to be affected differently by a strong acid and by a strong base. The absorption of nitrobenzene in solution in dimethylaniline and in concentrated sulfuric acid is entirely different; indeed, the former solution is colored red while the latter is colorless. Clearly, therefore, the manner of opening up the force fields is different; according to whether an acid or basic solvent is used and so we may speak of nitrobenzene as being amphoteric.

It was pointed out above that in the case of inorganic acids, bases, and salts, ionic dissociation is the extreme case in the opening up of their force fields. Now the effect of the selective absorption of light by a solution is to shift the equilibrium between the opened-up molecules and unopened-up molecules towards the reactive side, that is, to increase the former relatively to the latter. It should, therefore, be possible to increase the amount of ionization of a salt in solution by the action of light, and such effect should evidence itself in the catalysis of a given reaction or by an increase in the electrical conductivity of a solution. As a general rule, however, the force fields of inorganic salts are relatively simple and so the wave length of the light selectively absorbed by their solutions will be very short. Very few inorganic salts (except those visibly colored) exert selective light absorption in the region of the spectrum that can be photographed with a spectrograph in air, and therefore the absorption bands must lie beyond the frequency $1/\lambda = 5000$. There are, however, a few cases which can be experimented with and in one of these, namely, the chloroplatinic acids, Boll and Job² have found that under the influence of ultraviolet light the electrical conductivity of their solutions is materially increased. This is exactly what the force-field theory foretold.

An important confirmation would be found if it were possible to prove the catalysis of a simple inorganic reaction by the influence of light. As a general rule the velocity of such reactions is so great that the measurement of an increased velocity is precluded. There is one case, however, namely, that of KI and $\text{Hg}(\text{CN})_2$, which do not react in aqueous solution to give HgI_2 . The aqueous solution of each salt is diactinic to all the rays of light above $1/\lambda = 5000$ and, therefore, their absorption bands must lie at still shorter wave lengths. Such very short waves of light may be obtained from a hydrogen vacuum tube fitted with a fluorite window, and as such very short light waves are absorbed by air all experiments with them must be carried out *in vacuo*. A mixture of the two salts, finely powdered and slightly moist, was placed in a vessel cemented to the fluorite window. This vessel was exhausted so as to allow the rays to reach the

¹ *J. Chem. Soc.*, 103, 2085 (1913).

² *Compt. rend.*, 154, 881; 155, 826 (1912).

powder and it was then found that very small quantities of HgI_2 were superficially produced where the light fell on the mixture. These experiments must be looked upon as still being incomplete, but as far as they have gone the results are eminently satisfactory. It is in organic chemistry that the force-field theory finds its most obvious application, for so few of the reactions are ionic. For example, the opposite affinities of the nitro group and the phenyl nucleus give the key to the nitration of aromatic compounds. It is clear that when the latter are treated with HNO_3 , addition complexes tend to be formed in which the closed fields are opened up. Such addition compounds, if the potential gradients are sufficiently steep, will by transference of electrons give the nitro compound and water. It may readily be possible that the affinity of HNO_3 be not strong enough to open up the closed fields of the aromatic compound and in such a case it naturally will be advisable to use another strong acid as solvent. This explains why glacial acetic acid and concentrated sulfuric acid are so valuable in carrying out the nitration process. The power possessed by sulfuric acid in opening up the fields of aromatic compounds has already been mentioned and it is evident that its influence on the nitration reaction is not simply to be explained as that of a dehydrating agent. Again, the absence of action of HNO_3 upon the paraffins is also accounted for, since the spectroscope shows that there is no mutual influence between the two. Further, toluene is oxidized to benzoic acid by moderately concentrated HNO_3 , for its force field is not sufficiently opened to give the nitro derivative, but it is nitrated readily enough in a mixture of HNO_3 and H_2SO_4 . One further point of interest in the nitration of aromatic compounds is afforded by such compounds as *p*-dimethyltoluidine, which gives 1-methyl-3-nitro-4-dimethylaminobenzene when treated in HCl solution with NaNO_2 but gives 1-methyl-2-nitro-4-dimethylaminobenzene when dissolved in a mixture of HNO_3 and H_2SO_4 . The course of the reaction depends on the manner in which the force field of the amine is opened up.

There is some temptation to continue giving instances of phenomena which are simply explained by the force-field theory, as, for example, the unstable highly colored nitrophenol ethers of Hantzsch and Gorke¹ and similar compounds. One might point out that these compounds are simply an opened-up phase in metastable equilibrium. They are prepared from a salt in which the complex radical already exists in an opened-up condition. At the moment of formation the derivatives will also exist in a similarly opened-up condition and if due care be taken such derivatives may be preserved in that condition. In the presence of a suitable catalyst the metastable opened-up force field will condense until that condition is arrived at which is characteristic of the ordinary form of the com-

¹ *Ber.*, 39, 1073 (1906).

pound. This explanation of the existence of these unstable compounds, many of which have now been prepared, is very much simpler and more rational than that usually adopted, namely, that such bodies are chemical isomers of the stable modifications. The latter explanation generally involves the wandering of a radical, which experience derived from other compounds would not lead us to expect. Again, the present theory accounts at once for the abnormal reactivity of these unstable substances, because they have their force fields opened up to a high stage and they, therefore, obviously will be more reactive than the stable modifications.

The theory may also be applied to the phenomena of allotropy. It has already been shown by Smits that a most reasonable explanation of allotropy is to be found in the existence of definite molecular species, each allotropic modification being an equilibrium mixture of two or more such species.¹ The possibility of the existence of these molecular species is at once furnished by the force-field theory, for such species would simply be constituted by various complexes with their force fields in different states of condensation. The existence of such complexes is a very obvious deduction from the present theory, and, indeed, the theory would lead to the expectation of the phenomenon of allotropy being very wide spread. Our knowledge of allotropy, however, is rapidly being extended, for recent work² shows that the power of existing in allotropic modifications is possessed by numerous elements previously supposed to be confined within the limits of one form.

An interesting and somewhat suggestive conclusion is arrived at if the influence of an external magnetic field upon the molecular force fields is considered. The effect of such an external field on the force fields of the atoms of elements is shown clearly enough by the Zeeman effect. That there must result some effect when a molecular force field is brought into an external magnetic field is obvious. Since the former are electromagnetic in type it is clear that they will become keyed with the external field. The molecules will become polarized as it were, and unless the molecules are perfectly symmetrical as regards their force fields, a skew effect will tend to be established, since the external force lines are stationary. Such skew systems of force lines will result in the unequal retardation of light waves passing through the system, and, therefore, a plane-polarized beam of light will undergo rotation as regards its plane of polarization. It would, seem therefore, that the phenomenon of magnetic rotation also finds its explanation in the present theory. The suggestiveness of this is to be seen in the fact that it may be extended to the phenomenon of stereoisomerism and optical rotation generally. If the principle, advanced above, of the skew effect being the origin of the rotation of plane-polarized

¹ *Proc. K. Akad. Wet. Amsterdam*, 14, 788 (1912).

² E. Cohen, *Ibid.*, *passim*.

light be accepted, then the explanation of optical rotatory power follows naturally enough. The force field of any molecule which is asymmetric must of necessity itself be asymmetric, with the result that a skew effect will exist in the surrounding ether causing the rotation of the plane of polarized light. Now when the condensation of the force lines due to the several atoms of a completely asymmetric molecule is considered, there must be at least two ways in which such condensation can take place. In each case the same amount of energy will escape and the two skew effects resulting from such condensations will be equal and opposite. We, therefore, will have two entities almost identical if not entirely identical in chemical properties but with equal and opposite powers of rotating the plane of polarized light. The amount of rotation will depend upon the amount to which the force field has condensed. If such condensed force fields be attacked by solvents the rotatory power will tend to be altered. Again the rotatory power will be influenced by temperature, since it is obvious that the influx of energy, whether by increase of temperature or otherwise, will tend to open the fields and alter the skew effect. It equally follows that by the opening up of the condensed fields to a particular stage the skew effect can be nullified, with the result that racemization may ensue.

It is not necessary to emphasize the inherent advantage that this conception possesses over the old notion involved in the Le Bel and van't Hoff theory of the interchange of atoms or groups of atoms. After all, such interchange is abnormal and does not appear to take place in any other case with that readiness with which it is postulated to occur in stereochemistry. As a general conclusion drawn from the field of organic chemistry it may fairly be stated that the wandering of atoms or groups does not take place unless the product of such reaction is more stable than the original compound. The Le Bel and van't Hoff theory postulates the completely reversible interchange of groups in a completely asymmetric molecule. Such, indeed, might be accepted in a perfectly symmetrical system but where the asymmetry is an essential factor of the problem the process is antagonistic to the canons of organic chemistry.

The application of the force-field theory is based entirely on the principle of the rotatory power being due to the skew effect in molecular force fields. The dextro and laevo rotations are both the properties of one single primary structure, no isomerization being necessary to account for these phenomena. Although the present theory differs in one essential respect from the classical one, yet the whole is based on the complete asymmetry of the molecule, which is the real basis of the older theory.

The extension of the principle to all the phenomena of isomerism is sufficiently obvious to need no special discussion. Some emphasis must be laid on the fact that it is by no means necessary that there shall be one way and only one way in which the condensation of a given set of

force lines can take place, quite apart from the fact that individual stages in any one condensation process may have the power of metastable existence. The phenomena of geometric isomerism belong to the former category, while the highly colored unstable nitrophenol ethers of Hantzsch and Gorke and similar compounds belong to the latter.

If two differently condensed fields are obtained from one set of force lines, it is possible that the two condensed fields may be opened differently by solvents, and, therefore, the two substances will have different reactivities. Such differences usually are accounted for by attributing different primary structures to the compounds, but it would seem that this is entirely unnecessary.

Summary.

1. The existence of molecular force fields due to the electromagnetic fields of the constituent atoms is dealt with. It is shown that these force fields afford an explanation of chemical reactivity and reaction.

2. To the closed force fields and their opening up by the influence of solvents or light may be attributed all the phenomena of chemical reaction. Ionic dissociation is one special case of the whole.

3. In the existence of definite stages in the opening up of a given complex field, each with its power of absorbing definite light rays, is to be found the explanation of differently colored derivatives from the same compound.

4. The theory leads to the existence of intermediate stages in a chemical reaction and such stages have experimentally proved to exist.

5. When a compound is dissolved in a solvent an equilibrium is set up between the opened-up and non-opened-up molecules of the solute. Such a system has the power selectively of absorbing light rays, the effect of the light being to increase the number of opened-up molecules and thus to shift the equilibrium towards the reactive side. Some preliminary experiments on the photocatalysis of the reaction $\text{Hg}(\text{CN})_2 + 2\text{KI} = \text{HgI}_2 + 2\text{KCN}$ afford considerable support to this view.

6. The theory would also seem to afford a reasonable explanation of allotropy, magnetic rotation, stereoisomerism, optical rotatory power, and generally the phenomena of isomerism as a whole.

THE HEATS OF COMBUSTION OF AROMATIC HYDROCARBONS AND HEXAMETHYLENE.

BY THEODORE W. RICHARDS AND FREDERICK BARRY.

Received January 30, 1915.

During the last ten years, extensive series of thermochemical investigations have been carried on in the Harvard laboratories with the help.

of the adiabatic calorimeter, which has been modified in various ways to meet the requirements of different sorts of problems.¹

One of the earliest of these investigations was concerned with the measurement of heats of combustion,² and yielded results proving the efficacy of the adiabatic principle. In a second research of similar character, the effective procedure already developed for the complete burning of organic liquids in the explosion bomb was further improved;³ and the method was shown to be capable of such a degree of precision as to permit a quantitative comparison of the heats of combustion of isomeric substances, magnitudes heretofore often indistinguishable. The present paper describes further measurements of such constants; the outcome shows a distinct gain in consistency and accuracy even over the immediately preceding Harvard work. The concordance of the values obtained in some of the series of measurements, as recorded in this paper, indicates a degree of precision comparable with the accuracy of much exact quantitative analysis—even in some accepted determinations of atomic weights. The investigation seems at least to have clearly shown that heats of combustion may now be determined, by a method at once simple and facile, with a precision limited only by the efficacy of processes of purification with respect to the material used and by the possible accuracy of thermometric measurements when mercury instruments are employed. The data here submitted indicate that these limitations do not stand in the way of very exact measurement.

An accumulation of data of this degree of trustworthiness should lead to comparisons of a very interesting and suggestive character. If the corresponding heats of vaporization, heat capacities, and heats of formation of the products of combustion can be determined as accurately, general inductions may perhaps be drawn from such data concerning the relationships between molecular configuration, and changes of free energy and internal energy. Among the many aspects of the general connection between chemical structure and physical property, none can be more interesting or important than this.

When so many data are necessary, ease and speed of experimentation are imperative. On this account, the simplicity of the method as here described is evidently one of its important advantages. The mercury

³ Richards and Jesse, *THIS JOURNAL*, **32**, 268 (1910). Other applications of the method are to be found in papers by Richards and Jackson, *Z. Physik. Chem.*, **70**, 414 (1909); Richards and Burgess, *THIS JOURNAL*, **32**, 431 (1910); Richards, Rowe and Burgess, *Ibid.*, **32**, 1176 (1910); Richards and Mathews, *Ibid.*, **33**, 863 (1911); Richards and Rowe, *Z. Physik. Chem.*, **84**, 585 (1913).

thermometer, which has been decried by some commentators, has the great merit of direct and convenient reading. Moreover, this instrument suffers from less suspicion of inaccuracy arising from thermal conduction than the electric instruments; and is of course wholly free from the very persistent and subtle errors due to stray electromotive forces. It is true, of course, that the mercury thermometer has its own errors, which must be carefully guarded against, but the most disturbing of these is the change of the zero point, which does not come into consideration in differential work of this thermochemical type. Moreover, all the work described in the present paper is relative, so that by using the thermometer over the same range and under the same conditions with the different substances to be compared, the thermometric errors may be almost entirely eliminated. Its simplicity enables a single experimenter without assistance to carry out the work of combustion with the adiabatic calorimeter, and the work may be done with a minimum loss of time from maladjustment and from accident.

One must bear in mind also the fact that a higher degree of accuracy than to within 0.001° is not warranted by the purity of most organic substances, and that the mercury thermometer in good hands can easily reach this degree of precision. Of course, where great *sensitiveness* is required, a modern electrical resistance thermometer or multiple thermoelement can easily outdistance the mercury-in-glass instrument; but, on the other hand, one must not confound sensitiveness and accuracy. An example of this danger is afforded by a recent publication by W. P. White,¹ in which the temperatures are given to within 0.0001° , although the accompanying diagram shows that readings made on different days deviated as much as 0.01° . The correspondence of the results with the empirical curve, moreover, was often even much worse than this, although this does not clearly appear in White's abbreviated statement.² This paper was the best authority on this subject at the time when the work to be described was performed. It is doubtless true that, since that time, this experimenter and others have obtained better results with the thermoelement than the unsatisfactory showing of this paper of 1910;³ and the platinum resistance-thermometer may be yet better; but taking all things into consideration, after extended and intimate experience with a thermoelectric thermometer kindly made for us by Dr. White, we decided that the time had not yet come (1911) for the application of either highly sensitive but precarious instrument to the problem in hand.

¹ *Phys. Rev.*, 31, 162 (1910).

² The discrepancy referred to will be found on calculating the values, especially those corresponding to 40.0000° and 82.0000° , as pointed out to us by Prof. A. W. Rowe.

³ W. P. White, *THIS JOURNAL*, 36, 2292 (1914).

The investigations here described had two distinct aspects; first, the actual measurement of the heats of combustion of certain homologous and isomeric hydrocarbons; secondly, a study and criticism of the method employed, for the purpose of estimating and of controlling or eliminating the possible sources of error inherent in it.

Preparation of Materials.

Particular attention was paid to the purity of the hydrocarbons to be studied. Both natural and artificial compounds of carbon are liable to serious contamination with impurities, either of a similar kind or of widely different character, such as bromides or chlorides, some of which may find their way into the substance during the course of its preparation. For the purpose in hand, of course, the radically dissimilar impurities are usually more prejudicial than the similar ones, and the worst of all impurities, weight for weight, is water, because it has no heat of combustion whatever. In order to eliminate as much as possible these dangers, especial precautions were taken. The details for each substance are discussed below.

Benzene.—This substance was made from a commercially pure sample derived from coal tar. It was shaken with successive portions of sulfuric acid until the acid remained quite colorless after three successive agitations. The last traces of acid were removed by means of a solution of sodium hydroxide, and this, in turn, by repeated washing with water. The benzene thus prepared, after thorough drying with calcium chloride and with sodium, showed no traces of thiophene or its homologs on applying the delicate indophenin test with isatin and sulfuric acid, although the same reagents gave with the original material a deep blue coloration. The complete chemical separation of thiophene is necessary in the first place because it cannot be separated either by distillation or crystallization.¹ The sodium used for the final drying of the benzene was washed free from petroleum (under which it had been kept) with scrupulous care, because the paraffins of petroleum have a widely different heat of combustion from aromatic compounds of like boiling point. The metal was dried and cut in the air, washed for a long time with purified benzene, again cut and dried and pressed into wire through a clean press previously washed with benzene, the first portions of the wire being rejected. The dried liquid was crystallized with the greatest care, especial pains being taken to prevent access of the moisture of the air. During the first three crystallizations a slight change in the freezing point was noted as the freezing progressed; but in the fourth and fifth, the substance

¹ The boiling points are: benzene, 80.2°; thiophene, 84°. Thiophene separates with benzene when this is crystallized, in a solid solution which is 42% as concentrated the original liquid solution. Bijlert, *Z. phys. Chem.*, 8, 343 (1891); Beckmann, *ibid.*, 22, 609 (1897).

gave a melting point constant to within 0.003° during the freezing of a large part of the liquid. This constancy in the freezing point indicates a presence of less than 0.01% of water.¹ The final value of the melting point of benzene was found to be 5.484° , a value very close indeed to that (5.483°) since found by Shipley and one of us in an investigation dealing especially with the subject.²

Toluene.—Pure toluene was prepared by fractionation of the commercial distillate. This material was first agitated with several portions of sulfuric acid, and otherwise treated by a procedure similar to that followed in the first purification of benzene. The product was free from olefenes and from thiophene and its homologs. It was dried with carefully prepared sodium which had been freed from paraffin oils by evaporation, and by long continued soaking in toluene.

This purified material, which contained besides benzene and xylene probably no other noticeable impurities, was fractionated from a still of special construction, a description of which has been published elsewhere.³ The product of 40 cc. which distilled within a range of less than 0.01° was called *toluene A*, and was dried at 100° over sodium and kept over sodium. Of the two other samples, prepared by redistillation of the other distillate, one called *toluene B*, distilled over about the same interval as *A*, and another, *toluene C*, which was much less pure, distilled over 0.1° . The boiling point of the purest sample was taken with great care and found, by means of calibrated Beckmann thermometer, to be 10.25° above the boiling point of water under the pressure of 752.6 mm. Since under this pressure the boiling point of water is 99.726° ,⁴ that of toluene is 109.98° . According to the data of Young,⁵ this would become 110.31° at 760 mm. pressure.

Ethyl Benzene.—Two samples of ethyl benzene were prepared. One was made by the Fittig reaction from bromobenzene and ethyl bromide with sodium. These materials were themselves very pure to begin with, the bromobenzene having been made from thrice recrystallized thiophene-free benzene, and the ethyl bromide having been carefully purified by

⁵ Data in Crafts, *Ber.*, 20, 709 (1887), and Young, *J. Chem. Soc.*, 81, 777 (1902). Summarized in Young, "Fractional Distillation" (1903), pp. 14, 15. The boiling point here given is in accordance with the value submitted by Neubeck, *Z. physik. Chem.*, 1, 656 (1887), and by Kahlbaum, *Ibid.*, 26, 603 (1898), which are respectively 110.3° and 110.4° . It does not agree with those given by Young, *J. Chem. Soc.*, 73, 906 (1898) and by Timmermans, *Bull. Soc. Belg.*, 24, 244 (1910), which are, respectively, 110.8° and 110.7° .

fractionation. Thus it was possible to prepare a sample of ethyl benzene which when fractionated showed only traces of the acrid compounds which usually contaminate this hydrocarbon, possessing an agreeable, ethereal odor, and being perfectly colorless. At first it distilled wholly within a degree, and upon fractionation, after complete drying, it yielded a product which redistilled within three-tenths of a degree. This substance was labelled *ethyl benzene B*; and that part of it which distilled within one-tenth of a degree, *ethyl benzene A*. The boiling point of *ethyl benzene A* was determined during the final redistillation, which was carried out in a still of the same general design as that used for the fractionation of toluene, but of smaller dimensions. A small Reichsanstalt standardized Anschütz thermometer hung suspended in the tube, visible through the mica-covered apertures which pierced the asbestos insulation of this tube at the desired points. The boiling point was 136.03° (mean temperature) at 761.1 mm. which becomes 135.98° at 760 mm. pressure.¹

That all this trouble was worth while was shown by the combustion of a cruder sample made from the rejected residues in the fractionation of *ethyl benzene A*. It boiled over four degrees and yielded a result for the heat of combustion 0.4% lower than that of the pure product.

Another sample of pure ethyl benzene, labelled *ethyl benzene C*, was made by the condensation of benzene with ethyl bromide under the influence of aluminum chloride in the presence of finely divided mercury.² The substance was prepared with the same care as that observed in making the other material, and the product was equally well fractionated. Moreover, it distilled at almost the same temperature. It yielded, nevertheless, lower values for the heat of combustion, as will be seen; but there is every reason to believe that the discrepancy was due to the presence of a trace of bromine, because an appreciable quantity of bromide was found in the bomb after the combustion. It is uncertain whether all of the bromine could be recovered in the bomb, and also in what way this substance was originally combined, hence the exact correction for the presence of this bromine is impossible; but an approximate correction is made below, which shows that the amount of the impurity was of the same order as the difference between the two series of results.

Mesitylene.—The specimen of this substance, prepared as usual from acetone, was carefully fractionated. Fifty per cent. of the raw material distilled within 0.3° . After five distillations half of the ma-

¹ Cf. R. Schiff, *Ann.*, **220**, 92 (1883), who gives the boiling point of ethyl benzene as 135.7° at 758.5 mm. This value reduces to the mean 135.8° at 760 mm. Perkin, *J. Chem. Soc.*, **69**, 1191 *et seq.* (1896) gives the boiling point as 135.5° .

² Radziewanowski, *Ber.*, **28**, 1138 (1895).

terial had been brought within the range 0.2° . The corrected boiling point of the portion taken at the peak of the accumulation in the distillate was 164.72° at 760 mm., including all corrections.¹ Three samples were burned: (A) having a boiling point between 164.6° and 164.7° , (B) having a boiling point 0.1 of a degree higher; and (C) 0.2 of a degree lower. In spite of these different boiling points, it will be seen that all of the material gave essentially the same quantitative results. The thermometer had been standardized by the Reichsanstalt.

Pseudocumene.—A specimen of this substance (1,2,4-trimethyl benzene) made by rectification of the commercial distillate furnished by a competent German firm, showed a fairly constant boiling point near 169° . After drying over sodium on the steam bath, it was fractionated by eight distillations, a fraction being finally obtained which redistilled within a range of 0.1° , as in the case of mesitylene. The boiling point of this material averaged 169.27° corrected to 760 mm. This specimen was labelled *pseudocumene A*. Here again we thought it worth while to test the heat of combustion of a distillate with a lower boiling point in order to determine as before if the inevitable impurities might have a perceptible effect upon the heat of combustion. No important difference was, as a matter of fact, observed. The boiling point of the pseudocumene, as we have found it, lies between the values given by Warren and Perkin, which are, respectively, 169.8° and 168.2° .²

Normal Propyl Benzene.—This substance and all the following substances were prepared from benzene or of substances made from benzene which had been carefully purified in the manner already described. They were in every case carefully fractionated and dried by distillation from sodium, just before being used for combustion, and were usually kept sealed in glass tubes or preserved in tightly clamped glass-stoppered bottles. As all but one of the hydrocarbons were made either by the Fittig or Friedel-Crafts synthesis, exceptional precautions were taken that the final products might be freed from halogen, because the halogen derivatives have much lower heats of combustion than the hydrocarbons. That this purpose was accomplished was shown by tests according to the Carius or the Pringsheim method.³ Moreover, the residues in the bomb after combustion were tested with silver nitrate and nitric acid. In no case was more than a very slight opalescence observed, corresponding to an amount too small to have any perceptible effect upon the heat of combustion. The absence of these halides leads one to hope that the corresponding alcohols from which they were made were also absent. Alcohols are

¹ Schiff, *Lieb. Ann.*, 220, 94 (1883) gives 164.5° and Perkin, *Loc. cit.*, 164.1° .

² Warren, *Z. Chem.*, 1865, 666; Perkin, *Loc. cit.*

³ Pringsheim, *Ber.*, 36, 4244 (1903); *Ibid.*, 37, 2155 (1904).

especially troublesome, because they form mixtures having constant boiling point with alkyl halides and with the hydrocarbons.¹

Normal propyl benzene was synthesized from bromobenzene and normal propyl bromide with sodium. The reaction was retarded by cooling with ice in order to minimize molecular transposition. The product, having been once distilled, was treated with washed and dried ether and magnesium turnings to which a small quantity of activated magnesium had been added, together with a crystal of iodine, to catalyze the reaction. This mixture was refluxed for three hours, then treated with water and separated. The bromobenzene boiled at 156.2° . Afterwards the product was boiled with alcoholic potash, washed with water, dried and fractionated. The final product boiled with great constancy within 0.1° , at 158.0° under 760 mm. pressure. Schiff² gives the boiling point as 158.5° at 751.6 mm.

Every test showed this hydrocarbon to be entirely free from halogen. It might have contained a small quantity of isopropyl benzene, but its odor and the constancy of its boiling point militates against this possibility. Even if much isopropyl benzene had been present, no measurable change would have been caused in the heat of combustion.

Other methods of making propyl benzene, such as condensation of benzyl chloride with ethyl bromide and of iodobenzene with normal propyl iodide, were attempted, but were not as successful.

Isopropyl Benzene.—Two samples of isopropyl benzene were prepared, one by the condensation of isopropyl iodide and benzene by the Freidel-Crafts reaction; the other from isopropenyl benzene, made by the Grignard reaction from acetophenone after the method described by Klage.³

The Freidel-Crafts material was prepared in the simplest possible way, by the use of anhydrous aluminum chloride alone. The use of mercuric chloride and metallic aluminum as catalyzer was abandoned; because of the suspicion that mercury alkyl compounds might thus be formed. The reaction ran slowly for two days in a closed flask, then rapidly when refluxed for three hours; it was stopped by a bath of ice water, and hydrochloric acid was added to separate the emulsion.

The product was freed from hydriodic acid and iodine and from hydrochloric acid by repeated washings in sodium hydroxide solution, was carefully dried and then distilled. The distillate was boiled with alcoholic potash for fifteen minutes, dried again and fractionated in the still used for the fractionation of ethyl benzene. The finally chosen fraction

² *Ann.*, **220**, 93 (1883).

³ A. Klage, *Ber.*, **35**, 2640 (1902).

boiled at 152.85–153.15° under 765 mm. pressure,¹ and redistilled almost wholly within the same range. The product, which probably contained no isomeric hydrocarbon, yielded, after complete combustion under 20 atmospheres of oxygen, a residue which showed only a negligible opalescence when tested with silver nitrate and nitric acid. It was, therefore, a very pure product. This material was labeled *isopropyl benzene A*.

A second sample of isopropyl benzene was made by a radically different method with equal care. Acetophenone was added very slowly to the Grignard reagent at the temperature of melting ice; the ether was distilled off, and the residue then refluxed for six hours on the steam bath. The product, isopropenyl benzene, was then reduced by three times the reaction-quantity of sodium in absolute alcohol; and after the reaction, the product was washed and separated with dry ether, dried with anhydrous sulfate and twice distilled. The resulting liquid, of somewhat rancid odor, boiled at 152–153°. It was treated with alkaline permanganate until it showed no color-change after long standing, and until a sample added to a dilute solution of bromine and chloroform showed no evidence of further oxidation. This purified material was then fractionated in the usual way, and yielded a final fraction of 3 cc., which boiled at 152.5–152.8° under 751.4 mm. pressure. It was distilled from sodium and yielded a final distillate of about 2 cc. This product was called *isopropyl benzene B*. It is to be noted that the boiling points of these two products were fairly close together, although not identical.

Tertiary Butyl Benzene.—This hydrocarbon was synthesized from pure benzene and a residual sample of isobutyl bromide by the Freidel-Crafts reaction. The isobutyl benzene formed is under these circumstances wholly converted to the tertiary by molecular transformation.² The hydrocarbon thus made having once been distilled and thoroughly dried, was fractionated, and a final distillate was at length obtained which came over wholly within 0.2°. Its boiling point at 751.4 mm. pressure was 168.8–169.0°.³ The yield of this pure substance from 410 g. of benzene, and 100 g. of isobutyl bromide was about 10 g. Upon combustion, the resulting water gave no opalescence whatever with silver nitrate.

Cyclohexane was prepared in a pure state from very pure benzene by the Sabatier-Senderens reduction.⁴ The benzene was vaporized at 65°

¹ Cf. Perkin (*Loc. cit.*) who gives the b. p. 152.9°. The b. p. given above reduces to the mean 152.3° at 760 mm.

² Schramm, *Monatshefte*, 9, 615 (1888); Gossin, *Bull. soc. Chim de Paris*, 41, 446 (1884).

³ Cf. Schramm (*Loc. cit.*) who gives the b. p. of this substance at 736 mm. as 167–167.5°. Data are not available with which to convert these boiling points accurately to 760 mm., and thus to compare them.

⁴ *Compt. rend.*, 133, 321 (1901).

in a current of pure hydrogen, which had been made free from all usual contamination, and carefully dried by passage over red hot copper gauze and solid potassium hydroxide. The mixed vapor was led at 160° through a coiled tube three meters in length packed with iron-free pumice, on which finely divided nickel had been deposited. This had been prepared in such manner that it was free from chlorides and other negative catalysts. The composition of the condensed vapor was tested by freezing-point determinations made after each attempted reduction. Only after the mixture has been passed eight times through the reducing coil was the reduction thus shown to be complete.

The approximate freezing points of these mixtures are of interest: the first condensate began to freeze at $+4^{\circ}$, the second at -4° , the third at -21° , the fourth and fifth below -22° , the sixth at $+2^{\circ}$, and the seventh and eighth at about $+6.3^{\circ}$. Thus the first was almost pure benzene, and as more and more of the substance was converted into cyclohexane the freezing point passed through the eutectic point (below -22°) and finally rose as the benzene was eliminated.

From 800 cc. of benzene, about 120 of cyclohexane were thus made. A greater yield could have been obtained by the use at all times of a condenser packed in a freezing mixture, for there was much loss through evaporation. The material thus made was twice crystallized, while mechanically stirred, in a Beckmann freezing-point apparatus similar to that used for the crystallization of benzene. The bath was kept very constant at a temperature slightly above the freezing point of benzene; and care was taken that the cyclohexane was not contaminated with water. About a quarter or a third was rejected at each freezing, hence about 60 g. remained of the pure material. The product of the first crystallization was labeled *Cyclohexane B*; that of the second, *Cyclohexane A*. After having been carefully dried, cyclohexane A was distilled in a side-tube still which held a standardized thermometer wholly enclosed, and showed a boiling point of 80.8° under 760 mm. pressure, which remained constant within visible limits (*i. e.*, at least to within 0.03°). The melting point of this material was found with great care by comparison with that of pure benzene, the procedure being precisely similar to that by which the melting point of benzene had been determined. It was found to be 0.485° above that of benzene, or 5.97° .

In spite of our care, it is not impossible that a trace of benzene remained in this substance. Accordingly, its heat of combustion may be slightly lower than the true value, but we believe that more care to avoid this difficulty was taken in the present case than in previous investigations of others.

Cyclohexane burns with such violence in the bomb as to cause trouble in the thermal measurement. In one case, which of course had to be re-

jected, the insulated electrode was blown out of the bomb. The two determinations which are later given, however, are probably not more than 0.1% in error.

Sucrose.—Pure sugar was made from the commercial granulated material by successive crystallizations. It was dissolved in 50% redistilled aqueous ethyl alcohol and crystallized by the addition of more alcohol and by cooling. The precipitate was thoroughly centrifuged, and the process of precipitation was repeated four times. It was dried under reduced pressure, repulverized in agate, and dried again. It was kept over fused potassium hydroxide in a desiccator, and was so dry that it acted like a powdered silicate, and did not adhere either to pestle or platinum vessel. This purest sample was labeled *Sugar A*. A similar less pure sample was prepared in the same way, with only three instead of four crystallizations, but its heat of combustion was identical within the limits of experimental error; hence its purification was really sufficient—the further treatment received by sample *A* had been an act of supererogation. In the course of the crystallization of this sugar, all the precautions which would be observed in a most accurate investigation upon atomic weights were taken. These are well known and recognized, and it is perhaps unnecessary to detail them here. It is enough to say that, both as regards purity of the liquids, care in filtration and all the other minutiae of the work, every effort was used to prevent the ingress of impurity.

The Bomb and the Details of Combustion.

The apparatus employed has been in part described in the publications already cited, but certain additional features require explanation. The bomb used was of the Atwater type,¹ wholly lined with platinum. Because leaden gaskets around the rim are easily corroded, and because electroplating of the lead with gold or covering it with strips of gold foil had proved troublesome and unsatisfactory, we used a gasket of pure, soft annealed gold. In the later determinations the whole top of the bomb, in addition, was lined with a circular sheet of pure, soft gold, which covered the gasket as well as the center.

The bomb itself had been altered in two respects. After use during several years the lining had become worn at the edge which bore upon the gasket. This edge was planed down, and a ring of triangular cross sections was cut out of it in such a manner that a double edge was presented to the gasket (Fig. 1). The alteration insured a more complete closing of the bomb by moderate pressure, and prevented leakage. To the bottom of the bomb, legs of heavy wire were attached, a centimeter in length; and thus an easy circulation of the calorimeter water beneath

¹ This instrument, together with its accessories, is described in detail by Atwater and Snell, *THIS JOURNAL*, 25, 659 (1903).

the bomb was secured. The instrument thus altered was found to be satisfactory in every way.¹

The calorimetric vessel was a cylindrical can of pure spun silver, brightly polished on the outside. This vessel was somewhat smaller than those previously used in similar researches; thus the heat capacity of the calorimetric system was reduced, with the result that the temperature-rise per gram of material burned was nearly half again as great as in former measurements.²

Fig. 1.—Section of edge of bomb (actual size). Showing double ridge pressed against gold washer.

The calorimetric stirrer was of the usual vertical reciprocating type, consisting of two perforated rings firmly attached to slender vertical supporting rods; and provided with thin guiding wires which prevented engagement with the collar of the bomb. The supporting wires were cut to such a length that they never left the calorimetric system and were insulated from the outer attachments by thin rods of vulcanite. As a result of this modification no heat was lost to the system by conduction,

while the sucking in of outside air remained minimal.

The calorimeter was surrounded everywhere by a narrow air-jacket, being held by small pieces of cork within a slightly larger vessel of brightly polished nickel-plated copper, the walls of which were about the same thickness and conductivity as its own. The insulation was carefully tested electrically before and after each determination. This copper vessel, nicknamed a "submarine," was provided with a water-tight cover, pierced with tubes for the necessary entering parts of the apparatus. The cover, made of cast brass, was heavier than those formerly employed, and was supported by a correspondingly heavy rim of brass soldered to the jacket, which carried five swivelled thumb-nuts symmetrically arranged and permanently attached. Both cover and rim were perfectly plane on the bearing surface, so that the joint, protected by a gasket of

¹ A number of trial combustions were made with a Kröcker bomb of German manufacture. It was easily handled, and would in all probability have been a satisfactory instrument had it been constructed in accordance with the published and advertised design. As actually made, however, the lead gasket intruded into the bomb-chamber to such an extent that it was very badly corroded; moreover, the rim of the exposed part of the cover was of unprotected bronze; and the construction of the electric connection was flimsy and mechanically bad.

² By this alteration also, the surface of evaporation was reduced. Even in former work, however, in which larger vessels were used, error from heat absorbed by evaporation of the calorimeter water had been calculated to be negligible. See Richards and Jesse (*Loc. cit.*).

soft rubber, was easily made tight by gentle pressure and never leaked in consequence of the distortion of cover or rim, during several months of continuous use. In a practical way, this modification was important for obvious reasons. The somewhat lower conductivity of the cover (due to its greater thickness), was a matter of no moment, since the surface is small, and even with the greater thickness, the conduction of heat is very rapid. The whole calorimetric system, together with its protecting jacket, was held underneath a bath of dilute caustic alkali, the temperature of which could be regulated by the addition of sulfuric acid from a buret graduated as usual in tenths of a degree. The powerful stirrer and other mechanism of this external apparatus has been so often described that no further explanation is needed. The bath thermometer, placed on the opposite side of the bath from the acid-intake, was like the calorimetric instrument, and gave strictly comparable readings. Insulated ignition wires were led from the bomb electrodes through the chimneys in the cover of the calorimeter jacket which accommodated the stirrer. These chimneys were stopped above by cotton wool, loosely wired in place, in order to prevent circulation of atmospheric air. The stirring machinery was rigidly mounted, in such a manner as to insure fairly constant speed—a matter of first importance, as experience showed. The appended diagram shows the entire apparatus, drawn approximately to the scale (Fig. 2).

The calorimetric thermometer (maker's No. 11258) was one which had been made especially for this and similar work. It had been filled under an atmosphere of pure hydrogen, and the movement of the thread was prompt and regular. The scale, which was divided in hundredths of a degree, covered the temperature interval from 15.3 to 20.5° ; the length of the $1/100^{\circ}$ interval was about 0.8 mm., and intervals of 0.0005° could be readily estimated with a lens. Before reading, the thermometer was softly and evenly tapped upon the side; violent tapping, especially upon the top, may cause the column to jump and remain fixed several thousandths of a degree above its true point. This simple precaution is a very important matter. The best procedure for this particular instrument having been found, it was always practiced. The temperatures were always read to within 0.0005° , and the corrections were calculated also including the fourth decimal place, but this outcome was rounded off to the nearest unit in the third decimal place in the final recording of the results. The thermometer was read always with a very slowly rising temperature, never when the thread was falling.

This instrument has been four times standardized: by the Reichsanstalt in 1909 (P. T. R. No. 37900); by the United States Bureau of Standards in 1909 (B. S. No. 5506); and at a very great number of points by the authors in collaboration with Dr. A. W. Rowe in comparison with the

Fig. 2.—Complete assembled apparatus for calorimetric combustion. (In section.)

Baudin instruments 15200 and 15276 of the Bureau International des Poids et Mesures, and finally with the help of Dr. T. Thorvaldson. The Reichsanstalt work had been very crudely done, perhaps through a misunderstanding; on the other hand, the results of the Bureau of Standards at Washington corresponded fairly well with our own comparison with the Parisian Standard. The results are expressed in terms of the Parisian Standard as given by the Baudin instruments, but, as a matter of fact, it does not greatly matter which of these standards were used, as the work was wholly relative, and almost the same range was used for each experiment. If in the future it is found during the course of a critical study of the thermometric scale¹ now in progress here, that small corrections are in some cases necessary, these may easily be applied at any time. After some delay we have thought it best not to withhold the publication of this paper longer on this account.

It is worthy of note that such uncertainty as exists is not due to the mercury-in-glass thermometer used by us, but rather to the *standard to which it is referred*. This same uncertainty would apply to any other means (such as the electrical ones) of employing this same standard.

It should be noted that the instrument used in this work was always kept at temperatures near that of the room—it was never cooled to zero. Thus it was spared the internal upheavals which are caused in glass by any considerable changes of temperature.²

The hydrocarbon to be burned was dried with scrupulous care, and was sealed into small glass bulbs, previously weighed, in such manner that at room temperatures the bulb was completely filled. To make this possible the bulbs were made very thin, and were flattened on opposite sides; so that under high pressure they yielded until the liquid itself bore the strain, and at the higher temperatures they expanded readily under the internal tension (Fig. 3). The bulbs were filled by alternate heating and cooling, caused by contact with and removal from a piece of heated metal. A general heating of the bulb was dangerous, since under these circumstances the liquid evaporated almost explosively and often burst its fragile container. After filling, each bulb was kept at 16.7° in a water bath until constant in temperature; the liquid in the capillary was boiled out quickly by a small flame to a point close to the bulb; this was then chilled in cold water and sealed by a hot flame at the point from which the liquid had been thus withdrawn.³ The bulbs were cleaned carefully and were

¹ See THIS JOURNAL, 37, 81 (1915).

² These and other precautions are discussed in a recent paper by one of us, *Orig. Comm. 8th Intern. Cong. Appl. Chem.*, 1, 416 (1912).

³ The bulbs without their attached capillaries weighed from 0.3 to 0.5 g. They were designed to hold somewhat less than a gram of material; in every case such a quantity as would cause a rise in temperature of 3° when burned in this calorimetric system. According to the value of the heat of combustion of the material being used,

dried in a desiccator under reduced pressure. This process tested their ability to remain unbroken when placed in the partially exhausted tube. They were weighed to within 0.05 mg. with carefully standardized weights;

Fig. 3.—Glass bulbs for containing volatile liquids in various stages of preparation. (Somewhat larger than actual size.)

the weight was checked after a sufficient interval and was reduced to the vacuum standard. Leakage could always be detected by odor and by inconstancy in weight; of course all leaky bulbs were rejected.

The bomb was prepared substantially as in the latest of the previous investigations. A small, narrow, platinum crucible replaced the usual capsule; the bulb, placed at the bottom of this, was covered by a thin circular plate or shelf of glass (a microscope slide-cover), from which a small piece had been snipped to allow the easy escape of vapor.¹ Pure the bulbs were selected for size, which is, of course, easily measured by immersion. While the liquid was being boiled out of the capillaries, and during sealing, the bulbs were kept at the desired temperature in a thimble beaker, filled with water. The capillary protruded through a thick mica cover. Care had to be taken against forming tarry matter in the capillary by partial combustion, and against leaving residual liquid in the detached capillary. Loss of glass by volatilization in the blow pipe flame was negligible.

¹ Richards, Henderson and Frevert, Richards and Jesse, *Loc. cit.*

sugar in small quantity, usually less than 0.1 g., was spread evenly upon the little glass shelf; it was weighed by difference, and the weight reduced to the vacuum standard. The ignition wire of pure iron was cut to constant length (a procedure found to be as accurate as weighing), was coiled, and adjusted in such a way that several turns of the helix just touched the sugar. This precise adjustment was found necessary to prevent incomplete combustion and the formation of charred particles by spattering.¹ In consequence of the arrangement of the materials to be burned, the heat from the ignited sugar burst the bulb below it, and the vapors from the bulb had to pass through a zone of flame before they escaped into the combustion chamber. This favored completeness of combustion. Only occasionally when the bulb broke under pressure before ignition was the odor of unburned hydrocarbon detected in the open bomb.² Such trials were rejected.

Before the bomb was closed, 1 cc. of water was always introduced. This was in amount more than sufficient to insure the saturation of the enclosed air with water vapor before combustion, and thus to cause the complete condensation of the water formed by the reaction.

In order to diminish the amount of nitric acid formed during the combustion, the bomb, having been closed, was exhausted by air to a pressure of about 20 mm. of mercury. To the same end, as well as in order to reduce another correction, the ignition wire was made as short as seemed practicable; for the formation of nitric acid, *ceteris paribus*, seemed to result more from the combustion of the iron than from the burning of the hydrocarbon.³

The best oxygen pressure was found in these measurements to be in the neighborhood of 20 atm. Under a greater pressure the bulbs were likely to burst; moreover, at 30 atm., odoriferous gaseous products were formed. In all combustions the fairly constant pressure of 20 to 23 atms. was maintained, the variation in which could not have altered sensibly the heat capacity of the system.⁴

The colorimeter water, at a determined initial temperature somewhat

¹ This procedure, the general method, involving which was applied in previous investigations, has been here described in some detail, since of all involved it required the greatest nicety in manipulation; and determined in greatest measure the success of each operation.

² By the dilution of a known quantity of benzene vapor with successive additions of air, it was demonstrated that the odor test for unburned hydrocarbon was more than sufficiently sensitive to serve for the detection of all but quite negligible quantities. The benzene was chosen for this test because of its relatively faint odor.

³ This was shown by the parallel variation which was always observed between the corrections applied for wire burned and for nitric acid formed.

⁴ The oxygen used was made from liquid air. It had been analyzed for oxygen, and was found to contain never more than 2.5% of inert gas, largely argon. Subsequent tests showed it to be free from halogen.

below 16.5° , and always the same in amount was weighed to within ± 0.2 g.—an accuracy more than adequate.

The apparatus having been assembled and tested for insulation and correct adjustment, the whole calorimetric system was brought to thermal equilibrium in the neighborhood of 16.5° . The approximate temperature range expected had been estimated by calculation from the weights of the materials used; while the initial temperature had been selected in accordance with this value, usually so as to cause the final temperature to be near 20° . Effort was made to have both temperatures come upon smooth stretches of the curve of thermometer-calibration. The thermometer was cooled a trifle below the chosen point before immersion, so that initial readings could be taken on a rising thread. Equilibrium having been once established, observations were made at short intervals for 15 or 20 minutes, while the system was kept as closely as possible adiabatic. The rate of temperature rise due to stirring at the initial temperature was thus determined. Simultaneously, readings of the stem temperature and of the actual rate of stirring were recorded. This done, the charge was ignited and the temperature rise within was paralleled in the bath outside by the addition to the bath of sulfuric acid from the buret. It was found to be in no way difficult to hold the thermometer registrations of the bath temperature within 0.1° of those indicated by the calorimeter thermometer during the minute or more occupied by the rapid change of temperature; while toward the end, this correspondence could be maintained within 0.010 to 0.02° . Calculation, based upon blank experiments in which the rate of heat interchange was measured while differences of several tenths of a degree were maintained between the calorimeter and bath, indicated a much wider margin of safety in manipulation. The effective distribution of acid in the outer alkaline bath is an essential precaution. The rotary bath-stirrer completed 320 r. p. m., and was found to distribute the acid evenly in less than four seconds. The thermometric lag, occurring to the same extent with both instruments, is eliminated from consideration.

At the final temperature, which was approximately that of the environment, further readings were taken at intervals of two minutes until the rate of temperature rise became uniform; and thereafter at longer intervals for ten minutes or more. Thus the temperature rise due to stirring at the final temperature was determined. During this time also, the stem temperature and the rate of stirring were again recorded. The initial temperature had been read immediately before ignition. The final temperature was taken at any convenient time after the rise had become uniform. The time interval that had elapsed between these readings, usually about ten minutes, was known from the data; and the stirring correction was calculated for this interval from the observed rate at the

final temperature, at which it was unaffected by the sucking in of air from the outside, since this was at about the same temperature. The two observed rates of evolution of heat from stirring were usually closely the same; normally, that taken at the lower temperature was slightly larger, perhaps because of the greater viscosity of the water, but in such degree that no important error could have resulted in basing the correction upon the other. A correction derived from either the initial or the average rate would have approximated the true value somewhat less closely than that from the final rate, since the temperature rise was much more rapid at the start. This method of reading initial and final temperatures on almost stationary but very slowly rising thread, which is moving at nearly the same rate at both times, quite eliminates thermometric lag as a factor of inaccuracy in the difference between the readings.

The correction for stirring was somewhat variable, depending upon the speed, and the size and shape of the annular space between the bomb and the calorimeter wall. By placing thermometers at different heights, it was found that no stirring rate less than 65 strokes a minute was effective in preventing a dangerously persistent thermal stratification within the calorimeter; in consequence, the usual rate employed was 70 strokes a minute. The rise of temperature due to stirring at this rate might have been reduced by using a larger calorimeter, as in former work, but the advantage thus gained would have been slight in comparison with that lost. Because of its variability, the stirring correction was determined in each case to within a small limit of error.

The correction for stem exposure was in these determinations very small, since at the initial temperature there was but slight exposure and since the final temperature was near to that of the environment. Its magnitude was invariably less than 0.001° .

The correction for heat developed from that portion of the iron ignition wire actually burned was calculated from the known heat of combustion to Fe_3O_4 ; the small pieces of unburned wire found attached to the electrodes after the bomb had opened were always measured and allowed for.¹ The calculated value of this correction was checked by determinations carried out according to the usual procedure, in which wire alone was burned, of a length double that used in the combustions. These measurements verified each other and the calculated correction within the limit of observation. They proved, incidentally, that the electrical heating of this wire to ignite it, which had been made as uniformly slight as possible and calculated to be negligible, was so in fact.

The quantity of nitric acid formed in each combustion was determined by titrating the washings from the bomb with standard alkali. From this correction for heat developed in its formation was calculated from

¹ Richards and Jesse, *THIS JOURNAL*, 31, 277 (1910).

known data. Since the oxygen used contained only a small percentage of nitrogen, and because the bomb had been partially exhausted of air before oxygen was let in, this correction was very small. Its effect on the calorimeter approximated 0.0001° per centimeter of iron wire burned. All errors in the determination of this correction were quite negligible.

No further observations on the method and procedure are necessary. The notes of each experiment were recorded essentially in the manner detailed in a previous paper.¹

In order to effect economy of space in the following tabulation of results, the minor corrections, which depend upon the purely accidental nature of each particular experiment, are all algebraically added together in one column. The magnitudes of these corrections were about of the following order: Correction for calibration of the thermometer, $+0.013^{\circ}$; stirring, -0.015° ; for heat of combustion of wire, -0.018° . All these, together with the very small corrections for stem exposure and for nitric acid are included below in the column headed "Total corr." In all the tables except Table I, the rise of temperature due to the sugar taken to start the combustion (calculated from the outcome of Table I) is also included in this total correction.

The heat capacity of the system was increased 0.023% by slight alteration of the parts after the work described in Table VII; all subsequent work is corrected below, so as to reduce all to the original standard. The total heat capacity was equivalent to 2663.6 g. of water at first and 2664.2 later, as calculated from the rise of temperature caused by the combustion of sugar, assuming the Bureau of Standards' latest value (3945 cal. $[18^{\circ}]$ per gram weighed in vacuum) for the heat of combustion of the latter substance.²

The Quantitative Results and their Discussion.

³ NOTE.—The determinations recorded in Table I comprise all that were completed in a continuous series, save three. Of these, two, Nos. 4 and 6 in the continuous series,

The exceptionally close agreement of the values given in this table show how accurately it is possible to conduct experiments of this kind with the adiabatic calorimeter and the mercury thermometer. It will be noted that the temperature range was almost the same in each case, hence fundamental errors in the calibration of the thermometer could not appear. Of course, results as good as this can be expected on comparing different temperatures range only if the thermometer is everywhere thermodynamically consistent with itself, and this seems to be too much to expect of our present thermometric scale.¹

Feeling satisfied that the temperature rise during the combustion of sugar in our apparatus was hereby determined accurately enough for our purpose, we now proceeded to the thermally quantitative combus-

were rejected because carbon or charcoal was discovered in the bomb after combustion. The other, No. 3 of the continuous series, was rejected because its temperature range was 1° lower than that of the others, and was such that the initial and final temperatures fell upon points that marked sharp and irregular changes in the slope of the curve of thermometric calibration.

¹ Richards and Thorvaldson, *THIS JOURNAL*, 37, 81 (1915).

² The above record comprises all the results in an unbroken series of completed determinations, save one. This omitted result yielded the value 3.8470 for the rise per gram toluene, which showed a variation from the average of the preceding of nearly 1%. Such a discrepancy, which corresponds to a thermometric error of 0.024° or to a weighing error of 0.006 g., is far beyond any possible variation resulting from experimental error; and must be due to misreading, probably of weights.

tion of the volatile hydrocarbons, the results for which are given in the following tables. In each of these experiments, as already stated, the hydrocarbon was enclosed in a small, hermetically sealed bulb and the combustion was started by means of a small amount of sugar. The temperature rise due to this sugar is included with the other smaller corrections in the column headed "Total corr." It was in each case obtained by simply multiplying the weight of sugar by the factor 1.481° , just found, according to Table I.

¹ The washings of the bomb in one case yielded 4.9 mg. of silver bromide, corresponding to 2.84 mg. of ethyl bromide, the heat of combustion of a gram of which (according to Berthelot's figures) is 7.4 Calories less than that of a gram of ethyl benzene. Hence the correction to be applied is $0.00284 \times 7,400/2671 = 0.0078^\circ$.

The study of the individual results in this long series of determinations shows that, although the results are sometimes not quite so concordant

¹ Sample B of isopropyl benzene, made by the Grignard reaction, was doubtless less pure than A, made by the Friedel and Crafts reaction. Accordingly the results with Sample B are not included in the average.

² The result of determination 1 (made in Sample B) is not included in the average. Hexamethylene B contained more benzene than hexamethylene A, which was used in Nos. 2 and 3.

³ Immediate data mislaid at date of writing. It is known, however, that the measurement involved very closely the same temperature range.

as those with the sugar alone, they are, nevertheless, as closely concordant as the circumstances permit. In most cases the extreme variation from the mean is less than 0.002° in the final results, while in many cases the agreement is even better than this; and in no case do the variations cause the highest result with one isomer to overlap the lowest result with the isomer giving the larger output of heat. As regards the different preparations of substance, the discrepancy between the two samples of ethyl benzene has already been noted, and its cause explained. Unquestionably the samples of ethyl and isopropyl benzene, labeled *A*, purer than those labeled *B*, and the excellent results obtained with them will be used in the future discussion. As against this discrepancy it is interesting to note that in the cases of toluene, mesitylene, and pseudocumene, the different samples gave almost identical results in each case. This is doubtless because the impurities in these preparations were chiefly homologous hydrocarbons, which would have much less effect upon the heat of combustion than upon the boiling points that served as the criterion of purity. This comparison is especially instructive as showing the different effect of different kinds of impurities.

Let us now collect all these results for the rise of temperature caused by the combustion of one gram of these several hydrocarbons in a systematic table, and reduce the data to the usual standards, in the first place giving the ratio of the rise of temperature caused by each substance to that caused by exactly one gram of sugar, and in the next place giving the corresponding absolute value for the heat of combustion of one gram of each substance, based on the current absolute values for the heat of combustion of sugar.

Unfortunately the absolute value for the heat of combustion of sugar is not agreed upon by all authorities. The best of the earlier work has been done by Fischer and Wrede, who found as the absolute value 16.545 kilojoules (or kilowatt seconds).¹ A very careful study of the data concerning the mechanical equivalent of heat by Professor Harvey N. Davis, of Harvard, indicates that at 16° this is 4.1846, and at 20° 4.1800. Therefore, accepting this estimate, we may decide that the value over the range used in these experiments is closely 4.182, that is to say, one joule equals 0.23912 calorie. On this basis Fischer and Wrede's value for the heat of combustion of sugar becomes 3956 calories per gram.

On the other hand, the most recent work of the Bureau of Standards of Washington, published by Dickinson,² seems to have been very carefully performed, and to be worthy to supersede the German work. The value here given is 3949 calories (20°) per gram sugar weighed in air, or 3947 calories per gram weighed in vacuum. In 18° -calories this latter figure

¹ Fischer and Wrede, *Sitzb. kgl. preuss. Akad.*, 5, 145 (1908).

² *Bull. Bur. Stand.*, 11, 190 (July, 1914)

would become 3945. In the table below, the value given by the Bureau of Standards is used, but anyone preferring the other (Fischer and Wrede's) can easily add to each value 0.28%.

In the table below there are included also the results concerning xylenes obtained by one of us in collaboration with R. H. Jesse,¹ because this formed an integral part of the series. With these preliminaries the summarized table of results may be given:

TABLE XII.—SUMMARY OF DATA AND SPECIFIC HEAT OF COMBUSTION.

	Rise of temp. caused by 1.000 g. substance.	Ratio of this rise to that caused by 1.000 g. sugar.	Absolute heat of combustion of 1 g. Calories (18°).	Kilojoules.

On comparing these results with the earlier results of others, it is noticeable, first, that the value for benzene is slightly lower than that found by Richards and Jesse five years ago, their value having been 2.538 instead of 2.533 times that of sugar. Nevertheless, our value as given below is decidedly higher than that found earlier by Richards, Henderson and Frevert, and recognized by them as having been too low because of incomplete combustion. The manner of experiment, excepting small details, was very similar in our case to that in the case of Richards and Jesse, and the difference of 0.2%—a quantity distinctly greater than the error of experimentation—needs further elucidation. The matter is, in fact, being studied further in the Wolcott Gibbs laboratory, and it is hoped that before long more light upon it may be obtained. It is possible, indeed, probable, judging from the variations among the Harvard results and also from the varying results obtained by others,² that the complete

¹ Richards and Jesse, *THIS JOURNAL*, 31, 294 (1910).

² See W. A. Roth's able discussion of this subject in the Landolt-Börnstein Tables, page 910, 1912. Roth used the factor 4.189 for the conversion of kilojoules to calories. Accordingly his figures are slightly different from ours as given above. Attention should be called to the error in the next to the last and the preceding column on that page. Instead of "const. vol." and "g. Kal pro gram" the headings should read "Konst Druck" and "Konst. vol.," respectively, like the corresponding columns on p. 911. Roth's work is very thorough and painstaking. In this connection, attention

combustion of benzene in the bomb is a difficult matter, and although the method adopted in the Harvard work has probably secured the best combustion heretofore attained, there is good reason to believe that the further treatment by passing the gases remaining in the bomb over a hot catalyzer is necessary in the case of a substance as volatile as benzene. This has, in fact, been done in a yet more recent research by one of the authors, helped by Dr. H. S. Davis, and before long the further results of this research will be communicated. The same objection does not apply so seriously to the higher boiling liquids, where the vaporization is less rapid and the chance for the escape of unburned carbon monoxide is much less.

Our results also for toluene are higher than those of Roth, and of ethyl benzene, higher than those of Jesse.¹ It is probable that less trouble was taken to dry the substances than in our case, and possibly also our combustion was more complete. For cyclohexane, our results are above those of Roth and below those of Zubow, who found respectively 11127 and 11231 for the heat of combustion of a gram,² instead of our value 11164.

On the other hand, our value for normal propyl benzene is somewhat below that given by Genvresse. All these results and others are recorded in Roth's recalculation, already quoted.

Incidentally it should be noted that these values, as given by the combustion of the material in a closed bomb, correspond to the reaction in constant volume.

It is now a matter of much interest to record these results in the usual standard, namely, in terms of the gram molecule. The molal heats of combustion are, of course, very easily calculated from the specific heats of combustion by multiplying in each case by the appropriate molecular weight.

This table is very interesting from many points of view. In the first place, the striking similarity of the heats of combustion of isomers is distinctly shown. In the eight-carbon isomers recorded above (of which there are four), the range is only between 4559 and 4543 kilojoules, a difference of only $1/3$ of one per cent.; and in the case of the nine-carbon isomers, the range is not much greater, extending only from 5180 to 5208 kilojoules, a difference of a little over 0.5%. The increase of molal heat of combustion, due to the addition of CH_2 , remains nearly constant throughout the series. Between benzene and toluene it is 651 kilojoules; should be called to the interesting and comprehensive paper entitled "Thermochemische Untersuchungen," by W. A. Roth and Auwers, which has reached us too late for discussion here. The new values found by them for benzene, toluene and cyclohexane are very near ours (*Lieb. Ann.*, 407, 109 (1914)).

¹ R. H. Jesse, Jr., *THIS JOURNAL*, 34, 1340 (1912).

² See Landolt-Börnstein (1912).

between toluene and ethyl benzene, 644; between ethyl benzene and propyl benzene, 647; between propyl benzene and butyl benzene, 643—the average being 646. It is possible that the true average is slightly less than this, because the value of benzene given above may be slightly too low, as already stated.

TABLE XIII.—MOLAL HEATS OF COMBUSTION.

Formula.	Mol. wt. C = 12.000. H = 1.0078.	Absolute heat of combustion (in const. vol.) of 1 mol.	
		Calories (18°).	Kilojoules.
Benzene, C_6H_6	78.05	780.0	3262
Toluene, $C_6H_5CH_3$	92.06	935.9	3913
Ethylene benzene, $C_6H_4C_2H_4$	106.08	1089.8	4557
Xylene (<i>o</i>), $C_6H_4(CH_3)_2$	106.08	1090.2	4559
Xylene (<i>m</i>), $C_6H_4(CH_3)_2$	106.08	1090.2	4559
Xylene (<i>p</i>), $C_6H_4(CH_3)_2$	106.08	1086.4	4543
Mesitylene, $C_6H_3(CH_3)_3$	120.09	1241.7	5193

Isopropyl benzene, $C_6H_5CH(CH_3)_2$	120.09	1245.5	5208
Pseudocumene, $C_6H_3(CH_3)_3$	120.09	1238.8	5180
Butyl benzene (tert.), $C_6H_5C(CH_3)_2CH_2CH_3$...	134.11	1398.4	5847
Cyclohexane, C_6H_{12}	84.09	938.8	3926

The data are not yet plentiful enough to permit definite conclusions as to the effect of the more subtle features of the grouping upon the heat of combustion.

The six extra atoms of hydrogen in cyclohexane evolve 564 kilojoules upon burning as compared with benzene. The same amount of hydrogen gas would have evolved half again as much, but, of course, the situation is so complex that an exact interpretation of differences of this sort is as yet beyond our reach. It is hoped that this work may be continued, and not only further progress made with regard to compounds of this type, but also that the work may be extended to other compounds, so as to secure a great variety of accurate data upon which conclusions concerning the total energy relations of organic substances may be built. This is especially important, because, as is well known, many of Thomsen's carefully obtained data are vitiated by the defect of his "universal burner," and in many of the earlier results obtained from the bomb, the combustion was undoubtedly incomplete.

In concluding, we are glad to express our indebtedness to Dr. G. L. Kelley for generous assistance in developing the methods adopted and in directing an assistant employed in preparing and purifying some of the higher homologs; and also to the Carnegie Institution of Washington for the subsidy which alone has made the investigation possible.

Summary.

The principal results of this investigation may be summarized as follows:

1. The method of adiabatic calorimetry as applied to combustion in the Berthelot bomb has been further improved in several directions, making more accurate determinations possible.

2. The agreement among the results with any substance is close enough to show that the method is capable of all the necessary refinement.

3. The relative heats of combustion of sugar, benzene, toluene, ethyl benzene, normal and isopropyl benzene, mesitylene, pseudocumene and cyclohexane have been determined.

4. The striking similarity between the heats of combustion of various isomers appears. Nevertheless, real differences exist, and will doubtless some time, when more data are available, be capable of reference to differences in molecular stability and configuration.

5. The boiling points of these liquids have been carefully studied, especially those of exceptionally pure toluene (110.31°) and cyclohexane (80.8°); and the melting point of benzene also has been determined as 5.484° , while that of cyclohexane was found to be 5.97° .

A REVISION OF THE ATOMIC WEIGHT OF LEAD. THE ANALYSIS OF LEAD BROMIDE.

[SECOND PAPER.]

By GREGORY PAUL BAXTER AND THORBERGUR THORVALDSON.

Received March 8, 1915.

Since the work by Baxter and Wilson¹ on the atomic weight of lead by the analysis of lead chloride some years ago, which yielded the value 207.09 ($Ag = 107.880$), the atomic weight of lead has been under almost continuous investigation in the Harvard Laboratory. Attempts were made by Mr. W. A. Worsham to synthesize the sulfate from the metal, but serious difficulties were met in the production of lead sulfate free from occluded matter, and in the drying of the sulfate, so that this method was temporarily given up in favor of the analysis of lead bromide. The latter substance, in spite of the fact that it is somewhat less soluble than lead chloride, is, nevertheless, sufficiently soluble for the purpose. Preliminary experiments in the preparation of pure lead bromide were carried out by Mr. Worsham. The investigation was then continued by the present authors, and finally was taken up by Mr. F. L. Grover. This paper presents the results of Dr. Thorvaldson's experiments, while the following one describes the completion of the research by Mr. Grover.

The method employed was the usual one in the case of metallic halides, with special modifications made necessary by the idiosyncrasies of lead

¹ *Proc. Amer. Acad.*, 43, 365 (1907); *THIS JOURNAL*, 30, 187 (1908); *Z. anorg. Chem.*, 57, 174 (1908).

bromide. Weighed amounts of the salt, which had been fused in an atmosphere containing hydrobromic acid, were dissolved in hot water which had been slightly acidified. To the solution after cooling was added a solution of a weighed, very nearly equivalent, amount of metallic silver. Any deficiency of bromide or silver was then added in the form of very dilute standard solutions, so that the exact amount of silver required could be accurately estimated. Finally, the silver bromide was collected and weighed.

The Purification of Materials.

Water, nitric acid and ammonia were purified by distillation in the usual fashion.

Hydrobromic Acid.—At first hydrobromic acid was prepared as explained in the paper by Baxter, Thorvaldson and Cobb upon the analysis of ferrous bromide.¹ This acid was made from bromine which had been freed from chlorine by distillation from aqueous potassium bromide (Sample I). The hydrobromic acid was synthesized by saturating hydrogen with bromine and conducting the mixed gases over hot platinum. The hydrogen was made from "hydrone" and was purified by scrubbing and passing over stick potassium hydroxide. The acid gas was collected in water and the solution was purified by distillation. Material produced in this way still gave evidence of containing organic matter,² so that for the later preparations steps were taken to free the bromine from such impurities by converting it to potassium bromide and fusing the salt with potassium permanganate, as described in detail in the following paper. From this potassium bromide, bromine was set free by adding three-fourths of the theoretical quantity of potassium permanganate and sulfuric acid. In this way the bromine received still a third distillation from a bromide (Sample II). The product was converted into hydrobromic acid by direct combination with pure hydrogen in contact with platinum. The gas was collected in the purest water, and the solution distilled, with rejection of the extreme fractions.

Lead Bromide.—This substance was prepared by precipitation of lead nitrate with hydrobromic acid solution, and crystallization of the product by solution in hot concentrated hydrobromic acid and reprecipitation by diluting the solution with water.

Sample A consisted of residues from earlier work by Mr. Worsham, which were recrystallized from hydrobromic acid solution, as above, with centrifugal drainage. The material was somewhat blackened at the outset but was pure white after crystallization.

¹ THIS JOURNAL, 33, 326 (1911); *Z. anorg. Chem.*, 70, 329 (1911).

² This organic matter may have originated partly in the hydrogen made from hydrone. Baxter and Hoover, THIS JOURNAL, 34, 1659 (1912); *Z. anorg. Chem.*, 80, 203 (1913).

The source of Sample B was lead nitrate which had been purified by Dr. J. W. Shipley. The method of purifying the nitrate consisted in precipitating lead sulfate and washing this substance very thoroughly, converting it into lead sulfide by contact with a saturated solution of hydrogen sulfide, and solution in pure nitric acid. Three recrystallizations as nitrate followed, the mother liquors of the last two crystallizations being found free from sulfate. The nitrate was dissolved in water in a quartz dish and a slight excess of dilute hydrobromic acid was added. The crystals were separated from the mother liquor by centrifugal drainage in platinum Gooch crucibles, and were thoroughly rinsed with water. The lead bromide was dissolved in constant boiling hydrobromic acid in a quartz dish and again precipitated by dilution with water. Centrifugal drainage and rinsing followed. After a second recrystallization a portion of the material was reserved for analysis, Sample B₁. The remainder was once again recrystallized, Sample B₂.

Sample C was prepared from lead nitrate which, in turn, was obtained from precipitated lead chloride. The latter substance, after thorough washing, was changed to sulfide as above. The sulfide was washed and dissolved in nitric acid, and the lead nitrate was recrystallized three times. The preparation of lead bromide from this nitrate followed the lines indicated in the case of Sample B. Sample II of bromine was used.

Sample D. Lead nitrate for the preparation of this sample was obtained by recrystallizing the commercial product five times from nitric acid and once from aqueous solution. The bromide was prepared as above with Sample II of bromine.

The final crystallizations of the lead nitrate were carried out in platinum or quartz vessels, while the preparation and crystallization of the lead bromide was always conducted in quartz vessels. A quartz condenser was used for the distillation of the hydrobromic acid, and the distillate was collected in quartz vessels.

Silver.—Pure silver was prepared as frequently described in papers from the Harvard Chemical Laboratory. The particular specimen used in this work had already been used in the investigation upon ferrous bromide¹ (Sample A).

Preparation of Lead Bromide for Analysis.

The drying of lead bromide was effected by fusion in a dry atmosphere containing a considerable proportion of hydrobromic acid gas. In the earlier experiments the apparatus was identical with that used in the research upon ferrous bromide. Fuming hydrobromic acid gas was made by passing the synthetic gas into ice-cold water. A slight excess of bromine was removed by adding a small amount of ferrous bromide. Pure nitrogen was then bubbled through this solution, thereby acquiring a very consider-

¹ Baxter, Thorvaldson and Cobb, *Loc. cit.*

able hydrobromic acid content, and the mixture was dried by passing it over fused calcium bromide.¹ The lead bromide, contained in a platinum boat, which in turn was placed in the quartz tube of a "bottling apparatus,"² was heated in a current of nitrogen and hydrobromic acid, gently at first, so that the greater part of the moisture in the salt was expelled at a low temperature, later at gradually increasing temperatures until finally fusion took place. The bottling apparatus and tube, after the salt had been allowed to cool, were then swept out with a current of pure nitrogen, and this in turn was displaced with dry air. Thereupon the boat and contents, by means of the bottling apparatus, were transferred to the weighing bottle, without exposure to moisture.

When lead bromide, fused as above, is treated with water, either cold or warm, a clear solution is never obtained. The horny mass of fused material whitens superficially, and if the solution is boiled, a white precipitate appears. At first the difficulty was ascribed to hydrolysis of the salt during fusion, but no precautions as to the preliminary drying of the salt before fusion, so as to insure fairly complete elimination of the water, produced any difference in the result, so that the conclusion was reached that the difficulty is caused by hydrolysis during solution. So far as obtaining a clear solution of the salt is concerned, a simple remedy was found in acidifying the solution slightly. In the experiments described in this paper, acetic acid was used for the purpose, although in the work described in the following paper a small amount of nitric acid was found to be equally satisfactory. It was necessary, however, to obtain further evidence as to the cause of the difficulty. This was done as follows: Neutral lead bromide, precipitated by the addition of a solution of recrystallized potassium bromide to a solution of recrystallized lead nitrate, was thoroughly washed by decantation and centrifugally drained. Three grams of this lead bromide when heated with about 600 cc. of water dissolved partially, leaving, however, a considerable amount of white insoluble matter, which did not dissolve when the solution was replaced by a liter of water. Fearing that the lead bromide which served as the starting point of this experiment might have been slightly basic, the experiment was repeated with material which had been crystallized from slightly acid solution. Even here the salt did not give a clear solution, a similar white insoluble residue remaining. Thus, material which surely must have been initially neutral or acid behaved, so far as we could tell, as the fused material behaved. In order to discover whether the insoluble matter is basic bromide or hydroxide, some of it was washed thoroughly, dissolved in nitric acid and treated with silver nitrate. A precipitate of

¹ Baxter and Warren found calcium bromide to be a very efficient drying agent, *THIS JOURNAL*, 33, 340 (1911).

² Richards and Parker, *Proc. Amer. Acad.*, 32, 59 (1896).

silver bromide was produced, indicating the insoluble substance to be a basic bromide. In still another experiment some of the lead bromide which had been prepared from neutral potassium bromide and lead nitrate was dried in a current of hydrobromic acid at a temperature nearly as high as the fusion point. This material also yielded an insoluble residue. Since there seemed, therefore, to be reason to believe that lead bromide fused in an atmosphere containing hydrobromic acid is not basic, the analyses of the fused material were next carried out.

Before doing so, however, it was necessary to prove that during the solution of the bromide in the dilute acetic acid solution no volatile compounds of bromide are lost. About 4 g. of lead bromide were placed in a distilling flask with 400 cc. of water and 5 cc. of acetic acid, that is, ten times as much acetic acid was used as was ever used in an analysis. The solution was distilled and the distillate was collected and tested for bromide with silver nitrate. In the test portion about 0.004 mg. of bromine was found. Since the solution was more concentrated in lead bromide and since far more acetic acid was used than in any of the analyses, and since in practice the solution was never actually boiled while the lead bromide was dissolving, it seemed certain that the danger of losing bromine was negligible.

Even when the lead bromide was dissolved in acidulated water, there remained always a slight black residue, which was never observed when unfused material was dissolved. In later work by Mr. Grover and Dr. Hartmann in this laboratory it was found that this black residue consists in part of carbon formed by the charring of organic impurities, and in part of silicic acid, extracted probably from the quartz dishes. The proportion of this material was diminished when the hydrobromic acid was prepared from the purest bromine as previously described, but no specimen of fused material was ever obtained absolutely free from it. In this research the residue was very carefully examined for lead with negative results, and in the work described in the following paper evidence was obtained as to its real nature. From evidence obtained in the later research it seems probable that the weight of this black residue amounted to about 0.004%. This proportion would raise the observed atomic weight of lead by 0.015 unit in the comparisons with silver only, since it must have been collected and weighed with the silver bromide which is only slightly heavier than the lead bromide.

In order to dissolve the lead bromide, the boat after being weighed was transferred to a large Jena glass flask and was covered with nearly a liter of the purest water, to which about 0.5 cc. of glacial acetic acid was added. The solution was then heated almost to the boiling point until the lead bromide had dissolved. This required several hours. Next a quantity of the purest silver, very nearly equivalent to the lead bromide, was weighed

out and dissolved in nitric acid and this solution also was diluted to a total volume of about a liter. The lead bromide solution was transferred quantitatively to a glass-stoppered precipitating flask, and, both solutions being cold, the silver nitrate solution was slowly poured into the lead bromide solution. The solutions were then thoroughly mixed by shaking and allowed to stand with occasional shaking for a few days. Next the liquid was examined in a nephelometer for excess of bromide or silver, and any deficiency of either was made up by the addition of 0.01*N* silver or bromide solution. Usually the comparison was completed within ten days of the time of precipitation, but in two analyses, 5 and 6, the precipitates were left under the solution for about four weeks longer. No perceptible alteration in end point during this period could be observed. As soon as the exact end point had been found, a slight excess of silver nitrate was added and the silver bromide was washed and collected upon a platinum-sponge Gooch crucible. After being dried for several hours at about 180° the silver halide was weighed. Residual moisture was determined by the loss in weight on fusion in a porcelain crucible, and a correction for solubility of the silver bromide in the wash-water of 0.1 mg. per liter of water was applied.

The silver bromide from one experiment was tested for occluded lead salts by solution in potassium cyanide, reprecipitation with hydrochloric acid, evaporation of the solution and addition of (A) hydrogen sulfide, (B) sulfuric acid. The evidence was negative.

In the first five analyses the hydrobromic acid gas mixture was produced as described above, but since we still feared that the fused salt might be basic, in subsequent analyses the concentration of hydrobromic acid was considerably increased. This was done by using synthetic gas produced as in the apparatus employed by Richards and Hönigschmid in their work upon the atomic weight of calcium.¹ This hydrobromic acid was formed by saturating hydrogen gas with the purest bromine at a temperature in the neighborhood of 44° and passing the mixed gases over hot platinum. The hydrobromic acid gas contained a slight excess of hydrogen. It was dried by fused calcium bromide. During the fusion of the lead bromide a small amount of nitrogen was passed into the apparatus, but even then the concentration of the hydrobromic acid must have been far greater than in the earlier experiments.

The effect of this change in procedure was not to increase, but, on the whole, to diminish slightly the apparent proportion of bromine in the salt, but it is by no means certain that the slight differences were really caused by the change in the process of fusion, since the earlier analyses were naturally subject to the uncertainties of preliminary determinations.

The platinum boat did not remain absolutely constant in weight, but

¹ THIS JOURNAL, 32, 1583 (1910).

lost by amounts varying from 0.1 to 0.3 mg. in each analysis. No correction was applied for the change, which averaged -0.14 mg.

It is obvious that the foregoing data indicate a value for the atomic weight of lead decidedly above the earlier one found by Baxter and Wilson, although that in turn was nearly 0.3 unit higher than the one commonly accepted at the time. Even in the case of an atomic weight as high as that of lead, the difference is larger than the experimental error. The investigation was therefore continued by Mr. F. L. Grover, whose work

with both lead bromide and lead chloride is described in the following paper.

We are very greatly indebted to the Carnegie Institution of Washington for generous assistance in pursuing this investigation.

A REVISION OF THE ATOMIC WEIGHT OF LEAD. THE ANALYSIS OF LEAD BROMIDE AND CHLORIDE.

[THIRD PAPER.]

BY GREGORY PAUL BAXTER AND FRED LESLIE GROVER.

Received March 8, 1915.

CONTENTS.

INTRODUCTION: Part I: THE ANALYSIS OF LEAD BROMIDE. Purification of Reagents; Purification of Lead Nitrate; Preparation of Lead Bromide; Drying of Lead Bromide for Analysis; Analysis of the Lead Bromide; Results and Discussion.

Part II: THE ANALYSIS OF LEAD CHLORIDE. The Purification of Lead Nitrate; The Radioactivity of the Minerals; The Purification of Lead Chloride; The Drying of Lead Chloride; The Neutrality of Fused Lead Chloride; The Analysis of Lead Chloride; Results and Discussion.

Introduction.

The outcome of the investigation described in the preceding paper, that the atomic weight of lead is nearly 207.2, rather than 207.1 as previously found by Baxter and Wilson,¹ led us to pursue the subject further with the greatest care, in order if possible to discover the cause of the difference, and at any rate to come to a definite conclusion as to the real value of the constant in question. In the first place, it was conceivable, in spite of the evidence obtained, that the lead bromide which had been fused in hydrobromic acid was slightly basic. In the second place, recently the apparent relationship of lead to radioactive change has aroused interest as to the identity of lead from different sources, and suggested the possibility that the lead material used by Baxter and Thorvaldson was different from that used earlier by Baxter and Wilson. These points were carefully tested. In the first place, lead bromide was prepared with even greater pains than before, and analyzed. Since this work yielded evidence in accord with the results given in the preceding paper, lead chloride was then investigated anew, with the outcome that essentially the same result was obtained as with the bromide, namely, 207.2.

While this investigation was in progress, the exact value of the atomic weight of lead became of considerable importance in connection with the theory of atomic disintegration of the radioactive elements. According

¹ *Proc. Amer. Acad.*, 43, 365 (1907); *THIS JOURNAL*, 30, 187 (1908).

to the hypothesis of Fajans¹ and Soddy² at least two lead "isotopes" exist, one resulting from the expulsion of five α -particles from radium with an atomic weight 206, the other resulting from the expulsion of eight α -particles from thorium with an atomic weight of about 208.3. If ordinary lead is composed of, or contains, these isotopes, in proportions varying with its origin, then its atomic weight might be expected to vary according to its source. Richards and Lambert³ found that, in accordance with this hypothesis, radioactive lead extracted from radioactive minerals possesses an atomic weight different from that of ordinary lead, and differing also according to the mineral from which it is extracted, a result confirmed by Hönigschmid,⁴ M. Curie⁵ and Soddy.⁶ In order to find out whether ordinary lead is subject to similar variations, seven varieties of inactive lead material from known widely different geographical sources were examined. Not the slightest difference between any of these specimens could be detected so far as analysis of the chloride is concerned. Furthermore these specimens were found to be spectroscopically identical and none of them were radioactive, so far as could be determined. While the evidence thus obtained is by no means final as to the origin of ordinary lead, it certainly is striking that, if common lead is composed either wholly or in part of isotopes, its composition should be essentially constant.

PART I. THE ANALYSIS OF LEAD BROMIDE.

Purification of Reagents.

General reagents were purified by methods found amply satisfactory in the past.

Water.—All the pure water used in this work was prepared by double distillation, once from alkaline permanganate, and once from very dilute sulfuric acid. The condensers were block-tin tubes, fitted to Jena flasks with constricted necks, which served as stills. The connection was made by a water seal, no rubber or cork being used. The water was collected in Jena flasks or non-sol bottles, generally just previous to use.

Ammonia.—The concentrated C. P. reagent was gently boiled in a ground-stoppered flask, and the gas conducted through a glass tube to the surface of the purest water.

Nitric Acid.—Concentrated C. P. nitric acid was distilled through either a quartz or platinum condenser, with rejection of the first two-thirds of the distillate. The last third was collected in a quartz flask. The purity of nitric acid distilled through either platinum or quartz

has been several times investigated in the past, but recently we made this matter the subject of a special investigation,¹ and found no evidence that well cleaned platinum vessels are affected by nitric acid.

Bromine.—Crude bromine was subjected to the following treatment in order to remove chlorine, iodine, and organic matter. Special pains were taken to eliminate the last impurity, because of the difficulty met by Baxter and Thorvaldson in preparing lead bromide free from organic matter. The treatment used was essentially that employed by Baxter, Moore, and Boylston² in an investigation upon the atomic weight of phosphorus.

The crude material was first subjected to distillation from aqueous potassium bromide in order to remove chlorine. About 600 cc. of a 50% solution of commercial potassium bromide were placed in a one-liter distilling flask with a ground stopper, and in the solution was dissolved somewhat over 400 g. of bromine. The side tube of the flask was inserted for some distance in one end of a glass condenser, while the other end of the condenser tube delivered into a Jena flask cooled with ice. With this apparatus the bromine could be distilled from the solution with minimum loss. Three portions of bromine were distilled from the same potassium bromide solution.

Next, one-fourth of the product was converted into potassium bromide by addition to recrystallized potassium oxalate, and the remaining three-fourths of the bromine was distilled from solution in this potassium bromide in the fashion described above. This second distillation, from a bromide which already must have been nearly free from chloride, has in the past been found amply sufficient to remove chlorine. Nevertheless, as will be described, the bromine later received still a third distillation from even purer potassium bromide.

In order to remove organic matter, the bromine was next changed to potassium bromide and fused. All of the twice-distilled bromine was converted into potassium bromide by addition to aqueous potassium oxalate, which had been recrystallized until free from chloride, and the solution was freed from iodine by boiling, with occasional addition of small amounts of the pure bromine. Then the solution was evaporated to dryness, and the salt was fused in a platinum dish. During the fusion a small amount of recrystallized potassium permanganate was added in order completely to oxidize organic matter. Material which had been fused with permanganate had no perceptible odor even while warm, whereas, if the addition of the permanganate was omitted, the salt had a distinct "organic" odor. The treatment with permanganate also must have eliminated any residual iodine. The purification of much of the

¹ THIS JOURNAL, 36, 1088 (1914); *Z. anorg. Chem.*, 87, 353 (1914).

² *Proc. Amer. Acad.*, 47, 585 (1912); THIS JOURNAL, 34, 1644 (1912).

bromine, up to this point, was performed by Mr. M. R. Grose. From this potassium bromide, bromine was prepared as needed by dissolving in water and adding twice-recrystallized potassium permanganate and sulfuric acid which had been heated to fuming with a small amount of permanganate. Only about four-fifths of the bromine was freed from the bromide, so that the product thus received still a third distillation from a very pure bromide. The bromine was always employed in the form of hydrobromic acid.

Hydrobromic Acid.—Hydrobromic acid was used either in the gaseous form, or in solution. It was always synthesized from the purified bromine and pure hydrogen, since this method seemed to offer fewest possibilities for contamination during the process of manufacture. Pure hydrogen was generated electrolytically in a series of cells, each of which consisted of zinc amalgam—hydrochloric acid—platinized platinum¹ (see figure). Hydrogen gas prepared in this way is free from arsine and hydrocarbons.² It contains, of course, hydrochloric acid and water vapor, but these were easily removed by passing the gas through tubes containing fused potassium hydroxide. The gas was charged with bromine in a small bulb, and then was conducted over either platinized asbestos or platinized pumice in a hard glass tube heated to dull redness. The pumice seemed to retain its catalytic power longer than the asbestos. In order to produce the maximum yield, the bromine was kept at about 44° by means of a water bath, since at that temperature the vapor pressure of bromine is about one-half atmosphere. Usually a very slight excess of hydrogen was maintained, so that the resulting gas mixture was nearly, if not quite free from bromine. To prepare hydrobromic acid solution, the gas was conducted into water until acid of nearly constant-boiling composition was obtained. Then the solution was subjected to three distillations through a quartz condenser, the first runnings being discarded in each distillation.

Silver.—Silver was prepared by methods which have frequently been used in the Harvard Laboratories for the purpose. Since the purification of silver has been many times described in some detail, it is necessary only to outline the processes employed. Crude metallic silver was dissolved in nitric acid, and the chloride was precipitated in strongly acid solution with an excess of hydrochloric acid. The precipitate was thoroughly washed, dissolved in concentrated ammonia, and reprecipitated with an excess of nitric acid. Reduction of the chloride by means of sodium hydroxide and sugar followed, and the product, after thorough washing, was fused on charcoal before a blowpipe. The buttons of metal were cleaned by scouring and etching. Then they were dissolved in redistilled nitric acid,

¹ Cooke and Richards, *Proc. Amer. Acad.*, 23, 149 (1887).

² See also Baxter and Hoover, *THIS JOURNAL*, 34, 1657 (1912).

and the metal was again precipitated from neutral solution with ammonium formate, which had been made from redistilled materials. Prolonged washing was necessary before the wash waters were free from ammonia. The product was dried and again fused before a clean blast lamp, in a porcelain crucible lined with very pure lime. This lime was made from calcium oxide and nitrate, both of which had been very carefully freed from foreign metals by crystallization of the nitrate. After being etched with nitric acid, the buttons were purified electrolytically in a cell in which a piece of the purest silver served as cathode, one or more of the buttons as anode, and a nearly neutral solution of one of the buttons as electrolyte. The washed electrolytic crystals were finally fused upon lime boats in a current of pure hydrogen. In order completely to remove adhering lime, the buttons were etched with dilute nitric acid, thoroughly washed with dilute ammonia and water, and then dried by heating in a vacuum to about 400° in a hard glass tube. This specimen of silver is designated Sample I. In many of the experiments, specimens of silver prepared in an identical fashion for other investigations were employed. Sample II was purified by Mr. W. H. Whitcomb,¹ Sample III by Mr. A. C. Boylston,² and Sample IV by Dr. H. C. Chapin.³ Sample I was used in Analyses 6, 7, 9, 10, 11, 12, 16, 32, 34, 35, 36, 37, 38, 39, 40, 42, 44, 45, and 47; Sample II in Analyses 5, 8, 14, 15, 19, and 33; Sample III in Analyses 17, 41, 46, and 48; and Sample IV in Analyses 18 and 43. In Analyses 1, 2, 3, 4, and 13 it is uncertain whether Sample I or II was employed. So far as could be determined by the results of the analyses these four samples of silver were exactly alike. This matter is further considered on page 1058.

Purification of Lead Nitrate.

Since the lead bromide was always made by precipitation from a nitrate solution, the preparation of pure lead nitrate was one of the most important operations. Several methods were used for the purification of the salt: first, electrolysis with a dissolving anode; second, simple recrystallization of the nitrate; and third, precipitation of sulfate or chloride. In fact the second method was used also in conjunction with the first and third.

For the electrolytic purification a cell was used consisting of an anode of crude sheet lead, a platinum cathode, and, as electrolyte, a nearly saturated slightly acid solution of lead nitrate. The crystals of metallic lead which formed on the cathode during electrolysis were frequently removed by means of a glass rake, washed thoroughly, and centrifugally

¹ For an investigation upon the atomic weight of neodymium, not yet published.

drained in porcelain Gooch crucibles. The crystals rusted rapidly, hence they were subsequently reduced by fusion in a current of illuminating gas. Unglazed porcelain boats were filled with the crystals, and placed in an electrically heated porcelain tube. The illuminating gas was scrubbed with wet glass wool, and partially purified and dried by concentrated sulfuric acid and fused sodium hydroxide. Since the metal adhered strongly to the porcelain, the boat was then heated in the air, and the metal poured into a wooden mould.

The progress of the purification of this material was followed by photographing the ultraviolet spectrum of the lead spark by means of a Féry quartz spectrograph. In order to produce electrodes, the lead was melted in a hard glass tube or porcelain crucible, and drawn up into glass capillary tubes. The original sheet lead was found to contain a small amount of copper and a trace of silver. After the first electrolysis the copper and silver lines appeared in the spectrum in almost undiminished intensity. A second electrolysis followed. In this case the cathode was a small piece of the once electrolyzed lead, and the anode larger pieces of the same material. The electrolyte was made from the once purified lead by solution in nitric acid and crystallization of the nitrate. Since the greater part of the copper was contained in the mother liquor, the crystals were dissolved to form the electrolyte. During this second electrolysis, but not during the first, the anode was enclosed in a clean cotton bag to prevent the anode slime from contaminating the crystal deposit. The product of the second electrolysis was washed, dried and fused, as described above. Spectrographic examination of the twice electrolyzed material showed that copper and silver were still contained in the metal, although the proportions of these impurities may have diminished slightly.

With the hope that the transfer of silver and copper from anode to cathode would proceed less readily with a chloride electrolyte, a portion of the once electrolyzed material was subjected to a second electrolysis through a hot saturated solution of lead chloride containing a small amount of hydrochloric acid. The electrolytic crystals were somewhat larger than those obtained from the cold nitrate process. They were washed and dried as before, and spark electrodes were made from a portion of the product. While silver and copper lines were still plainly visible in the spectrum, the diminution in the proportions of these metals was greater than in the nitrate electrolysis. Since, however, the electrolytic purification seemed, on the whole, unsatisfactory, no further attempts were made to purify the material in this way.

None of this electrolyzed material was used directly for the preparation of lead bromide, but it was first subjected to crystallization as nitrate. About 170 g. of lead which had been twice electrolyzed from nitrate were dissolved in nitric acid, which had been distilled in quartz, and the excess

of acid was removed by evaporating almost to dryness. The residue was dissolved in water and evaporated in a platinum dish on an electric stove nearly to the saturation point. Instead of allowing the salt to crystallize by cooling, it was precipitated by adding a large quantity of redistilled nitric acid to the hot solution, which was then allowed to cool. The relatively pure crystals were centrifugally drained in platinum Gooch crucibles, and were washed with several portions of concentrated nitric acid. The salt was then recrystallized twice more in the same way. In order to determine whether purification was effected in this process, metallic lead was made from a portion of the nitrate by electrolysis upon a platinum cathode, and the electrolytic crystals were washed and converted into spark electrodes. In the ultraviolet spectrum of this metal no copper or silver lines could be seen, nor were there any other lines visible which were not observed in all of the lead samples which we prepared. This sample of lead nitrate is designated Sample A.

Sample B of lead nitrate was made in exactly the same way from metal which had been electrolyzed once through the nitrate, once through the chloride. In order to obtain some evidence as to the proportions of impurities in the original lead, the mother liquors from the three crystallizations of the nitrate of Sample A were freed from the greater part of the lead by evaporating with an excess of sulfuric acid, diluting, and adding alcohol. To the filtrate from the lead sulfate, ammonia was added in excess, and the very slight precipitate, apparently iron in large part, was removed by filtration. The filtrate was evaporated to small bulk, and after precipitation with an excess of potassium hydroxide, the copper and silver oxides were collected on a filter paper, ignited, and weighed. From the original 170 g. of lead nitrate, 0.0088 g. of copper oxide and silver were obtained, which indicates a percentage of silver and copper together of only 0.004. The electrolytic metal from which Sample B was made was found in the same way to contain less than 0.003% of silver and copper.

Another sample of lead nitrate was purified simply by repeated crystallization. About one kilogram of commercial salt was dissolved in water and the solution was filtered through a platinum-sponge Gooch crucible. Then the solution was evaporated, and the salt was crystallized four times in Jena vessels with addition of a large excess of redistilled nitric acid, as previously described. After the fourth crystallization, the material was transferred to platinum vessels, and recrystallized three times more, with a second filtration through platinum-sponge between the sixth and seventh crystallizations. All the nitric acid was distilled in quartz, and the crystals were centrifugally drained and rinsed with nitric acid. This material is designated Sample C.

Sample D of lead nitrate was purified first by Dr. J. W. Shipley, by precipitating lead chloride from a solution of the commercial nitrate,

converting the thoroughly washed lead chloride into sulfide by suspending the chloride in water and saturating with well scrubbed hydrogen sulfide gas, and finally dissolving the sulfide in nitric acid. The nitrate was crystallized once in glass, and then was subjected to three additional crystallizations in platinum. The solution of the nitrate was filtered through platinum sponge after the first crystallization.

The ultraviolet spark spectra of Samples C and D were found to be identical with those of Samples A and B. The geographical origin of these samples of lead is unknown to us, but it is highly probable that the sheet metal, at any rate, is of American origin, although the nitrate may have been either American or European material. This question of origin will be discussed more fully in a later portion of this paper (page 1048).

Preparation of Lead Bromide.

To prepare lead bromide, pure lead nitrate was dissolved in water in a quartz dish, and a slight excess of the purest hydrobromic acid solution was added. The precipitated bromide was collected on platinum Gooch crucibles without mat of any sort, before any free bromine appeared in the mother liquors, and was centrifugally drained and washed. On account of the low solubility of lead bromide, crystallization of the product from water was avoided by the device described in the preceding paper, of dissolving the lead bromide in hot constant-boiling hydrobromic acid in a quartz dish, and reprecipitating the salt by the addition of water and cooling. During the solution of the lead bromide in hydrobromic acid for the first time, bromine was set free, presumably by traces of included nitric acid. Therefore, before draining the crystals in platinum, they were thoroughly washed by decantation with ice-cold water. All of the lead bromide analyzed was recrystallized in this way at least three times, and Sample CD, which was a mixture of Samples C and D, was further crystallized three times more, that is, six times in all. The purified material was preserved in platinum over fused potassium hydroxide in a desiccator. Since lead bromide darkens in the light,¹ the salt was protected from light so far as possible. The various preparations of lead bromide are designated by the letter corresponding to the nitrate samples from which they were made.

Drying of Lead Bromide for Analysis.

The lead bromide was prepared for analysis by fusion in an atmosphere charged with hydrobromic acid gas, after the salt had been dried as far as possible in a vacuum desiccator over fused potassium hydroxide. Lead bromide which has been fused in this way, when treated with water yields a considerable amount of insoluble basic salt. Evidence that the salt which has been fused in hydrobromic acid is initially neutral,

¹ Norris, *Ann. Chem.*, 117, 189 (1861).

and that the basic salt is formed by hydrolysis during solution has already been presented in the preceding paper, and in our work with lead bromide no new evidence contradictory to this point of view was obtained. In fact, in two experiments (Analyses 5 and 11) where the lead bromide was initially very moist when the drying commenced and hydrolysis therefore was to be expected if it occurs at all during the drying, the fused material proved identical in composition with the other specimens. The difficulty was avoided in the analytical work by dissolving the salt in water which had been made slightly acid with nitric acid. Even under these conditions no evidence could be obtained of loss of either hydrobromic acid by evaporation, or of bromine by oxidation. As in the previous research, the agreement of the analyses of different preparations is valuable confirmation of the claim that the fused material was strictly neutral.

Another possibility which we considered was that of dissociation of the salt into either metal or sub-bromide with loss of bromine. A decomposition apparently occurs when lead bromide is exposed to light, although heating or even fusion in a neutral atmosphere gives no evidence of dissociation. The point was tested, however, by experiments in which the lead bromide was fused in hydrobromic acid containing free bromine, as well as in hydrobromic acid containing considerable hydrogen. So far as the appearance of the preparations and the results of the analyses are concerned, absolutely no difference could be detected.

The apparatus for fusing in hydrobromic acid gas was modified considerably from that used previously, enough so that it seems worth while to show a detailed diagram of the apparatus (see figure). Hydrogen was evolved by means of electrolytic generators, A, each consisting of the cell zinc amalgam—hydrochloric acid—platinized platinum (see page 1030). These generators were constructed entirely of glass. The gas was purified and dried by passing through several tubes containing fused potassium hydroxide B, and was then partly saturated with the purest bromine in a flask C, which was kept at a temperature of 44° or below. The hydrogen and bromine were combined in a hard glass tube D, containing either platinized asbestos or platinized pumice, heated electrically to dull redness, and the resulting hydrobromic acid was collected in constant-boiling hydrobromic acid solution in the flasks G and H, until the solutions in the two flasks were saturated at room temperature. As the saturation point was approached, the hydrobromic acid gas which escaped from the flask unabsorbed, was collected by being conducted into water through the outlet I. The small amount of bromine, which occasionally accompanied the hydrobromic acid, and which was dissolved in the fuming solution, was eliminated by introducing a small amount of very pure iron into the flasks G and H through the side arms. The resulting solution of ferrous bromide retains very effectively every trace of free bromine,

and is far more effective than a tube of dry ferrous bromide. The iron used for the purpose was free from every impurity except possibly platinum. It was obtained by reduction of the purest ferric oxide by Baxter and Hoover¹ in a determination of the atomic weight of iron in this way. Nitrogen was charged with hydrobromic acid gas by passing through the fuming solution, through the stop-cock F, and the gas mixture was dried by means of fused calcium bromide in the tube J, before being led into the fusion apparatus V. While fused calcium bromide is not a perfect drying agent, Baxter and Warren² have found that a liter of gas passed over this substance at 25° retains only 0.0002 g. of moisture. A current of hydrogen charged with hydrobromic acid could be produced by passing hydrogen through the cold bromine, then over hot platinum, and finally through the fuming hydrobromic acid solution and the calcium bromide tube, while a current of hydrobromic acid and bromine was obtained by warming the bromine flask considerably above 44°, at which temperature the bromine has a vapor pressure of one-half atmosphere, then through the catalysis tube, and through a drying tube containing calcium bromide. This latter arrangement, which was used only a few times, is not shown in the diagram.

Nitrogen was made by the Wanklyn process, by charging air with ammonia in a gas washing bottle, I., filled with concentrated ammonia solution (sp. gr. less than 0.92). In order to reduce the oxygen, the gas mixture was passed through an electrically heated tube, M, filled with copper gauze, and the excess of ammonia was absorbed in dilute sulfuric acid in the two gas washing bottles N. The hydrogen formed by dissociation of the excess of ammonia was oxidized in the tube O, containing hot copper oxide. The nitrogen was now purified and dried in the six towers P. The first one contained beads wet with a concentrated solution of potassium hydroxide. The other five contained concentrated sulfuric acid, which had previously been heated to fuming with a very small amount of potassium dichromate. Residual moisture was absorbed in a tube, R, containing phosphorus pentoxide which had been resublimed in a current of oxygen. Finally, last traces of oxygen were absorbed by hot copper in the hard glass tube S.

Air was purified and dried in the towers T, two of which contained beads wet with silver nitrate solution, one, fused potassium hydroxide, and two, concentrated sulfuric acid, and in the phosphorus pentoxide tube U.

The hydrogen, nitrogen, hydrobromic acid, and air apparatus was constructed entirely of glass. Joints were either fused or ground, the necessary flexibility for detaching the different parts being afforded by numerous glass grids. The ground joints and stopcocks through which the bromine

¹ THIS JOURNAL, 34, 1657 (1912).

² *Ibid.*, 32, 342 (1910).

or hydrobromic acid passed were kept clean and dry, but many of those used for nitrogen, air, and hydrogen were lubricated with a small amount of soft paraffin.

When the lead bromide was fused in either nitrogen or hydrogen charged with hydrobromic acid, either a platinum or a quartz boat was used, but when the fusion atmosphere contained bromine, of course a quartz boat was employed. The boat containing the partially dried lead bromide was placed in a quartz tube which formed part of the usual form of "bottling apparatus"¹ (V in figure). After the air had been swept out with a slow current of pure nitrogen, and this in turn by the fusion atmosphere containing hydrobromic acid, the salt was gently heated with an electric coil or with an aluminum block furnace, in order to drive off as much as possible of the residual moisture before fusion. The temperature was then raised by means of a "Ni-chrome" sleeve, until the salt was fused. As soon as the salt had solidified, the fusion atmosphere was displaced with pure nitrogen, and this finally with pure dry air, and the boat and contents were transferred to the weighing bottle, in which they were to be weighed, without exposure to the outside air. While the hydrobromic acid was being displaced by nitrogen and air, a portion of the gas was sent back through the tube I, in order to prevent possible contamination of the atmosphere of the bottling apparatus with hydrobromic acid while the boat was being transferred to the weighing bottle. The weighing bottle with its contents was then placed in a desiccator, and left near the balance for some time before being weighed. Neither the platinum nor the quartz boat was appreciably attacked in these experiments.

Analysis of the Lead Bromide.

The fused and weighed lead bromide was dissolved and first compared with a weighed, very nearly equivalent, quantity of the purest silver, then the precipitated bromide was collected, dried, and weighed. This process is identical with the one which has been found very successful, both in the Harvard and in other laboratories. Very few deviations from the ordinary method of procedure were made. This method gives a comparison of the atomic weight of lead with those of silver and bromine, but any subsequent change in the standard of comparison, silver, will necessitate a change in the same proportion in that of lead.

Although lead bromide is not so soluble in water as lead chloride, yet a liter of water at ordinary temperatures will dissolve about 9 g. of salt. Solution of the fused material, however, takes place slowly, and we found it highly desirable to conduct the solution in nearly boiling water, as has been explained in the previous paper. When neutral lead bromide is dissolved in water, the salt is partially hydrolyzed, with precipitation of a basic bromide. In the earlier work by Baxter and Thorvaldson,

¹ Richards and Parker, *Proc. Amer. Acad.*, 32, 59 (1896).

this hydrolysis was prevented by adding a considerable amount of acetic acid. Since, however, lead acetate is a slightly dissociated substance, we were somewhat concerned for fear this salt might be occluded by the silver bromide, and therefore we decided to substitute for acetic acid a quantity of a strong acid of equivalent acidity. At first, an exactly known amount of hydrobromic acid was used, but very shortly we discovered that a small amount of even nitric acid could be employed without the loss of a perceptible amount of either hydrobromic acid or bromine. The latter point was tested very carefully by distilling solutions of lead bromide containing nitric acid, collecting the distillate in alkali, and after evaporation, testing the solution for bromide.

In one experiment about 4 g. of lead bromide were dissolved in a liter of water, and 0.2 cc. of concentrated nitric acid was added. The solution was boiled in a Jena flask, fitted to a quartz condenser, and the distillate was collected in dilute ammonia. After 300 cc. of distillate had passed over, the ammoniacal solution was evaporated upon an electric stove to a volume of about 10 cc., and the solution was tested for bromide by adding a small amount of silver nitrate. Comparison with a standard solution of bromide in a nephelometer showed only 0.01 mg. of bromide in the solution. A repetition of the experiment, using 5 g. of lead bromide and 2.0 cc. of concentrated nitric acid, yielded a distillate containing 0.03 mg. During the solution of lead bromide for analysis the conditions were far less favorable for the liberation of hydrobromic acid and bromine, because, in the first place, much less nitric acid was found necessary to prevent formation of basic salt, and in the second place, while the solution occasionally was heated barely to boiling, very little vapor actually escaped from the solution flask. Additional experiments were made in order to find out how much nitric acid really was necessary in order to liberate an appreciable amount of bromine. For this purpose, the above experiments were repeated, using gradually increasing amounts of nitric acid. To a solution of 4 g. of lead bromide in 1200 cc. of water, nitric acid was added in successive portions, and the solution was distilled into a solution of halogen-free sodium carbonate. Each portion of distillate consisted of 25 cc., and before the succeeding distillation was carried out, the liquid distilled was replaced by an equal amount of water. The separate distillates were acidified with nitric acid, and after silver nitrate solution had been added, nephelometric comparisons were made with solutions of known bromide content.

Nitric acid added (cc.).....	0.10	0.60	2.10	4.65	9.65
Bromide found (mg.).....	0.000	0.000	0.005	0.015	0.150

These figures show conclusively that error from evaporation of either hydrobromic acid or bromine could not possibly have taken place during the solution of the lead bromide for analysis.

The method of carrying out the solution was as follows: The boat containing the weighed sample of lead bromide was transferred to a two-liter Jena glass Erlenmeyer flask, containing about one liter of the purest water. The weighing bottle was rinsed with hot water and the rinsings added to the flask. A column of seven bulbs, ground into the neck of the flask, was inserted to catch any possible spray if the solution happened to boil, and to serve as a reflux condenser. Finally two drops (0.10 cc.) of redistilled nitric acid were added. The flask and its contents were then heated over an electric stove, until solution was complete. This required several hours. In fact, the solution was generally heated over night.

Even after the lead bromide was dissolved, there still remained, usually floating on the surface of the solution, a small amount of black material. Preliminary investigation, both by Dr. Thorvaldson and ourselves, showed that the residue contained neither platinum nor lead. Furthermore, the platinum boat itself remained practically constant in weight. In a few preliminary experiments, this residue was neglected, but in most of the experiments, the weight of the black residue was determined by filtration upon a weighed platinum-sponge Gooch crucible. Similar material was found by Baxter and Thorvaldson, as described in the previous paper, and the nature of the residue has been discussed in a recent paper by Baxter and Hartmann,¹ where evidence is presented which shows it to consist of carbon and silica. In the course of our experiments we were able to make a quantitative analysis of a portion of material. The Gooch crucible containing the residue from several analyses was gently ignited. The black appearance of the residue disappeared with obvious combustion (sparks), confirming the conclusion that a portion of the residue is carbon. A white residue, presumably of silica, could still be seen. This was carefully removed by gently rubbing with a clean finger, and the crucible was carefully dried and reweighed.

Original weight of crucible.....	24.05098
Weight of crucible + residue.....	24.05200
Weight of residue.....	0.00102
Weight of crucible after ignition.....	24.05167
Weight of carbon.....	0.00035
Weight of cleaned crucible.....	24.05100
Weight of silica.....	0.00067

It is interesting to see that about one-third of the residue was carbon, and two-thirds silica. The carbon undoubtedly originated largely in dust and lint from the room, but possibly in part in residual organic matter in the reagents in spite of the pains taken to prevent the difficulty. It seems likely that the silica resulted from attacking of the quartz dish in which the lead bromide was recrystallized. Whatever the origin of

¹ THIS JOURNAL, 37, 113 (1915).

the residue, it could have had little effect upon the final result, because the weight was determined in each separate experiment, and because the proportion of residue was very small. In thirty-six experiments with lead bromide and chloride, we found on an average only 0.004% of residue. The method of determining the residue in each separate experiment seemed far preferable to applying an average correction to the results, because the percentage varied from almost nothing to nearly 0.01% in a few experiments. In Analyses 1 and 2 there was no visible residue, and no filtration was therefore carried out. These two analyses, nevertheless, gave results essentially identical with those in which the residue was considerable. Since the silver bromide has very nearly the same weight as the lead bromide from which it is obtained, and since the black residue, if not determined, would be collected and weighed with the silver bromide, neglecting the residue would affect the comparisons with silver only, which would then yield results a little more than 0.01 unit too high for the atomic weight of lead.

In filtering the solution of lead bromide, the thistle-tube holding the weighed platinum-sponge crucible was inserted in the upper tubulature of a large bell-jar, and the solution was caught in a three-liter precipitating flask. The solution came in contact only with glass, and was caught in such a way that spattering could not possibly have taken place. After the filtration of the solution, the platinum mat was very thoroughly washed with a large volume of warm water, and the crucible was dried over an electric stove at about 250° for half an hour. It was easily shown that the carbon residue did not oxidize during the drying, by reheating the crucible over a long period and reweighing. Furthermore, the platinum mat remained undissolved by the slightly acid solution of lead bromide. One crucible showed a gain in weight after cleaning of 0.00007 g. during six filtrations, and another a gain of 0.00002 g. during five filtrations.

Before precipitation, the solution of lead bromide was diluted until less than 0.02 *N*. Usually this concentration was reached during the washing of the crucible. When the corrected weight of the lead bromide had been found, a quantity of pure silver, very nearly equivalent to the lead bromide, was carefully weighed out. This silver consisted almost entirely of one or two large buttons, but the final adjustment of the weight was secured with tiny electrolytic crystals which had been heated to 500° in a vacuum. The silver was dissolved in a flask provided with a column of bulbs to prevent loss by spattering, but effervescence during solution was prevented by using a fairly concentrated solution of nitric acid, and by heating very gently. As soon as the metal had disappeared, the solution was diluted to about 200 cc., and heated until the nitrous acid formed during the solution of the silver had been destroyed. Then

the solution was further diluted in the dissolving flask until the concentration was no higher than 0.03 *N*.

In precipitating the silver bromide, generally, because of convenience, the silver solution was added to the bromide solution, although in a few instances the reverse method was employed, in order that if occlusion of either bromide or silver occurred it might be detected. That slight occlusion was likely to take place was obvious from the fact that during the early precipitations, where the concentrations of the solutions were somewhat higher than those given above, material apparently was extracted from the precipitate by long standing. For this reason, too, especial pains were taken during precipitation to agitate the mixed solutions thoroughly.

The silver nitrate solution was added to the bromide solution slowly with continual gentle agitation. At the end of the precipitation the flask was closed with its glass stopper, and gently shaken for a very short time. Then it was allowed to stand with occasional shaking for a week, before the supernatant liquid was tested in a nephelometer for excess of bromide or silver. Portions of 25 cc. of the clear liquid were transferred to test tubes, and treated, in one case, with a cubic centimeter of 0.01 *N* bromide; in the other, with the same amount of 0.01 *N* silver nitrate. After thorough stirring, they were occasionally examined in the nephelometer until the ratio of the opalescence in the two tubes became constant. If an excess of either bromide or silver was found, and this was usually the case, the deficiency was made up by adding 0.01 *N* solutions to the main solution in the flask, and the solution was shaken and again allowed to stand before being tested. The process was continued until the solution contained equivalent amounts of bromide and silver. At this point, owing to the slight solubility of silver bromide, the test portions remained very nearly clear after the addition of the bromide and silver solutions. In a few analyses the end point seemed to change very slightly with time, indicating that occluded or entangled matter was being slowly leached from the precipitate. This change in the end point was at the worst only a matter of a few tenths of a mg., and came to an end within two or three weeks. In all the analyses testing was continued until we were sure that no further change was occurring.

As stated above, in three analyses, Nos. 10, 11, and 13, the bromide solution was poured into the silver nitrate solution. The results of these analyses were no different from the results of those precipitated in the reverse fashion.

The precipitation of the silver bromide was made in a room illuminated only with red light, and during the subsequent manipulations even diffused white light was never allowed to fall upon the precipitate for more than an instant.

As soon as the exact end point had been determined, 0.02 g. of dissolved silver nitrate were added for each liter of solution, and after standing for a short time, the supernatant liquid was poured through a large weighed platinum-sponge Gooch crucible. The precipitate was washed ten times by decantation with a solution containing 0.01 g. of silver nitrate per liter, and once or twice with chilled water, and was transferred quantitatively to the crucible with ice-cold water. The crucible and contents were dried at 160° for about 15 hours in a well ventilated electric oven, and then, after being allowed to reach the temperature of the balance room in a desiccator, were weighed. The main mass of precipitate was transferred to a small porcelain crucible, which was weighed with its cover, and then, after being heated above the fusing point of the silver bromide, was weighed again. The loss in weight was assumed to represent moisture retained by the silver bromide. In accordance with the results of previous similar experiments by others, the silver bromide was never found to contain more than 0.006% of residual moisture, the average proportion being 0.003%. The filtrate and the silver nitrate wash water were assumed to contain no dissolved silver bromide, since the solubility of silver bromide, even in pure water, is only 0.1 mg. per liter at room temperature. Furthermore, since the pure water used in the rinsing and transference of the precipitate was previously chilled, the amount of silver bromide thus lost must have been very small indeed, judging from the diminution in the solubility of silver chloride with the temperature. Since the volume of the aqueous washings was only a few hundred cc., no correction is applied for dissolved silver bromide.

The precipitating flask was rinsed with a small amount of distilled ammonia. These rinsings were diluted to 250 cc., and the bromide content was determined in a nephelometer by adding silver nitrate solution, and comparing with standard solutions of bromide. As a rule, about 0.1 mg. was found in this way.

All weighings were made upon a No. 10 Troemner balance, used only for exact work. The atmosphere of the balance case was partially dried by solid potassium hydroxide. In order to dissipate electrostatic charges upon the objects weighed, the balance case also was provided with a small amount of crude radium bromide.

The gold plated weights were standardized to hundredths of a milligram by the Richards¹ method.

All weighings were made by substitution for counterpoises as nearly as possible like the objects weighed in shape, volume, and material, except in the case of the small platinum crucible used in collecting the black residue, which was substituted for weights.

Results and Discussion.

Before the results recorded in the preceding table were obtained a preliminary series of determinations was carried out. In these analyses no attempt was made to collect and determine the black residue. Furthermore, several were subject to other uncertainties. The results varied from 207.08 to 207.22, with an average of 207.16. Since these determinations were comparable with those made by Dr. Thorvaldson, whose results are recorded in the preceding paper, it seems unnecessary to give further details. After the procedure had been mastered and various sources of error had been discovered and eliminated, the foregoing "final" series was carried out with the purest materials. All analyses which reached the stage of precipitation are recorded.

The agreement of the various determinations in each series is very satisfactory, when the high atomic weight of lead is taken into consideration. In the comparisons with silver the extreme values differ by 0.08 unit, corresponding to 0.0006 g. of silver for a five gram portion of lead bromide, but except for Analyses 3 and 4, the difference is 0.05 unit, corresponding to 0.0004 g. of silver. In the determination of the silver bromide the agreement is almost as good. Analysis 31 diverges widely from all the others in the series, but, since in this experiment contamination of the silver bromide with glass chips was suspected, the result of this experiment is omitted in computing the average.

In comparing the two series, it can be seen that the titrations against silver give a slightly higher result than the experiments where the silver bromide was weighed. This indicates that for a given amount of silver used, too much silver bromide was obtained, as the following table shows:

Analyses.	Ag : AgBr.	Analyses.	Ag : AgBr.

² Baxter and Hines, *Am. Chem. Jour.*, 31, 224 (1904).

³ Determined in this laboratory by Mr. C. F. Hawkins. Not yet published.

Baxter¹ has already found the probable value of the ratio $\text{Ag} : \text{AgBr}$ to be 0.57445.

This apparent excess in weight of the silver bromide may have been due either to occlusions by the precipitated silver bromide or to contamination from the ground stoppers of the precipitating flasks, which necessarily were opened several times. The former explanation is less probable, for several of the silver bromide precipitates were very carefully tested for lead with negative results, by solution and reprecipitation, and examination of the mother liquor. With regard to the latter difficulty, every precaution was taken to avoid grinding during the insertion and removal of the stopper, and before using the flask the ground surfaces were made as smooth as possible by wet grinding. In any case the uncertainty in the average of Series I and II is no greater than 0.01 unit.

It is also interesting to compare the results obtained with different specimens of lead bromide, as well as the effect of varying the fusion atmosphere.

So far as can be told the variations in these results are wholly accidental.

PART II. THE ANALYSIS OF LEAD CHLORIDE.

Because the outcome of the foregoing work as well as of that of Baxter and Thorvaldson indicates a distinctly higher figure for the atomic weight of lead than the value obtained by Baxter and Wilson by the analysis of lead chloride, it became highly important to repeat the work upon lead chloride. At about this time we were informed of the results of Richards and Lambert's analyses of radioactive lead chloride, which indicate a considerably lower value for the radioactive material than for ordinary lead. Thus the question as to whether common lead always possesses the same atomic weight immediately became a vital one. We decided

¹ *Proc. Amer. Acad.*, 42, 201 (1906); *THIS JOURNAL*, 28, 1322 (1906).

² This is the result of one analysis only.

³ In the only analysis in which the silver bromide was collected, contamination of the precipitate was suspected (Analysis 31).

therefore to combine with the investigation of lead chloride the comparison of lead material from different geographical sources. Lead ores were secured from different parts of the United States, from Germany, and from New South Wales, and from these minerals pure material was prepared in essentially the same way in every case. The ores were either nearly pure galena or cerussite in all but one instance. Radioactive minerals in particular were avoided in order to eliminate uncertainty from the possible presence of radioactive lead.

The Purification of Lead Nitrate.

In order to provide a cross connection with the bromide work, one specimen of lead nitrate which had been used in preparing the bromide was also employed as a source of lead chloride. This specimen was Sample D, which had been made from commercial lead nitrate by precipitation of lead chloride and many crystallizations as lead nitrate (see page 1033).

Sample E was prepared from large pieces of clear cerussite from the British Broken Hill Mine, New South Wales, Australia. After solution of the mineral in an excess of nitric acid, an insoluble residue was removed by filtration through an asbestos mat, and the filtrate was evaporated until lead nitrate began to separate. As soon as the solution was cold the mother liquor was poured off and the crystals were centrifugally drained and washed several times with nitric acid. The product was then four times crystallized in quartz, by solution in hot water and precipitation with nitric acid as previously described (see page 1033). Again the crystals were dissolved, and the solution was filtered through a platinum sponge crucible, held in a platinum thistle tube, into a platinum dish, and the salt was three more times crystallized in platinum. Evidence that the material was amply pure before the process was complete was obtained by preparing metallic electrodes from a portion of the five times crystallized material and photographing the spark spectrum. No lines could be seen which were not produced also by the pure specimens of lead prepared previously.¹

A well crystallized specimen of galena from Joplin, Missouri, U. S. A., served as the source of Sample G. A few adherent crystals of zinc blende were mechanically dislodged and the galena was crushed in a large iron mortar. The powder was then digested hot with an excess of 5 *N* nitric acid, and the residue of sulfur, lead sulfate and undecomposed galena was removed by filtration. Since the supply of material was ample the residue was rejected. The filtrate was evaporated until lead nitrate began to separate, and was allowed to cool. After centrifugal separation and rinsing, the crystals were dissolved in water and the solution was filtered

¹ Although Richards and Lambert found the spectrum of radioactive lead to be indistinguishable from that of common lead, there is no reason to expect that ordinary impurities could not be detected in this way.

through an asbestos mat to remove traces of lead sulfate. Four crystallizations in quartz and two in platinum, with intermediate filtration through platinum sponge, followed. The spectrum of metal prepared from the four times crystallized salt was found to show no sign of foreign metals.

A second specimen of cerussite from Wallace, Idaho, U. S. A., was purified exactly as Sample E, except that the nitrate was crystallized four times in platinum vessels, instead of seven times. At this point a spectrographic examination failed to bring to light any metallic impurity. This was designated Sample H.

The three foregoing minerals were all obtained from the Harvard Mineralogical Museum.

Through Dr. F. Krantz of Bonn, Germany, a third specimen of cerussite and one of galena, of guaranteed German origin, were secured. The cerussite was obtained from Commern in the Eifel Mountains, Rhenish Prussia. It was purified exactly as Sample H and the final product was tested for impurities spectrographically with negative results. This specimen is designated Sample I.

Argentiferous galena from Grube Holzappel, Nassau, was converted to nitrate by digestion with nitric acid and the nitrate was four times crystallized in platinum. When metal prepared from this purified nitrate was tested spectrographically, the two strong silver lines of wave lengths 3280 and 3383 were visible, although faint, showing that where lead is badly contaminated with silver even more prolonged purification by crystallization of the nitrate is necessary than was here employed. In order to obtain some idea of the proportion of the impurity, about 1 g. of this nitrate was dissolved in water and, after the addition of a small amount of bromide, the solution was examined in a nephelometer. The very slight opalescence was estimated by comparison with a standard to represent about 0.001 mg. of silver, *i. e.*, 0.0002%, an entirely negligible proportion. This nitrate was not further crystallized, but after it had been converted to chloride and the chloride three times crystallized, electrodes prepared from the final material gave not the slightest indication of silver. This was Sample F.

Dr. M. L. Hartmann very kindly furnished material for Sample J. The mineral consisted of yellow wulfenite (PbMoO_4) and red vanadinite ($\text{Pb}_5(\text{VO}_4)_3\text{Cl}$), and had been collected by Dr. Hartmann in the Tucson mountains, Arizona, U. S. A. The crushed mineral was boiled with 6 N nitric acid for some hours and a curdy, yellow precipitate together with an insoluble residue was removed by filtration. When the filtrate was evaporated to small volume and allowed to cool, lead nitrate and a curdy precipitate separated. The latter was removed in suspension by washing the lead nitrate with concentrated nitric acid. The nitrate was dissolved, filtered and crystallized twice in Jena glass and, after filtration through

platinum sponge, three times in platinum. No impurities could be detected spectrographically.

Through the kindness of Professor E. P. Kohler a specimen of galena was obtained from Metalline Falls, Washington, U. S. A., where it occurs in glacial boulders. During the treatment of the mineral with nitric acid so much lead sulfate was produced that the latter substance was recovered by boiling with sodium carbonate and solution in nitric acid. The combined material was crystallized once in glass and four times in platinum. In the spectrum of this material the silver lines were very faintly visible, although when tested with bromide in a nephelometer, no opalescence could be detected. Judging from our experience with Sample F, the proportion of silver could not have been as much as 0.0001%, a proportion which surely must have been eliminated during the three crystallizations as chloride. This specimen is Sample K.

The Radioactivity of the Minerals.

All seven minerals were carefully tested for radioactivity in a quantitative gold leaf electroscope. The natural leak of this electroscope was increased forty times by the black oxide of uranium, while no one of the substances examined increased the leak by an amount that could be detected. Since Richards and Lambert found the radioactive chloride to be several times as active as uranium oxide where the difference in atomic weight amounted to about half a unit, the sensitiveness of the tests for radioactivity was ample for the purpose.

The Purification of Lead Chloride.

Lead chloride was prepared from the purified lead nitrate by precipitation with hydrochloric acid and crystallization of the product. The latter process served to remove not only traces of nitrate included during the precipitation, but also any metallic impurities which might have escaped elimination in the nitrate crystallization. The difficulties due to isomorphism make it desirable in the preparation of salts of a pure metal to crystallize in at least two different forms. As has already been stated, the traces of silver retained by the nitrate of Samples F and K were effectually eliminated in the chloride crystallization.

About 75 g. of nitrate were dissolved in water and the solution was filtered through platinum sponge into a quartz dish. Constant boiling hydrochloric acid which had been freshly distilled through a quartz condenser was then slowly added, with constant stirring, until an excess was present. Chlorine was never freed in the mother liquor. After the precipitate had settled, it was thoroughly washed by decantation with chilled water and was drained in a platinum centrifugal apparatus. The last wash waters, when tested with diphenylamine, were found to be essentially free from nitrate. The salt was next recrystallized either from water or,

because salt crystallized from water was subsequently found to be basic, from very dilute (0.006 *N*) hydrochloric acid, in platinum vessels. The salt was heated to boiling with the solvent in a large platinum still, and, when the solution was nearly saturated, it was poured into a large platinum dish and was cooled with ice. The mother liquor was used to dissolve fresh portions of the salt until all had been recrystallized. Every sample was three times recrystallized except Samples D₂ and E₂, which were twice recrystallized.

The Drying of Lead Chloride.

After preliminary drying in a vacuum desiccator over fused potassium hydroxide the salt was finally fused in a current of dry hydrochloric acid gas. Experiments described later showed that in the desiccator the moisture content was reduced to a few hundredths of a per cent.

The apparatus for fusing the salt has been used for some years for a similar purpose. Hydrochloric acid gas was generated by dropping concentrated sulfuric acid into fuming hydrochloric acid solution, and was scrubbed and dried by passing through five towers containing beads moistened with concentrated sulfuric acid. All the sulfuric acid previous to use was heated to fuming. Nitrogen was prepared by the Wanklyn process as previously described in this paper, except that the small amount of hydrogen resulting from the catalytic decomposition of the ammonia was not removed. Air also was purified and dried as previously described.

The fusion of the salt was conducted in a platinum or quartz boat in a quartz tube which formed part of a bottling apparatus. After the salt had been gradually heated in a current of hydrochloric acid gas up to the melting point, the acid gas was then displaced by nitrogen and this finally by air. Then the boat and contents were transferred to the weighing bottle in which the boat had been initially weighed, and the system was reweighed.

The Neutrality of Fused Lead Chloride.

In the earlier investigations by Baxter and Wilson, since the lead chloride which had been fused in hydrochloric acid was found to give a clear solution, the assumption was made that the fused salt was neutral. In preliminary experiments in this research, however, upon attempting to dissolve the fused salt in hot water a considerable quantity of white insoluble material separated as soon as the concentration of the solution became high. Similar insoluble material was eventually found to be soluble in acid and to contain chlorine and therefore to be basic chloride. A marked difference between the two cases exists, however. In Baxter and Wilson's experiments the total concentration of salt was never more than half as great as in these preliminary experiments. So far as analysis

of the salt was concerned no difficulty was introduced, for if the water in which the salt is dissolved is acidified slightly at the outset, no insoluble material separates. In these respects lead chloride resembles the bromide very closely. The question is so important, however, that much time was spent in proving that the fused salt really is neutral, and that the basic salt is formed by hydrolysis during solution.

In the first place we established the fact that unfused lead chloride which has been crystallized from dilute hydrochloric acid solution, and which therefore must have been either neutral or possibly slightly acid, when dissolved in water to yield a nearly saturated solution at room temperature, is slightly hydrolyzed to give a precipitate of basic salt. Lead chloride, which has been crystallized from water solution, behaves in the same way, but this is due in part to the fact that such material is already basic at the outset, as will presently be shown. Thus it was proved that the basic salt resulting from solution of fused lead chloride in water was at least in part due to hydrolysis during solution.

The second question as to whether a *portion* of the insoluble material was originally contained in the fused salt was more difficult to settle. The problem was finally solved by the method already employed by Richards¹ to determine the neutrality of fused barium chloride. The procedure was as follows: Two portions of lead chloride which had been crystallized from very dilute hydrochloric acid and dried for some time in a vacuum desiccator, were weighed out simultaneously. These crystals had been ground in an agate mortar during the drying in order to break open inclusions of mother liquor. One portion was dissolved in water with the addition of a trace of nitric acid and was analyzed by comparison with silver in the usual fashion, the details of which will be given shortly. The second portion was carefully fused in hydrochloric acid gas, bottled and weighed. A small quantity of material which sublimed from the boat into the tube was dissolved in water and, after evaporation of the solution in a weighed platinum crucible, the weight of residue was determined. This sublimate was kept as small as possible by taking care to heat the salt barely to the fusion point in a slow current of gas. From the loss in weight during fusion, corrected for the weight of the sublimate, the percentage of moisture in the original material could be ascertained. The fused specimen also was dissolved and compared with silver. Obviously, if no hydrolysis occurs during fusion of the chloride, the ratio of the fused chloride to silver should be the same as the ratio of the unfused, after correction for moisture content.

The data for two parallel pairs of experiments are given below. The analyses of the fused salt appear also in the final tables.

The difference between the mean ratio of fused and unfused salt to silver corresponds to an excess of chlorine of 0.0001 g. in the fused salt or an equal deficiency in the unfused material. Because of some uncertainty in the correction for residual moisture in the unfused salt, closer concordance could hardly be expected. The results prove, as far as the method allows, that lead chloride which has been carefully fused in a current of dry hydrochloric acid gas contains no appreciable amount of basic salt.

In connection with the foregoing experiments similar ones were carried out with lead chloride which had been crystallized from water solution. Since these experiments showed first that the salt thus prepared contains basic material, and second that this basic chloride is converted to the neutral salt by fusion in hydrochloric acid gas, the experiments are discussed below in detail. The method of procedure was exactly similar to that described above.

A complication in computing the percentage of water in the unfused salt from the change in weight during fusion is introduced by the fact that when the basic salt contained in the unfused material is fused in hydrochloric acid, hydroxyl (or possibly oxygen) is replaced by chlorine. Thus the water content of the salt is equal to the loss in weight during fusion plus the gain in weight due to replacement of hydroxyl by chlorine. A first approximation to the latter increase in weight was calculated from the apparent deficiency of chlorine found in the comparison of the unfused chloride with silver. Then a more nearly correct value for the water

¹ This happens also to be the mean of 17 experiments, including these two, subsequently recorded.

content was calculated. The whole process of approximation was eventually repeated three times in order to find the water content of the unfused basic chloride to 0.01 mg.

Mean, 1.29017.

In the four analyses in which the original salt had been crystallized from water previous to fusion, (Analyses 32, 33, 34 and 35) the average ratio of fused salt to silver is 1.28904, a value essentially in agreement with the average of experiments where the salt was crystallized from dilute hydrochloric acid, 1.28905.

These results indicate: first, that owing to hydrolysis lead chloride which has been crystallized from water contains roughly 0.1% less chlorine than the neutral salt and, second, that during fusion in hydrochloric acid gas, material originally basic becomes neutral, a result which cannot be attained with many chlorides such as those of zinc and magnesium.

The Analysis of Lead Chloride.

After the lead chloride had been fused and weighed, the boat and contents were placed in a two liter Erlenmeyer flask, the neck of which was provided with a column of bulbs to catch spray and to serve as a condenser, and was covered with about a liter of distilled water to which 0.1 cc. concentrated nitric acid had been added to prevent the precipitation of the basic salt. The flask and contents were then heated upon an electric stove until the salt was dissolved.

By actually distilling a lead chloride solution of concentration similar

¹ Analysis 35, page 1057.

² The salt which was used in the water determination was lost. This value is the average from three other specimens of similar material (Analyses 32, 33 and 34).

to the analyses (5 g. per liter) with different amounts of nitric acid, it was found that even 4 cc. of nitric acid did not cause an appreciable loss of chlorine.

A slight black insoluble residue of carbon and silica was left floating upon the surface of the solution, as in the case of the bromide. This was collected upon a platinum sponge crucible and determined as described on p. 1041. The average proportion of insoluble residue in twenty-one analyses was 0.004%. The weight of the residue was subtracted from the weight of salt.

The comparison of the lead chloride solutions with silver was effected almost exactly as in the analysis of the bromide (see p. 1041). The concentration of the chloride solution at the time of precipitation was nearly 0.03 *N*, that of the silver solution 0.05 *N*. In Analyses 34 and 36 the chloride solution was poured into the silver solution; in all the others the reverse method of precipitation was employed. No attempt was made to collect the silver chloride in the experiments for comparing the lead chloride with silver.

In the first eight analyses, after the solutions had stood in contact with the precipitated silver chloride for nearly a week with occasional shaking, they were cooled to 0° previous to testing in a nephelometer for excess of chloride or silver, and maintained at that temperature until equivalence of chloride and silver had been reached. Richards and Willard¹ found that the diminution in the solubility of silver chloride thus produced is an assistance in the determination of the end point. In the subsequent analyses this cooling was omitted, since we found that the accuracy of our experiments was not perceptibly increased by the process, which is somewhat troublesome. Needless to say, in the comparison of tubes in the nephelometer, readings were taken until they became constant, and each analysis was tested several times on successive days after the end point had been reached. In the last six analyses two pairs of tubes were always prepared and examined at the same time. Even at the large volume of the analyses the effect of the addition of 0.1 mg. of silver could be detected without cooling to 0°.

During the first two weeks very slight variations in the end point sometimes took place, probably owing to the extraction of occluded chloride or silver. At the end of three weeks no perceptible change was occurring and Analyses 32 and 48 were allowed to stand six weeks without the production of any alteration in the end point from the one found at the end of the third week.

In four separate experiments the silver chloride precipitated by adding an excess of silver nitrate to the solution of the salt was collected and weighed. The lead chloride solution was prepared as previously described

¹ *Pub. Car. Inst.*, 125, 15 (1910); *THIS JOURNAL*, 32, 16 (1910).

and was precipitated by adding a solution of a weighed, very nearly equivalent amount, of very pure silver nitrate containing several cubic centimeters of nitric acid. In Analyses 49 and 52 the silver nitrate solution was added to the chloride solution; in Analyses 50 and 51 the reverse method of precipitation was followed. The precipitate was left in contact with the mother liquor for two weeks, with occasional shaking, in order to allow occluded material to be extracted. Then an excess of 0.05 g. silver nitrate for each liter of mother liquor was added, and after a day's standing the precipitate was washed and collected upon a large weighed platinum-sponge crucible. The precipitate was washed twelve times with silver nitrate solution containing 0.05 g. per liter and once with chilled water before transference to the crucible with ice cold water.

The crucible and contents were dried at 235° for sixteen hours in an electrically heated porcelain air bath before they were weighed. In order to determine how much moisture was retained by the dried chloride, it was transferred to a small porcelain crucible and weighed, then heated to fusion inside a larger crucible and again weighed. The loss in weight, which represents the moisture expelled, was never more than 0.002% of the weight of the salt. Although the dried, unfused salt was superficially very slightly discolored, the fused material was colorless.

A correction of 0.05 mg. per liter was applied for silver chloride dissolved in the mother liquor and silver nitrate wash waters. This correction is calculated from the solubility product of silver chloride at 20° as determined by Kohlrausch,¹ 1.0×10^{-10} . The silver chloride dissolved in the aqueous washings together with that dissolved from the precipitation flask by rinsing with ammonia was estimated by nephelometric comparison in each experiment. This never amounted to more than 0.75 mg. per liter.

Vacuum corrections for lead chloride and silver chloride were applied by adding 0.000060² and 0.000071 g., respectively, for each apparent gram of substance.

Results and Discussion.

It is obvious that there is no evidence of dissimilarity in the various samples of chloride. The extreme difference in Series III, 0.04 unit, corresponds to less than 0.0006 g. of silver or 0.0007 g. of lead chloride, with a 5 g. portion of chloride. In Series IV, with larger quantities of lead chloride the extreme difference is half as large, corresponding to 0.0005 g. of silver chloride and to the same amount of lead chloride. The agreement of the averages with different specimens of lead chloride is even better.

¹ In this experiment the residue was so small that it was not determined.

The average of Series III is very slightly lower than that of Series IV. The difference, 0.01 unit, indicates a slight deficiency in the weight of silver chloride or a slight excess in the weight of silver or both. However, at the most the discrepancy corresponds to less than 0.0003 mg. of substance.

In the following table a more complete comparison of the different specimens of material is made:

Sample of PbCl ₂	Mineral.	Source.	Series III. PbCl ₂ :2Ag.	Series IV. PbCl ₂ :2AgCl.	Average.
D		Commercial nitrate	207.22		207.22

Series IV	PbCl ₂ : 2AgCl.....	0.97021	4	207.22
Average.....				207.20
Average, weighted according to number of analyses.				207.20

In all four series the results vary between essentially the same limits, so that the safest method of combining the four series is to compute the arithmetical mean. Weighting the average of each series according to the number of analyses does not alter the value of the mean. Of the four series, those in which the lead halides are compared with silver, Series I and III, are probably, on the whole, less subject to error. These two series agree almost exactly, both with each other and with the average of all four series. This final average, therefore, 207.20, seems to us to represent fairly the result of our work.

One more comparison may very well be made at this point, between the different silver samples. Since it is uncertain whether in the first five analyses Sample I or II of silver was used, these experiments are not included in the table.

Here again evidence of dissimilarity in material is lacking.

In comparing the present work with the earlier work of Baxter and Wilson, it is obvious that the discrepancy, 0.1 unit, is larger than the experimental error in either research. We are unable to offer any certain explanation of this difference. It is improbable that in the earlier work the silver chloride was contaminated with occluded material, for the precipitate was carefully examined for lead salts with negative results.² Furthermore, if lead chloride were occluded by the silver chloride, it would have raised the apparent atomic weight of lead, whereas the difference is in the opposite direction. On the whole, less difficulty was experienced in the earlier work than in the later from insoluble residue in the fused salt, for the final material left no visible residue upon solution. It might be suggested that the lead material used in the earlier work actually possessed an atomic weight different from that of any used in the present investigation. This seems unlikely, since no difference could be detected between any of the varied materials examined later. Unfortunately none of the material remained from the first investigation, so that comparison was impossible. Another possibility is that in Baxter and Wilson's experiments, during the fusion of the lead chloride in a current of hydrochloric acid in a glass tube, sufficient alkali chloride sublimed from the glass into the lead salt, or on the boat, to produce the difference. Only 0.025% of sodium chloride or 0.035% of potassium chloride would have been necessary, which represent about a milligram of impurity with a 4-5 gram portion. This seems on the whole the most probable explanation. It must be remembered, however, that because of the high atomic weight of lead, it is far more sensitive to experimental error than is an atomic weight of lesser magnitude. Because of the far larger number of experiments, and the more complete treatment, we feel that the present work should supersede the earlier research, even though the cause of the difference is not wholly certain.

With regard to the bearing of our work upon the theories of atomic disintegration, it is evident that no far-reaching conclusion may be drawn. If lead is a product of radioactive change, it might reasonably be expected to vary in atomic weight according as it originates in uranium or thorium, or both. This seems to be the case only with material extracted from

¹ This is the result of one analysis only.

² *Loc. cit.*, p. 367.

uranium and thorium ores. But this material differs from common lead in still possessing radioactivity, even though spectroscopically the radioactive and common material seem to be identical.¹ It still remains to be finally determined whether it is possible to separate radioactive lead into constituent parts, one of which may be ordinary lead.² It certainly is remarkable, however, if common lead is composed wholly or in part of isotopes of different atomic weights, that the proportions should be as constant in geographically and mineralogically different specimens of material as the constancy in the atomic weight indicates.

It is not at all certain, however, that during the expulsion of the α -particle the weight of the atom undergoes no other change, for as Hönigschmid³ has pointed out, the difference between his own recent determinations of the atomic weights of uranium and radium is not an even multiple of the atomic weight of helium. Possibly, after all, ordinary lead is the end product of the disintegration of uranium or thorium, or both.

At present we are engaged in an attempt to discover a comparative method for the determination of the atomic weight of lead as different as possible from the one employed here.

Summary.

1. Eleven specimens of lead salts from many different geographical and mineralogical sources were purified by various methods, and were found to be identical so far as could be determined by spectroscopic examination and by analysis of the chloride and bromide. None of these specimens were found to be radioactive to an appreciable extent.

2. Electrolytic deposition with a dissolving anode through nitrate or chloride electrolyte was found to be an unsatisfactory method of purifying lead from small amounts of silver and copper. Crystallization of the nitrate proved to be an efficient method.

3. Neutral lead bromide and chloride were found to hydrolyze upon solution in water, with precipitation of basic salts. Lead chloride which had been crystallized from water was found to be basic, although when crystallized from very dilute hydrochloric acid it is neutral.

4. Lead bromide and chloride which had been fused in an atmosphere of dry hydrobromic and hydrochloric acid gases, respectively, were found to be neutral.

5. By the analysis of both lead bromide and lead chloride the atomic weight of common lead was found to be 207.20, if $A_g = 107.880$, or 207.18, if $A_g = 107.870$.

THE VAPOR PRESSURE OF IODINE BETWEEN 50° AND 95°.

BY GREGORY PAUL BAXTER AND MERRITT ROY GROSE.

Received March 1, 1915.

Some years ago the vapor pressure of iodine was determined in the Harvard Laboratory¹ by the "air current" method throughout the temperature range 0° to 55°. This earlier research was interrupted by the end of the college year during attempts to continue the work at still higher temperatures. In the present investigation the difficulties met at the close of the earlier work were overcome and the method has been extended to cover the temperatures up to 95°.

The procedure in general was to pass a measured volume of pure, dry air, first over the pure iodine, and then into a solution of sodium carbonate to absorb the volatilized iodine. From the carbonate solution, after acidification and reduction of the liberated iodine by means of hydrazine, the iodine was precipitated as silver iodide, which was collected and weighed. In the experiments below 55°, sodium sulfite was used to absorb the iodine, but at higher temperatures this proved too easily oxidized by the oxygen of the air current. An aqueous solution of hydrazine did not reduce the iodine rapidly enough, while sodium hydroxide, attacked the glass apparatus very rapidly.

The purification of the iodine was carried out by methods which have been found effective in earlier researches.² Commercial iodine was dissolved in aqueous potassium iodide and distilled from a retort into a Jena flask cooled with running water. The product was several times rinsed with water, and was then suspended in water and reduced to hydriodic acid by means of well scrubbed hydrogen sulfide gas. After being boiled for some time to remove hydrocyanic acid which might have had its source in cyanogen impurity in the iodine, the solution was filtered to remove coagulated sulfur, and was then oxidized in a retort with a slight excess of potassium permanganate. In the latter process there is set free only five-eighths of the iodine, which was then distilled from the solution of potassium and manganous iodides as before. Although this second distillation from an aqueous iodide must have eliminated every trace of

¹ Baxter, Hickey and Holmes, *THIS JOURNAL*, 29, 127 (1907).

² *THIS JOURNAL*, 26, 1577 (1904); 27, 876 (1905).

chlorine and bromine, the product was again reduced with hydrogen sulfide and the hydriodic acid solution was oxidized with recrystallized permanganate. The final product was thoroughly rinsed with water, drained on a perforated porcelain funnel and superficially dried over sulfuric acid for some time.

During the course of the work the tube containing the iodine was several times broken so that the contents were wet with the thermostat water. After such an accident the iodine was redistilled from the final solution of potassium and manganous iodides obtained in the purification of the iodine, which was carefully saved for the purpose. Naturally, rinsing and drying of the iodine followed in each case.

Since iodine which has been dried over sulfuric acid still retains water, the partially dried material was finally distilled in a current of dry air in a hard glass tube. The tube was constricted at three points and the iodine was distilled from porcelain boats into the first section, then into the second and third and finally from the tube into a Jena glass retort. The iodine was gently scraped from the walls of the retort.

Sodium carbonate and silver nitrate were both twice crystallized, the latter from nitric acid solution, in order to remove chlorides.

In order to prepare hydrazine, the sulfate was treated with a solution of a large excess of sodium hydroxide in a platinum retort, and the hydrazine was distilled through a platinum condenser. The product was then redistilled. The approximate concentration of the solution was found by comparison with a standard solution of iodic acid in the presence of sodium acetate.

The air used for the sublimation of the iodine was first passed through a tube filled with hot copper oxide, then through a series of towers, one of which contained beads moistened with a solution of potassium hydroxide containing potassium permanganate; one, silver nitrate solution; and three, concentrated sulfuric acid. The last traces of moisture were removed by resublimed phosphorus pentoxide. The apparatus was constructed wholly of glass. The air used in the vapor pressure experiments was not passed over hot copper oxide, but otherwise was similarly purified.

The apparatus used for saturating the air with iodine and for absorbing the iodine was constructed in very much the same way as that used in the earlier research. A spiral glass tube, of about 1 cm. internal diameter, contained the iodine, which formed a column about 30 cm. long. Air was passed through a ground joint from the purifying train into one end of this tube. The other end of the tube was connected by means of a ground joint with the first absorbing tube containing a concentrated solution of sodium carbonate. A second absorbing spiral containing sodium carbonate solution was fused to the first, and in some experiments a third absorbing tube was attached to the first two by a ground joint.

Since, however, no iodine was ever found in the third absorber, in later experiments it was omitted. During a run, the iodine tube and first absorbing tube, including the connecting joint, were immersed in the water of the thermostat. It was necessary of course that this joint should be both tight and dry. Both results were secured by covering the joint completely with a piece of rubber tube securely wired in place. Since the joint was at the temperature of the thermostat it was to be expected that no iodine would condense between the saturating and first absorbing tube, and this was invariably the case, except in two of the preliminary experiments where a very small amount of solid iodine was found in the joint. The outlet of the iodine tube was constricted to 2 mm. to prevent diffusion into the absorbing bulb.

From the second absorbing tube the air passed into the large aspirator bottle used to produce the air current. This bottle, which had a capacity of more than 8 liters, was provided with a thermometer, an open tube mercury manometer, and an outlet tube through which the water content flowed into a carefully standardized bottle of about 8 liters volume in the experiments at the lower temperatures, of about 5 liters volume in the experiments at the higher temperatures. The rubber stoppers in the upper and lower tubulatures of the aspirator bottle were made tight with grease and in addition were wired in place and covered with shellac. The aspirator bottle was also jacketed with plumbers wool to secure constancy in temperature, and the temperature of the water at the outset was adjusted to that of the room so that no appreciable change in temperature of the water occurred during an experiment. The temperature of the room itself was controlled within a very few degrees by a thermostat.

The thermostat had a capacity of 25 liters, and was jacketed with an inch of plumbers wool. The greater part of the necessary heat was furnished by a burner under the thermostat tank, but the fine adjustment of temperature was secured by an incandescent light bulb controlled by a mercury-toluene regulator in the usual way. A mechanical stirrer proved very efficient in preventing variations in temperature in different parts of the bath. In order to avoid disturbances from evaporation at the surface of the bath, in experiments above 70° the water was covered with a layer of paraffine, which also reduced greatly the heat necessary to operate the bath and prevented unpleasant humidity in the laboratory even at 95°.

The corrections of the thermometers were found to hundredths of a degree by comparison with one standardized by the Physikalisch-Technische Reichsanstalt, due allowance being made for the exposed thread.

The procedure of an experiment was the usual one. After the apparatus had been connected, and the iodine tube with the first absorbing tube containing nearly saturated sodium carbonate solution had been allowed

to come to the temperature of the thermostat, the aspirator was started. No water was collected from the aspirator bottle, however, until air began to bubble through the sodium carbonate solution in the first absorbing bulb. At this point the reading of the manometer in the aspirator bottle was taken and at the end of the experiment the pressure in the aspirator bottle was brought to exactly the same point. The temperature of the water in the aspirator also was noted. When the receiving bottle was full of water, its temperature was taken and if this temperature was different from the initial temperature of the aspirator, a correction was applied to the volume of the water. The difference was never more than 2° . At the end of the experiment the temperature of the air in the aspirator bottle was read and also the barometric pressure upon a Green barometer.

As soon as the absorbing tubes had been disconnected from the iodine tube at the close of an experiment, a small amount of hydrazine was added to the absorbing tube nearest the iodine tube. This served to collect any iodine vapor still unabsorbed and to decolorize the absorbing solution, which in experiments at higher temperatures was usually somewhat brown.

As the temperature rose the amount of carbon dioxide freed by the action of the iodine upon the sodium carbonate became appreciable. Some of this undoubtedly was held by the cold sodium carbonate solution in the second absorbing bulb, and some was dissolved in the water of the aspirator bottle. In order to remove this carbon dioxide a bulb containing a solution of potassium hydroxide was inserted in the aspirating system between the second absorbing bulb and the aspirator bottle in many of the experiments at 80° and above. Even at 85° it was doubtful whether any real benefit was produced by the potassium hydroxide bulb, so that it is certain that its omission at the lower temperatures introduced no error. At 90° the experiments in which the above precaution was taken yielded somewhat higher results, as would be expected.

The carbonate solution from both absorbing bulbs was rinsed into a large glass stoppered Erlenmeyer flask and an excess of hydrazine was added. Dilute nitric acid in slight excess was next slowly introduced through a funnel extending to the bottom of the solution. As soon as the brown color indicating an excess of acid appeared the flask was tightly stoppered and left till colorless. Then more nitric acid was added, and if any further quantity of iodine separated, the flask was again closed and left till colorless. Care was taken to prevent free iodine from reaching the surface of the solution until the flask was stoppered.

A very dilute solution of a slight excess of pure silver nitrate was used to precipitate the iodine. A large excess was avoided because of the danger of the occlusion of the silver nitrate by the iodine.¹ After long standing

¹ K  thner and Aeuer, *Lieb. Ann.*, 337, 123 (1905); Baxter, *THIS JOURNAL*, 27, 880 (1905).

the precipitate was washed with water and collected upon a platinum-sponge Gooch crucible. It was dried at 180° in an electric oven before being weighed.

Calculation of the results was carried out as follows:

From the weight of silver iodide the weight of volatilized iodine was determined. The volume of this iodine as vapor was then calculated upon the assumption that 253.9 g. of iodine at 0° and 760 mm. would occupy 22.40 liters. The volume of air into which this iodine vaporized was reduced to the same conditions by means of the following formula:

$$V = v \frac{(B - h - m)}{760} \frac{273}{t + 273}$$

in which

v = corrected volume of water run out.

B = barometric reading corrected to 0°.

h = vapor pressure of water at the final temperature of the aspirator.

m = diminution in pressure indicated by the manometer.

t = final temperature of the aspirator.

Since the pressure within the iodine tube was that of the room,¹ the vapor pressure of iodine is then equal to

$$\frac{\text{volume of iodine vapor}}{\text{volume of iodine} + \text{volume of air}} \times \text{barometric pressure.}$$

This method of calculation involves the following assumptions:

1. That no solvent effect is exerted by air upon iodine.
2. That one mole of iodine has a volume of 22.40 liters.

It is well known that in the cases of chlorine and bromine at ordinary temperatures and pressures molecular quantities of these elements occupy considerably less than the theoretical volumes. Furthermore V. Meyer² found that at 253° the density of iodine vapor compared with air is 8.86, whence the volume of a mole is 22.2 liters. However, since in our experiments the pressure of the iodine vapor was low even at the higher temperatures, the above assumption seems safe.

Crafts and Meier,³ have found experimentally that iodine vapor is essentially undissociated at the boiling point of sulfur. Hence, it is improbable that, even at the great dilution of the iodine vapor in our experiments, any measurable dissociation could have taken place.

The bottles in which the water was measured were standardized by filling them from a standardized liter flask, after they had been wet with water and allowed to drain. Previous to use they were allowed to drain the same length of time. The cubical coefficient of expansion of glass is

¹ This was shown by a manometer located immediately before the iodine tube.

² *Ber.*, 13, 397 (1880).

³ *Ibid.*, 13, 861 (1880).

so small, 0.0025%, that no correction is necessary for the slight differences between the temperature of standardization and that of experiment.

In order to make sure that complete saturation of the air with iodine was attained, the rate at which the air was passed through the tube was varied in different experiments within wide limits, the time required for a volume of a liter being in some cases as small as one-half hour and sometimes as much as an hour. The velocity of the air current shows no apparent influence.

Weights were standardized to tenths of a milligram, and a vacuum correction of +0.00007 g. was applied to the larger weights of silver iodide.

At 50° the vapor pressure of iodine, 2.154 mm., agrees exactly with that previously found by Baxter, Hickey and Holmes. At 55° the value found here is slightly lower, but that is not surprising, because in the earlier work difficulty was experienced above 50° from separation of iodine at the ground joint between the iodine tube and the first absorbing tube. Our results are uniformly lower than those of Wiedermann, Stelzner and Niedershulte.² The curve plotted with our values against the temperature (Curve 1) makes a very satisfactory extension of the one obtained by Baxter, Hickey and Holmes, and is not very different from that plotted

¹ KOH bulb used.² *Verh. phys. Ges.*, 3, 159 (1905).

Curve 1.

with Ramsay and Young's¹ results over the same temperature range, thus giving a very satisfactory comparison of a static and a dynamic method.

Many attempts were made to find a mathematical relationship between vapor pressure and temperature, and two of these were successful enough to warrant drawing attention to them. If the logarithm of the vapor pressure is plotted against the logarithm of the absolute temperature, the result is not far from a straight line. This curve can be represented very closely by the equation

$$\log p = -106.3930 + 46.611 \log T - 0.031677 T$$

which differs from the thermodynamic equation developed by Clausius only in that the absolute temperature appears in the numerator instead of the denominator of the last term. The results obtained with this equation over the range 0-95° are given in Table II.

TABLE II.

Tem- perature centigrade. Degrees.	Vapor pressure calculated. Mm.	Vapor pressure observed. Mm.	Differ- ence. Mm.	Tem- perature centigrade. Degrees.	Vapor pressure calculated. Mm.	Vapor pressure observed. Mm.	Differ- ence. Mm.

55	3.050	3.069	-0.019				

The most satisfactory results were obtained by plotting the logarithm of the vapor pressure against the reciprocal of the absolute temperature. Through the range under consideration the points fall almost upon a straight line (see Curve 2), and by using the function $1/(T-19)$ instead of $1/T$ the plot becomes exactly a straight line within the limit of error of the experimental results. This means of course that the vapor pressure can be calculated from an equation of the form $\log p = A - B/(T - 19)$. This equation has already been proposed by Antoine.² It is essentially the thermodynamic equation without the term involving the logarithm of the absolute temperature. With the values 9.7522 and 2863.54 for A and B, respectively, Table III was computed.

Above 95° both equations yield values increasingly higher than those observed by Ramsay and Young, possibly because the vapor pressure is becoming irregular as the melting point 114° is approached. Below

50	2.151	2.154	-0.003	95	35.26	35.24	+0.02
55	3.056	3.069	-0.013				

It is also interesting to calculate from the experimental results the molecular heat of sublimation of solid iodine by means of the Clausius equation

$$L = T \, dp/dT \, (V - V_1)$$

where L = heat of sublimation.

T = absolute temperature.

¹ *Z. Electrochem.*, 20, 296 (1914).

dp/dT = change of vapor pressure per degree of temperature, expressed in atmospheres.

V = volume of one mol of iodine vapor at T° and at vapor pressure, expressed in liters.

V_1 = volume of one mol of solid iodine at T° in liters.

The change in vapor pressure with the temperature was calculated by dividing the difference in vapor pressure in each five degree interval by five. The absolute temperature was taken as the mean of the five degree interval. The vapor pressure at this temperature was estimated from a large scale curve. V_1 is so small, compared with V , that it is neglected in the calculations. The final result is multiplied by 0.02425 to convert it from liter atmospheres to kilogram calories. The values in kilogram calories multiplied by 4.183 give the results in kilojoules.

TABLE IV.

Temperature. Degrees.	Vapor pressure estimated. Mm.	Molecular heat of sublimation. Kilogram calories.	Molecular heat of sublimation. Kilojoules.
273 + 52.5	2.575	15.0	62.7
273 + 57.5	3.630	14.6	60.9
273 + 62.5	5.070	14.8	62.0
273 + 67.5	7.000	14.7	61.6
273 + 72.5	9.61	14.9	62.4
273 + 77.5	13.03	14.6	60.9
273 + 82.5	17.48	14.7	61.6
273 + 87.5	23.33	14.6	60.9
273 + 92.5	30.75	14.6	61.2
		Mean, 14.7	61.6

These values agree as well as could be expected, for at 75° an error in the determination of the vapor pressure of four-hundredths of a millimeter produces an error of 1% in dp , and of 0.3% in V . In fact, the agreement of the heats of sublimation is good confirmation of the accuracy of the experimental work.

The mean value of the molecular heat of sublimation between 50° and 95° is only slightly lower than the mean between 0° and 55° as found by Baxter, Hickey and Holmes, 15.1 kilogram calories or 63 kilojoules.¹

There seems to be only a slight tendency in the heat of sublimation to diminish up to 95°, although Ramsay and Young's results between 95° and the melting point 114° do indicate a perceptible drop.²

Summary.

1. The vapor pressure of solid iodine is found to have the following values:

¹ *Loc. cit.*, 135.

² Baxter, Hickey and Holmes, *Ibid.*, 135.

Temperature. Degrees.	Vapor pressure. Mm.	Temperature. Degrees.	Vapor pressure. Mm.
50	2.154	75	11.21
55	3.069	80	15.09
60	4.285	85	20.21
65	5.962	90	26.78
70	8.196	95	35.24

2. These results together with those obtained by Baxter, Hickey and Holmes between 0° and 50° may be expressed very closely by either of the two formulas

$$\log p = -106.3930 + 46.611 \log T - 0.031677 T$$

$$\log p = 9.7522 - 2863.54/(T - 19).$$

3. The average molecular heat of sublimation of iodine at these temperatures is calculated to be 14.7 kilogram calories or 61.6 kilojoules.

A portion of the apparatus and materials used were provided through the generous assistance of the Carnegie Institution of Washington.

CAMBRIDGE, MASS.

ON FRACTIONAL DISTILLATION WITH REGULATED STILL-HEADS.

[SECOND COMMUNICATION.]

DISTILLATION OF TERNARY MIXTURES.

BY M. A. ROSANOFF, JOHN F. W. SCHULZE AND R. A. DUNPHY.

Received January 18, 1915.

On the basis of an interesting series of experiments, F. D. Brown¹ describes the distillation of mixtures through a regulated stillhead in terms of the following law, or rule: "In distillations with a stillhead maintained at a constant temperature, *the composition of the distillate is constant*, and is identical with that of the vapor evolved by a mixture whose boiling point equals the temperature of the stillhead." Sometime ago this rule was examined by Rosanoff and Bacon in connection with mixtures whose boiling-point curve passes through a maximum or a minimum,² and it was shown that in a case of this type two different distillates may be expected at certain temperatures, depending upon the composition of the liquid originally introduced into the still; but that, whichever of the two possible distillates is produced, the distillation proceeds in conformity with Brown's law, in as far as the composition of the distillate is constant, and is identical with that of the vapor evolved by a mixture whose boiling point equals the temperature of the stillhead.

But both Brown's experiments and those just mentioned dealt exclusively

¹ Brown, *J. Chem. Soc.*, 37, 59 (1880); *Ibid.*, 39, 521 (1881).

² Rosanoff and Bacon, first communication of the present series, *THIS JOURNAL*, 37, 301 (1915).

with binary mixtures. And yet the possibilities¹ that the regulated still-head may have, especially in the industries, would mostly be in connection, not with simple binary mixtures, but with mixtures of three components or more. It seemed highly desirable, therefore, to investigate the working of the regulated stillhead in the case of a typical set of ternary mixtures, with a view to discovering the general principle involved.

The three substances chosen for the experiments were toluene, carbon tetrachloride, and ethylene bromide: their binary boiling-point curves and their ternary boiling-point surface show, as expected, neither maximum nor minimum, and therefore the case may be considered as of the simpler type. Further, the substances differ considerably in their physical properties, and thus we could expect to be able to analyze our distillates accurately by a rapid physico-chemical method.

And first the analytical method was worked out by one of us,² the work including a determination of the boiling-point surface. Then, in order to know what vapors might be expected to issue from the stillhead uncondensed, we determined³ the composition of the vapors evolved by various mixtures boiling at the temperatures: 83°, 91°, 99°, 107°, and 115°. After these preliminary steps had been taken, we were able to attack our main problem.

The powerful metallic stillhead which had been employed in the study of binary mixtures with maxima and minima in the boiling-point curves⁴ was again made use of in the present investigation. The liquids—toluene, carbon tetrachloride, and ethylene bromide—were the identical ones that Schulze had used in working out the analytical method, and a re-statement of the method of their purification is unnecessary. Each experiment consisted in fixing the temperature of the stillhead at one of the points for which we had previously determined the ternary partial pressures (composition of the vapors); then introducing into the still a mixture boiling at a somewhat higher temperature than that of the stillhead, and collecting for analysis a number of fractions sufficient to indicate the character of the distillate at every instant, and its variation—if any. Then a new run would be made, with the stillhead at the same temperature as before, but this time with a different mixture initially in the still. Thus two runs were made with the stillhead kept at 83°, and three runs at each of the remaining four temperatures. The results of the fourteen runs are reproduced in the tables below. In addition, six further runs were made

⁴ See Rosanoff and Bacon, *Loc. cit.*, Fig. 2.

by way of a check on results that appeared somewhat doubtful; but as these additional results were practically identical with those obtained at first, their reproduction here would be superfluous.

Throughout the experiments it was important to maintain the same atmospheric pressure, *viz.*, 749.0 mm., under which the boiling points of the various ternary mixtures had been determined by Schulze;¹ for under a changed atmospheric pressure the set of liquids boiling at the temperature of the stillhead would have been different from the set previously employed in studying the composition of the ternary vapors, and consequently we should not have known what vapors to expect. The required external pressure was established, and maintained constant, with the aid of a 100 liter manostat tank connected by sufficiently wide tubing with our receiver.

The volume of liquid mixture introduced into the still amounted each time to about 400 cc. The volume of each fraction of distillate was from 15 to 20 cc., and the distillates were "analyzed" by determining their refractive indices and their densities, both at 25°. All percentages given below are by weight.

The theoretical question before us was, whether Brown's law is applicable to mixtures of more than two substances. That in part the law must hold true whatever the number of components, might be confidently expected: namely, the composition of the vapor issuing from the stillhead at any instant must quite generally be "identical with that of the vapor evolved by a liquid whose boiling point equals the temperature of the stillhead." For what issues from the stillhead, is a vapor that is saturated at the temperature of the stillhead, and therefore one that would be evolved by a liquid boiling at the temperature of the stillhead. The question whether the issuing vapor will have a constant composition is more involved. In the case of binary mixtures with neither maximum nor minimum in the boiling-point curve, there is only one mixture boiling at the temperature of the stillhead, and therefore the escaping vapor can also have but one composition. Binary mixtures with a maximum or a minimum in the boiling-point curve must still follow Brown's law and yield a vapor of constant composition, although here, as stated before, one of two different vapors may be expected at certain stillhead temperatures. The addition of a third component introduces a new degree of freedom: a given set of three substances may be mixed in an infinity of proportions to give mixtures boiling at one and the same temperature, but each mixture will evolve its own vapor. While, therefore, with the stillhead kept at the common boiling temperature of these mixtures, the escaping saturated vapor will at every instant be identical with that evolved by one of the infinity of mixtures in question, its composition will by no

¹ Schulze, *Loc. cit.*

means be determined by the stillhead temperature alone, as in the case of binary mixtures. The composition of the vapor must certainly depend also on that of the mixture originally introduced into the still. But given a certain definite mixture in the still to start with, it would not be easy to foretell whether during a single distillation (the distillation of that particular mixture) the issuing vapor would have a constant composition or not.

It appeared plausible to expect that a vapor of constant composition would be produced only in those cases where the ratio of the amounts of the two less volatile components is the same in the vapors as in the liquids in equilibrium with them; but that usually, even during a single distilla-

tion, the vapors issuing from the regulated stillhead would not be uniform. We thought it best, however, to submit the question to direct experiment, and our results are tabulated above.

Fig. 1.

In the accompanying figure the curves represent the composition of the vapors evolved by the various liquid mixtures boiling at the stated temperatures.¹ The composition of the vapors yielded by the regulated stillhead are indicated by the several sets of points (the number near each set of points being that of the table, the results of which the set represents).

Conclusions.

Our tables and the figure answer plainly the questions under investigation.

(1) We had expected that at each stillhead temperature the distillates would have the same composition as vapors evolved by liquid mixtures boiling at the temperature of the stillhead; in other words, that the points

¹ See Rosanoff, Schulze and Dunphy, *THIS JOURNAL*, 36, 2480 (1914).

(by which we represent the composition of the distillates) would lie, in the diagram, *on the curves* which represent the composition of such vapors. As a matter of fact, the points are almost on the curves, the distance between each point and the curve to which it belongs representing in most cases only a fraction of one per cent.

(2) The different sets of points corresponding to each curve are widely separated, which shows that in the case of mixtures of three or more substances different distillates will be yielded by a regulated stillhead, if different mixtures are introduced into the still to begin with.

(3) The points of each separate set do not coincide, which shows that even during a single distillation the composition of the distillate does not remain constant.

(4) What is, however, of the greatest importance practically, is that this variation of the distillate during a single distillation is comparatively slight, as shown by the points of each set being close together. Moreover, the nearer the temperature of the stillhead is to the boiling point of the most volatile component, the more nearly constant is the composition of the distillate. Thus, as the diagram shows, for a stillhead temperature 7° above the boiling point of carbon tetrachloride, the separate points of each set can scarcely be distinguished; likewise, of course, the composition of the distillates as numerically expressed in Tables I and II is very nearly constant. *Practically the regulated stillhead can thus be used to obtain a uniform distillate from poly-component as well as from simple binary mixtures.*

(5) On the basis of the results obtained by Brown, of those of the first communication of the present series, and of those of this present communication, the working of the regulated stillhead may now be summed up in terms of the following general rule: *In distillations with a stillhead maintained at a constant temperature, the composition of the distillate is at every instant identical with that of a vapor evolved by a mixture whose boiling point equals the temperature of the stillhead. If the mixture is binary, the composition of the distillate is, in the course of a single distillation, constant. In those cases in which the binary boiling-point curve passes through a maximum or a minimum, the composition of the distillate depends on that of the mixture originally placed in the still. If the number of substances in the mixture is three or more, the composition of the distillate not only depends on that of the original mixture, but varies in the course of a single distillation. This variation, however, is moderate, and the nearer the constant temperature of the stillhead is to the boiling point of the most volatile component, the more nearly constant is the composition of the distillate. An important limitation of this rule will be demonstrated in our next communication.*

In conclusion it is a duty to recall that the cost of the apparatus used in this study was defrayed out of a grant from the Rumford Fund of the

American Academy, for which we here again cordially thank the Rumford Committee of the Academy.

A NEW METHOD OF PREPARATION AND SOME INTERESTING TRANSFORMATIONS OF COLLOIDAL MANGANESE DIOXIDE.

BY EDGAR J. WITZEMANN.

Received February 22, 1915.

Within the last few years several papers on the formation of colloidal manganese dioxide have appeared. Thus far, however, the intermediate formation of colloidal manganese dioxide in the ordinary oxidations of organic compounds with potassium permanganate has not been reported. The following paper is a report of some observations on this subject. In the course of the experiments it was found that the gelatinous form of colloidal manganese dioxide first obtained is slowly and automatically converted into a limpid colloidal solution. This transformation was studied somewhat more in detail and was found to be readily influenced (1) by the temperature at which the gel form was prepared, (2) by the concentration of the reacting solutions, (3) by the temperature to which the gel was subjected during the transformation, and (4) by the variations in the small concentrations of alkali necessary to cause the oxidation to take place rapidly.

The unusual chemical properties of manganese dioxide have for a long time occupied the attention of chemists, so that its existence as a colloid did not escape observation very long. Georger¹ boiled pure finely powdered Mn_2O_4 repeatedly with concentrated nitric acid and then washed the residue with water. When the wash waters were no longer acid the hydrated manganese dioxide went into solution, giving a brown liquid. He observed that the manganese dioxide is easily precipitated by the addition of very small amounts of nitric, sulfuric, or hydrochloric acids, ammonia, potassium or barium hydroxides and other compounds. Swiontkowski² found that on reducing a solution of potassium permanganate with pure neutral hydrogen peroxide a coffee-colored solution of colloidal manganese dioxide was obtained. This colloid was not obtained if the hydrogen peroxide was not neutral and was readily precipitated by the addition of very small quantities of acids and salts. Spring³ and Spring

³ *Ber.*, 16, 1142 (1883).

and Boeck¹ prepared colloidal manganese dioxide by the action of hypochlorous acid on manganese hydroxide and of potassium permanganate on sodium thiosulfate. The precipitate formed dissolved in part, on washing thoroughly with water, to give dark brown solutions. The undissolved part corresponded to $\text{Mn}_8\text{O}_{12} \cdot 4\text{H}_2\text{O}$. The dissolved part, after evaporation of the water, gave $\text{Mn}_7\text{O}_{12} \cdot 4\text{H}_2\text{O}$. Spring and Boeck determined the concentrations of various electrolytes necessary to precipitate colloidal solutions of manganese dioxide and found the values to be relatively quite small. In fact it is this sensitiveness to the presence of electrolytes, no doubt, that has prevented the observation of this colloid in more instances. Aland likewise reported² that the addition of potassium permanganate to sodium thiosulfate gave no precipitate but that on the addition of sodium chloride solution manganese dioxide is precipitated. Deiss³ prepared stable colloidal manganese dioxide hydrosol direct by reducing potassium permanganate solutions with arsenious acid in the presence of sodium hydroxide. By the use of this solution he was able to observe a number of new and interesting properties of this colloid, some of which will be mentioned in more detail below. Marck⁴ reported some new observations on the formation of colloidal manganese dioxide by the reduction of potassium permanganate with hydrogen peroxide. But his results and additional data were published later in a somewhat more accessible form.⁵ Some remarkable facts about the catalytic activity of colloidal manganese dioxide are brought out in the above paper.

My own observations on the formation of colloidal manganese dioxide during organic oxidations began several years ago. On one occasion especially,⁶ while oxidizing pyruvic acid with potassium permanganate at room temperature in the presence of potassium hydroxide, the reaction mixture remained perfectly liquid after the addition of potassium permanganate, although no unchanged potassium permanganate was present as shown by the red-brown color. Gradually the mixture became more and more viscous until it set into a fairly stiff jelly. This jelly was made filterable by heating for a time.

Later⁷ the formation of colloidal manganese dioxide was observed many times in the oxidation of acrolein diethylacetal to glyceric aldehyde diethylacetal in the synthetic preparation of *dl*-glyceric aldehyde. In this oxidation 540 cc. of water were placed in a three-liter flask and 50 g.

acrolein acetal were added. To this, 1100 cc. of an aqueous solution containing 60 g. of potassium permanganate (*i. e.*, nearly saturated at room temperature) were added from a dropping funnel at the rate of 100 cc. in five minutes. Throughout the addition the mixture was vigorously agitated in an ice bath. By the time the last of the potassium permanganate is being added the whole reaction mixture has increased in viscosity very markedly. The viscosity continues to increase gradually until in 15 to 30 minutes the entire mass has set into a dark brown jelly with a shiny mirror-like surface. This gel was so stiff that frequently the flask could be inverted for an instant without disturbing the gel. Gradually, if left undisturbed, little globules of colorless liquid appeared on the upper surface. In a short while the sides of the gel broke away from the wall of the flask and fluid filled the crevice. Presently crevices filled with liquid were formed throughout the whole mass of the gel. The quantity of liquid increased as the gel continued to contract and break up until finally the gel was submerged in the syneresis water. At about this point the syneresis water usually began to be more or less brown in color. The mixture was now placed on a steam bath and the coagulation of the very sensitive colloidal gel hastened.

When the same quantities of materials given above were used, but when the potassium permanganate was added at the rate of 100 cc. in 10 minutes, the increase in viscosity appeared some time before the addition was complete and more or less gel formation occurred toward the end of the addition, so that it was frequently difficult to agitate the reaction mixture thoroughly because of its high viscosity. In some instances coagulation took place as soon as the maximum viscosity appeared; gel formation in this case did not interfere with the process of agitation. It may be, when the potassium permanganate oxidation of acrolein acetal is carried out as originally prescribed by Wohl,¹ *i. e.*, where the permanganate is added very slowly, that the intermediate formation of colloidal manganese dioxide is almost entirely concealed. In fact, it may even be that this procedure² was originally adopted to avoid the difficulty of stirring the gel. Be that as it may, it is clear from my own experiments, that by carrying out this oxidation as described above (1) a great deal of time is saved, (2) a greater yield of the oxidation product desired is obtained, and (3) the interference offered by manganese dioxide gel to adequate agitation is avoided.

Because of the interesting and rapid transformations of this colloidal manganese dioxide, it was desirable to learn if some cheaper and more accessible organic substance would not reduce the potassium permanganate in such a way as to produce the same colloidal phenomena.

¹ *Ber.*, 31, 2394 (1898); Wohl and Neuberg, *Ber.*, 33, 3095 (1900).

² Wagner, *Ber.*, 21, 1230 (1888).

The first experiments were made with formaldehyde. 200 cc. of an aqueous solution containing 5.7 g. potassium permanganate were added to 10 cc. of 40% formaldehyde in 50 cc. of water containing a little sodium carbonate. The mixture warmed up rapidly in spite of constant agitation in the ice bath. Granular manganese dioxide was precipitated at once. The above experiment was repeated with one-half of the materials and the potassium permanganate was added very slowly. Manganese dioxide was precipitated as before. The colloidal manganese dioxide is no doubt precipitated by the potassium carbonate formed by the oxidation of the formaldehyde. The small excess of alkali added in the beginning is necessary to make the reaction take place more rapidly.

With Glucose.

(a) From the above it seemed probable that colloidal manganese dioxide would only be stable in those reaction mixtures in which the salts formed are relatively little ionized. 5 g. glucose were dissolved in 20 cc. of warm water. The mixture was now cooled in an ice bath. A few cubic centimeters of 10% sodium hydroxide were added and 100 cc. of potassium permanganate (60 g. per 100 cc.) were added through a dropping funnel in five minutes while agitating the mixture in an ice bath. The mixture rapidly became viscous and in 5 to 10 minutes set into a stiff jelly. From this point on, the transformations were entirely similar to those described above in the oxidation of acrolein acetal. Instead, however, of placing the flask containing the brownish solution, in which lumps of gel were suspended, on the hot plate it was kept at room temperature. Twenty-four hours later the brown solution had deepened in color and the lumps of gel had been changed into a thin semi-liquid gel which had separated to the bottom of the flask. In a few days more all signs of gel had disappeared and there was only a small amount of granular (perhaps crystalline) mass on the bottom of the flask. The colloid in this form was stable for months.

The limpid liquid thus obtained was dark brown, almost black, in color. In thick layers it was opaque to diffuse daylight, but in layers about $\frac{1}{16}$ inch thick it was transparent and when held over pencil marks had the effect of making them look darker in color and therefore somewhat more sharply legible. It was found that this colloid could be diluted to any extent with distilled water without causing colloidal manganese dioxide to precipitate out at any point in the dilution. The only observable effect was a gradual weakening of the brown color as the dilution progressed. This brown color persists to a very high dilution. In general the more concentrated solutions are the most stable. In one case 60 cc. of the concentrated colloid was diluted to 1.5 liters with distilled water. The solution which was too dense to be transparent while in the bottle was clear and red-brown in color when observed in a test tube. This solution was

filtered through a close thick filter (S. and S. No. 584) and only a small trace of insoluble matter remained on the filter.

It will not be necessary to enumerate all of the properties of colloidal manganese dioxide previously observed and to relate just how the above solutions showed the same characteristics. Only a few of the most striking properties will be mentioned. Deiss¹ observed that solutions of colloidal manganese dioxide dropped from a capillary tube into still water give beautiful vortex rings. If a fairly dilute solution of the above colloid is used the successive series of rings are developed very beautifully. The first ring increases to a certain size and breaks into 3 to 5 new small rings. These in turn develop until they each also break into 1 to 3 new rings. In favorable instances several more generations of rings are produced. All these rings are connected with each other by thin lines of manganese dioxide, thus giving the whole system a striking clustered or festooned appearance. This apparently little-known phenomenon was described first by Thomson and Newall² and is not limited to colloids like milk, blood, ink, etc., but is also shown by many salt solutions. Potassium permanganate of appropriate concentration gives beautiful rings. If the colloidal manganese dioxide is dropped into the solution of a salt the colloid is precipitated in the form of miniature rings. If the proper dilution of the colloid is dropped into a dilute solution of a salt (barium chloride, for example) the coagulation does not take place until the elaborate system of rings described above has been developed. It is interesting to note in this connection that the same rings and coagulated ring systems may be obtained with silver chloride, silver bromide, silver chromate, barium sulfate, etc., by dropping the proper reagents into a suitable concentration of the precipitant.

Bredig and Marck¹ studied the behavior of colloidal manganese dioxide with hydrogen peroxide very exhaustively. No attempt was made to repeat their careful quantitative experiments, but their qualitative experiments were easily duplicated with the colloid as obtained above. It was thus found, on adding hydrogen peroxide to a dilute but distinctly brown solution of the colloid, that the solution was decolorized at once but no oxygen or precipitate was formed. With somewhat stronger solutions a marked fading of the brown color took place, accompanied presently by the slow evolution of oxygen and the formation of a faint flocculent precipitate. Still stronger solutions gave a copious precipitate and oxygen very freely. Bredig and Marck explain these results by as-

suming that in dilute solutions a salt, $\text{Mn} \begin{array}{c} \diagup \text{O} \\ | \\ \diagdown \end{array}$, is formed which has no

¹ *Loc. cit.*

² *Proc. Roy. Soc.*, 39, 417 (1886).

catalytic activity, but in more concentrated solutions the catalytic properties of the unchanged manganese dioxide become effective. Their observations on the catalytic activation of the reduction of mercuric chloride with hydrogen peroxide by the addition of traces of colloidal manganese dioxide were also verified qualitatively.

Perhaps one of the most interesting properties of this colloid as obtained in the above and succeeding experiments is the behavior of the drops and splashings on the inside wall of the flask. These drops and thin films undergo the same syneresis described above except that here the syneresis water flows away or evaporates. The consequence is that once the cracks have begun to appear the various segments contract and curl up exactly like thin layers of drying liquid mud. If the films of colloidal solution are very thin they show after drying the metallic colors phenomena of thin films. In washing such flasks many of these scales become detached and show up brilliantly against the dark brown background of precipitated manganese dioxide. Deiss¹ considers the formation of these and other mirrors (Ag, Au, etc.) as dependent on colloidal phenomena.

(b) The preparation of colloidal manganese dioxide as described in (a) was repeated a large number of times. In these experiments additional observations on the transformation were made. It was found that on diluting the freshly prepared colloid, *i. e.*, before gelling had taken place, it could similarly be diluted to any extent without causing any precipitation of manganese dioxide. These solutions are less stable than those described in the preceding paragraphs. If other portions were diluted at different stages as the gelling progresses it was found that presently only a part of the material was dissolved. When the gelling was at its maximum nothing was dissolved and the water in which the gel was placed remains quite colorless.

Another striking indication that a molecular transformation is here taking place is shown by the marked change in color. When first prepared the colloidal solution is a rich cherry-red in color, but the red phase of the color fades out gradually as the transformation takes place, leaving a rich brown color.

From all that has gone before it is clear that we have a colloidal solution with a rather high viscosity automatically, without any marked change in temperature, being quickly converted into an insoluble gel which in turn is subsequently slowly changed into a limpid colloidal solution of the same compound. That is, there is a transformation from one molecular state in the solution into a markedly different one—a transformation which outside of colloidal chemistry might easily be spoken of as a transformation of an α -form of colloidal manganese dioxide into a β -form or *vice versa*. As a matter of fact it is quite probable that what really takes

¹ *Loc. cit.*

place is the transformation of an emulsoid form of "colloid" manganese dioxide into a suspensoid.

Examples of spontaneous isothermic transformations of the kind just described (*i. e.*, the transformation of a highly viscous colloid or gel into a colloid of low viscosity) are apparently quite rare among colloids. In some ways the transformations of molten sulfur on further heating are quite similar. But since sulfur is an isocolloid the analogy between it and the above heterogeneous colloid is only relative. Perhaps the transformation of the emulsoids of gum arabic or gelatin in water into suspensoid by the addition of definite small amounts of ethyl alcohol to the cold emulsoids is more strictly analogous.¹ It had previously been known that the addition of ethyl alcohol to these solutions would cause the gum or gelatin to separate as an amorphous or crystalline precipitate,² but Scarpa observed, if smaller concentrations of alcohol were added and the mixture kept cold throughout the addition, that a suspensoid was formed from the emulsoid, as was shown by the enormous fall in viscosity, by its electrophoric properties and by the difference in its behavior toward inorganic ions.

Our own transformation differs from that of Scarpa in that no external reagent was added in order to produce the transformation.

The spontaneous increase in the degree of dispersion of colloidal solutions of glycogen, benzopurpurin, hemoglobin, etc.,³ with increasing age of the solutions are in some respects similar, but not nearly so striking.⁴

The so-called "peptizations" of hydrogels⁵ by the addition of alkali are similar in effect to the observations described above. It seemed possible that some reaction between the sugar and the alkali might produce a difference in the chemical nature of the medium such that the gel would be liquified in it. Accordingly the glucose and alkali were allowed to stand in the aqueous solution for one week before adding the permanganate in the customary manner. The glucose solution became markedly yellow as was expected, due to characteristic chemical changes produced by the action of alkali under these conditions. When the glucose solution thus prepared was oxidized with permanganate the transformations of the colloidal manganese dioxide were just the same as those described in (a). So that it seemed clear that the changes produced in the glucose

by the alkali alone are not responsible for the transformations in the colloidal manganese dioxide.

L. Michaelis,¹ A. Mayer, G. Schaeffer and E. Terroine,² and v. Henri³ have observed that the size of colloidal particles varies very markedly in dye suspensions and metal and metallic sulfide sols under minute variations in the concentrations of electrolytes. And Mayer, Schaeffer and Terroine have shown that positively charged colloidal particles tend to increase in size under small concentrations of alkali, while acids cause them to diminish in size.⁴ In the case of negatively charged colloids the conditions are reversed. Now Bredig and Marck⁵ have shown that colloidal manganese dioxide is negatively charged. Further, as will be seen from the following paragraph, the transformation takes place more rapidly the more alkali there is present. So that the generalizations of Mayer, *et al.*, fit all of the observed facts and furnish a very simple explanation of the transformation of the gel into the sol. It must be stated, however, that if alkali causes this change the concentrations required to bring it about slowly, as it was observed at first, are rarely strong enough to color red litmus paper blue. It may be that the colloid protecting action of the excess glucose serves to assist the alkali effect at these low alkali concentrations, by preventing the precipitation of the manganese dioxide during the first stages of the transformation. The fact noted above, that on diluting the transformed colloidal manganese dioxide the most dilute solutions are least stable, may now be explained as being due to the fact that the alkali concentration is decreased to such an extent that condensation takes place. The rate of condensation is faster the smaller the alkali concentrations, *i. e.*, the greater the dilution.

The explanation of the first phase of the transformation of colloidal manganese dioxide involves phenomena much better known than those discussed in the preceding paragraph. There has been much work done on the changes in the viscosity of emulsoids since 1902.⁶ In general it

⁴ There is a tendency in discussing general properties of this kind to speak of the OH ion and H ion effect. It may be true that some colloids are not influenced by the other ion but in the case of colloidal manganese dioxide the character of the other ion is important. Colloidal manganese dioxide is precipitated by Ba(OH)₂ solutions but not by NaOH or KOH. In this case the precipitating effect of the divalent ion or the molecular Ba(OH)₂ supercedes any effect of the OH ion itself. Throughout the remainder of this paper the word alkali will be used meaning KOH or NaOH only.

⁶ P. von Schroeter, *Z. physik. Chem.*, 45, 75 (1903), gelatin; v. Henri, *et al.*, *Compt. rend. soc. de Biol.*, 55, 1668 (1903) and H. Garrett, *Phil. Mag.*, [6] 6, 374 (1903)

has been shown that whereas suspensoids undergo condensations slowly so that days are required to complete observations, in emulsoids much more marked increases in viscosity take place in as many seconds or minutes. So that rapid condensation of the fresh colloidal manganese dioxide into a gel is rather to be expected.

All the properties of the colloidal manganese dioxide may therefore be explained by the simultaneous action of two forces: the one tending to condense and precipitate the colloid and the other tending to disperse the colloid. The former is a very rapid-acting process and is hastened by increase in temperature and absence of alkali. The latter is a slow-acting process in any case, but can be accelerated greatly by relatively small increases in the alkali concentration and less markedly by increase in temperature up to a certain rather low maximum. One would expect that with two interacting processes of this character quite a variety of results could be obtained by varying the conditions. This is perhaps most strikingly shown by the variations in the gel, as representing the maximum viscosity, that were observed in the experiments described below.

On the chemical side very little may be said with certainty about the changes involved here. According to Morawski and Stingl¹ the precipitated manganese dioxide has the composition $\text{KH}_2\text{Mn}_4\text{O}_{10}$ (plus or minus small amounts of impurities). The emulsoid is therefore possibly a highly hydrated form of this compound and the transformation consists in a systematic gradual squeezing out of this water until the highly dehydrated suspensoid is obtained.² The process is also probably accompanied by a decrease in the size of the molecular aggregates of manganese dioxide. Of course the truth or error of the above can only be determined by extensive further work.

It was found that the transformation of the colloid is readily affected by changes in concentration and in temperature. For instance, when 2.5 g. glucose were dissolved in 20 cc. of water and treated with a little gelatin, silicic acid and protein; A. Muller, *Ber.*, 37, 11 (1903 or 4), organic colloids; Du Pré Denning, *Diss.* Heidelberg, 1904, ferric hydroxide; G. Fano, G. ² Cf. Scarpa, *Loc. cit.*, for a similar effect on gelatin and gum arabic solutions produced by adding ethyl alcohol.

10% sodium hydroxide and 100 cc. of permanganate (30 g. in 1100 cc.) as in (a), the changes were typical, so far as the gel formation was concerned, but the liquefaction of the gel was only observed to a very limited extent. On the other hand, the manganese dioxide was not properly precipitated. That is, the concentration of alkali was not sufficient to disintegrate the gel rapidly.

When the above experiment was repeated by warming the glucose solution to 30°, using a little more alkali and adding the potassium permanganate as before, the temperature of the mixture rose to 45° and the mixture gelled almost instantly after the addition was completed. Coagulation in this case did not take place suddenly as it does when the concentration is double the above (Cf. Experiment 3 below). When this coagulated mass, having the appearance of thick apple butter, was allowed to stand it showed signs of liquefying and in eight days at room temperature liquefaction was complete. The limpid colloidal solution thus obtained, where complete precipitation was expected, was typical in every way.

If the same amount of glucose and water are treated with 15 cc. sodium hydroxide and then with 50 cc. potassium permanganate (60 g. in 1100 cc. water), in an ice bath, gel formation does not take place within 3 hours in the ice bath nor within 3 hours after removing it from the bath. The mixture had a somewhat higher viscosity than the transformed colloid obtained in (a), but after standing over night even this slight difference in viscosity disappeared. By increasing the concentration of the alkali, even when the permanganate concentration was doubled, the intermediate gel stage was avoided and transformation was limited to a slight loss in viscosity. This experiment showed very strikingly that the transformation is clearly dependent on the alkali concentration, whatever explanation may be accepted, and that any effect of the glucose as a colloid protector is of secondary importance in this case.

The effects of temperature were further studied as follows:

(1) The reaction was carried out as in (a) using a little more alkali. When the gel had set the mixture was placed in the refrigerator. The transformation was typical but very slow. In four days the gel had completely liquefied in the usual way.

(2) Repeated (1) but allowed the mixture to stand at room temperature. The gel completely liquefied over night.

(3) Repeated (1) except that cooling during the addition of permanganate was omitted. The temperature of the mixture went up to 45°. In about two minutes after the addition was complete the manganese dioxide set into a gel and then almost instantly coagulated completely. It was not preserved any longer.

Without giving any further details it may be said that in general, no matter what the temperature or concentration are, the viscous or gel stage tends to be formed in all cases. The rate at which this viscous stage is dispersed into the limpid stage depends primarily on the concentration of the alkali used, but also on the temperature at which the colloid is formed and also on the temperature at which it is maintained subsequently.

With Other Substances.—2.5 g. each of galactose, fructose, lactose, and sucrose were dissolved in 10 cc. of water and treated with 2 cc. 10% sodium hydroxide and with 50 cc. potassium permanganate solution (60 g. per 100 cc.) in the ice bath. With galactose and fructose the results were practically the same as with glucose. With lactose, gelling took place only after an hour. With sucrose, a skin was formed on top of the solution before gelling took place. The gel underwent syneresis very rapidly. When the same amount of sucrose was similarly treated in the presence of 10 cc. of 10% sodium hydroxide the green color of potassium manganate was more persistent and when the red-brown color of colloidal manganese dioxide appeared, gelling and syneresis were slower. Very little, if any, of the manganese dioxide passed into solution again. Using 2.5 g. tartaric acid as the sodium salt and 2 cc. 10% sodium hydroxide as above, reduction took place with the intermediate formation of potassium manganate, and this was gradually reduced to manganese dioxide which finally set into a stiff gel. The gel did not go into solution again. Similar experiments with 3.5 g. of glycerol showed rapid reduction and coagulation to the gel stage and but little tendency to go into solution again. The above experiments were not extended in order to determine whether conditions could be found in which the results would in all ways resemble those obtained with glucose.

Hypothetical Applications.

Although the above experiments on colloidal manganese dioxide are of much interest in themselves, their interest is considerably heightened when looked at from another point of view. The enormous role of compounds of manganese in catalytic phenomena is well known. More recently, however, the role of manganese compounds in biochemical reactions has been studied rather intensively. Without attempting to review the literature (only a few recent references will be given) a few instances of its effects may be pointed out. It has been observed that small amounts of manganese compounds stimulate alcoholic fermentation as carried out in the fermentation industry.¹ The growth of fungi (*Aspergillus niger*, etc.) is markedly stimulated by the presence of manganese salts.² Many plant experiments have been made and manganese in

¹ Kayser, Marchand, *Compt. rend.*, 145, 343 (1907).

general also has a stimulating effect on the growth of plants.¹ It is now known for instance, that the production of wheat per acre may be increased 10%, in certain soils, by sprinkling a manganese salt upon the soil. Pyrolusite (MnO_2) is one of the most effective compounds in this respect. Other experiments appear to have shown that manganese compounds stimulate metabolism in animals and increase the hemogenetic power.² And it is proposed that manganese should properly be administered therapeutically with iron in order to make the latter effective. Further, the addition of minute amounts of manganese salts increases the activity of the enzyme laccase.³ All the foregoing processes are thought to be regulated by enzymes and the manganese must therefore enter into the action of the enzyme in some way. Since enzymes are admitted to be colloidal it may be that the manganese enters into combination with the colloidal particles. These enzymes are very sensitive to slight changes in the temperature and in the chemical character of the medium in which they exist. In most cases there is no adequate chemical explanation of the variations in the activity and least of all is there any known explanation as to how minute traces of certain foreign substances can influence these reactions so markedly. Of course it is quite likely that the manganese in these cases enters into the enzymic activity in the hydrolyzed form.⁴ Now if the regulatory effect in colloidal enzymes is dependent on a variation of the total surface of the colloidal particles of the enzyme a relatively small variation would cut down or increase the catalytic activity of the enzyme enormously. If, now, something was added to the enzyme which would increase the tendency of the colloidal enzyme to remain in a greater degree of dispersion, under conditions which normally would be unfavorable to this effect, then this something would have a positive influence on the enzymatic actions under consideration. Since manganese dioxide does so definitely have this tendency to become more dispersed, it is not inconceivable that the effect of manganese compounds in biochemical reactions may be accounted for on this basis.

Summary.

1. It was found that colloidal manganese dioxide is formed not only by the use of inorganic reagents but is normally formed in the oxidation of a series of organic compounds.

2. That colloidal manganese dioxide is especially easily obtained by incompletely oxidizing glucose (as well as fructose and galactose) in alkaline solution with potassium permanganate.

3. That the colloidal manganese dioxide is formed under these conditions first passes into a viscous or gel stage which subsequently changes into a limpid colloidal solution.

4. That the properties of the first stage agree well with those of a typical emulsoid, while the later stage seems more characteristically a suspensoid.

5. That the transformations of the emulsoid are typical and would be normal in every way if it were not for a slower but simultaneous transformation of the emulsoid into a suspensoid, owing to the effect of the alkali in accordance with the generalizations of Mayer, *et al.*

6. That both transformations are readily affected by variations in temperature, concentration of the reacting mixture and concentration of the alkali (KOH or NaOH).

7. That low temperatures are more favorable to the formation of the colloid.

8. That the concentrated colloid described here is readily coagulated by warming.

9. Suggestions are made indicating possible relationships between the remarkable properties of manganese in biochemical reactions and the properties of colloidal manganese dioxide as described above.

CHICAGO, ILL.

A CONDUCTIVITY STUDY OF THE REACTION BETWEEN CALCIUM NITRATE AND DIPOTASSIUM PHOSPHATE IN DILUTE SOLUTION.¹

BY W. A. WITHERS AND ALEX. L. FEILD.

Received January 7, 1915.

It is generally agreed that a soluble calcium salt reacts with dipotassium phosphate in the presence of an excess of ammonia to form an amorphous precipitate of tricalcium phosphate with no tendency to become crystalline on standing. When, on the other hand, ammonia is not added, there occurs a reaction in regard to which there is a great difference of opinion. The present investigation was made in order to determine the nature of the latter reaction.

Introductory.

It has been known for some time that tricalcium phosphate, when precipitated in neutral solution, has a composition which only approximates to the theoretical, due to the hydrolytic action of the solvent. This

¹ Read at the meeting of the North Carolina Section of the American Chemical Society, Raleigh, N. C., May 2, 1914.

hydrolysis has been studied by Warington¹, Georgievics,² and recently by Cameron and Hurst,³ and Cameron and Seidell.⁴ In these researches the solid tricalcium phosphate was added to a certain volume of water. Analyses were made after equilibrium conditions were reached. From a consideration of the data available, Cameron and Hurst draw the following conclusions:⁵

"From these facts it appears that no matter what compound, or mixture of compounds, containing only calcium and phosphoric acid ($\text{Ca}_3(\text{PO}_4)_m$), be placed in water there will result free phosphoric acid in the solution with separation of calcium hydroxide. The calcium hydroxide may then react to form a more basic and less soluble phosphate, or simply form a mixture with the phosphate, the solubility of which is decreased by its presence."

Furthermore, it was shown by Warington⁶ and verified by Cameron and Seidell⁶ that the decomposing action of water upon tricalcium phosphate depends upon the relative masses of the phosphate and water that are brought together.

An extensive study of equilibrium conditions in the system, lime (CaO)–phosphoric acid (P_2O_5)–water, has been made by Cameron and Seidell,⁷ and yet more fully by Cameron and Bell.⁸ The last-mentioned investigators conclude that in dilute solution, giving a neutral or nearly neutral reaction to phenolphthalein, the solid phase will be tricalcium phosphate or a solid solution of nearly the same composition; and, furthermore, that if there is a range of solution in equilibrium with tricalcium phosphate such a range would be very small.

It will now be understood that a reaction involving the formation of tricalcium phosphate will not in general be a simple one, due to the partial hydrolysis of the tricalcium phosphate to a more basic phosphate or a solid solution, containing lime as one constituent. For the sake of convenience, however, we shall consider that the tricalcium phosphate formed corresponds in composition to the theoretical, whenever equations are given for the reaction between calcium nitrate and dipotassium phosphate. Any hydrolysis which takes place can be considered subsequently and independently.

There is much disagreement among the text-books in regard to the reaction under consideration. Some give equations for the reaction which are so obviously incorrect that they will not be considered here—

⁸ *Ibid.*, 27, 1512; 28, 1222 (1906).

such as the immediate formation of dicalcium phosphate. The various reactions which deserve our consideration are represented by the following equations:

The second step in Equation 1 is usually considered to take place very slowly, but more quickly upon acidifying.¹

Equation 1 is given by Remsen.²

Similarly the second step in Equation 2 would occur only after long standing. Lang and Kaufman³ give an equation analogous to (2) as being that generally accepted by texts as representing the reaction between silver nitrate and disodium orthophosphate.

The present investigation makes use of conductivity measurements to determine what reaction, or reactions, actually take place when calcium nitrate is added in increasing quantities to a given quantity of dipotassium phosphate. 'The volume is kept constant.' The concentration employed throughout the investigation is 1 g. of K_2HPO_4 per liter, to which calcium nitrate is added in quantities up to 500 mg. nitrogen, as calcium nitrate, per liter. Whenever solutions of phosphoric acid or monopotassium phosphate are used, their concentration is equivalent to 0.5455 g. PO_4 per liter, which is the amount of PO_4 present in 1 g. of dipotassium phosphate.

After deciding which equation correctly expresses the reaction, this conclusion is verified by determinations of the composition of the liquid phase at various stages of the reaction. The method of conductivity titrations is employed for these determinations.

Method and Apparatus.

The solutions of calcium nitrate used were standardized by precipitating as calcium oxalate and titrating the precipitate with 0.1*N* permanganate, standardized by means of pure ferrous ammonium sulfate. The phosphoric acid and phosphate solutions were analyzed by precipitating with magnesia mixture, igniting, and weighing as magnesium pyrophosphate. Duplicate analyses agreed very closely.

¹ Ostwald, "Principles of Inorganic Chemistry" (1902), p. 522.

² Remsen, "Chemistry" (1890), p. 538.

³ THIS JOURNAL, 27, 1515 (1905).

The solution of potassium hydroxide contained a small quantity of carbonate, and was carefully protected from the atmosphere. It was standardized by a conductivity titration with hydrochloric acid, which, in turn, had been analyzed by weighing as silver chloride. The nitric acid solution was similarly standardized by the conductivity method against the standardized potassium hydroxide solution. Both of these solutions had a normality of 0.0574. 10 cc. of either acid or base reacted with 100 cc. of the phosphate solutions, according to equations which will be given later.

The same cell was used in all measurements of conductivity, and was of the "dipping electrode" type for dilute solutions as furnished by Eimer and Amend. It was standardized by means of 0.005 *N* potassium chloride solution, and showed a cell constant of 0.1222. Corrections were made in all cases for the conductivity of the distilled water from which the solutions were made up. Measurements were made according to the usual method of Kohlrausch. The slide-wire, furnished by Fritz Kohler, was carefully calibrated, and the resistances used had a guaranteed accuracy of a few tenths of one per cent. The electrically heated thermostat was operated throughout the investigation at 30°, and was controlled by a vapor-pressure thermoregulator, previously described by one of us,¹ which kept the bath constant within 0.01°.

When a single conductivity measurement was to be made upon a solution, a portion of the solution was removed and placed in a thin-walled test tube immersed in the bath. The conductivity cell was then dipped into the test tube, and, after temperature equilibrium was reached, the bridge reading was taken.

When a conductivity titration involving a number of measurements was made, 100 cc. of the unknown solution, diluted with distilled water to 200 cc., was placed in a spherical short-necked flask supplied with a three-hole stopper. Through this passed a stirring rod, the conductivity cell, and the tip of a buret containing the reagent which was added in the desired amount. After each addition of reagent from the buret the contents of the flask were stirred and allowed to attain the temperature of the bath before bridge readings were taken. In addition the cell was raised and lowered several times during this interval so as to allow the solution between the electrodes to mix with the surrounding solution.

The general principles underlying this and similar methods of physico-chemical volumetry have been discussed in detail by P. Dutoit.² The apparatus used by him is essentially the same as the one herein described, except that we use a different form of cell, which cannot be affected by such operations as stirring, and addition of reagent.

Part I. Experimental.

Conductivity Measurements.—Varying quantities of a solution of calcium nitrate were added to a solution of dipotassium phosphate of constant composition (1 g. per liter). Three series of measurements were made on these mixtures, as follows: 1. Immediately after mixing; 2. At the end of 24 hrs.; 3. At the end of 48 hrs. During the entire time the solutions were kept in stoppered bottles at a temperature of 30°, and were repeatedly shaken, especially before conductivity measurements were made.

The results are given in Table I. Values are expressed in ohms⁻¹ cm³.

Equilibrium conditions seem to have been practically reached at the end of 24 hrs., but the values for the 48 hr. period will be considered as representing more nearly such a condition. There is, however, very little difference between the two sets of values—less than 1% in all cases. As a matter of fact both of these sets of values are approximately attained after the lapse of several hours.

Fig. 1 shows graphically the conductivity values for the varying additions of calcium nitrate—the dotted curve representing initial conditions (immediately after mixing), while the continuous curve represents values at the end of 48 hrs. In Fig. 2 is represented, on a larger scale, the first portion of the two curves.

The Conductivity Curve—Time 48 hrs.—We will first confine our attention to the continuous curve representing conditions at the end of 48 hrs. It will be observed (Fig. 1) that there is a decided break in the curve at a point corresponding to the addition of about 120 mg. N as calcium nitrate. In accordance with the well-known principle discussed

by Dutoit¹ and by Miolatti and Pizzighelli,² such a break undoubtedly represents the completion of some reaction. Now of the equations

Fig. 1.

given above for the reaction between calcium nitrate and dipotassium phosphate, the only one which requires these particular proportions (120 mg. N to 1 g. of K_2HPO_4) is Equation 3. Both Equations 1 and 2 require 160 mg. N as calcium nitrate for complete reaction with 1 g. of K_2HPO_4 .

All evidence to be presented later in this article appears to strengthen this conclusion. Although several of the leading texts state that dicalcium phosphate is a final product of the reaction, we have not observed any formation of this salt in solutions which have stood several months. If such a formation occurs, it progresses with extreme slowness.

It will be noticed that the first portion of the curve shows rather striking irregularities. The maximum which occurs at a point corresponding to the addition of 5 mg. N evidently represents the beginning of the formation of a precipitate. The solutions containing quantities of calcium nitrate up to this amount remained perfectly clear on standing. That small part of the curve representing the addition of from 5 to 10 mg. N shows the occurrence of some reaction whose exact nature is rather doubtful. We can say

Fig. 2.

¹ Loc. cit.

² J. prakt. chem., 77, 417; C. A., 2, 2346.

with certainty, however, that the portion between 10 and 120 mg. N represents a reaction which, neglecting any hydrolysis of the tricalcium phosphate, can be represented by Equation 3. Further addition of calcium nitrate gives a curve which is practically a straight line, showing that this excess of calcium nitrate gives rise to no definite reaction with precipitate or solution. The results given later in this article indicate that an excess of calcium nitrate decreases slightly the amount of PO_4 present in solution, which effect may be looked upon as a further precipitation of tricalcium phosphate, or a lowering of the solubility of the same. Moreover, under the conditions of our experiment, tricalcium phosphate appears to dissolve as the dicalcium salt.

Conductivity Curve—Time 0 hrs.—In making conductivity measurements upon freshly mixed solutions it was noticed from the values obtained that the solutions were undergoing, in many cases, a comparatively rapid change. This change in conductivity occurred only for a short while after mixing, and was always toward a lower value.

An attempt was made, therefore, to make a series of measurements as soon as possible after mixing in order to obtain the maximum value. The results are those given in Table I, Column 1, and are represented graphically by the dotted curve in Figs. 1 and 2. Both solutions were brought to the temperature of the bath independently, and then mixed rapidly so as to avoid heat loss. In this way bridge readings could be taken within one or two minutes after mixing. Nevertheless, this set of readings can not be considered as accurate as those obtained later upon the same mixed solutions. The points as plotted lie on a fairly smooth curve. It intersects the curve representing conditions at the end of 48 hrs. at a point corresponding to about 200 mg. N as calcium nitrate, and from that point onward practically coincides with it. On account of the difficulty in obtaining the readings, it is impossible to say whether there is any break along this portion of the dotted curve. There is, however, a well defined maximum at a point corresponding to 7.5 mg. N, which is probably analogous in its significance to that present in the lower curve, and marks the point at which the precipitation reaction begins.

A special study of one solution mixture was made in order to determine, if possible, something concerning the rapidity and progress of the change in conductivity mentioned above, which is doubtless due to some chemical reaction. A solution containing the usual quantity of dipotassium phosphate (1 g. per liter), to which 80 mg. N as calcium nitrate had been added, was selected for this experiment. The change seemed to be particularly noticeable at such a concentration of the latter salt.

Conductivity values, determined at various intervals, are given in Table II.

TABLE II.

80 mg. N as calcium nitrate to 1 g. K_2HPO_4 . Volume, 1 liter.

Time. Min.	Specific conductivity.	Time. Min.	Specific conductivity.
0	0.001667	11	0.001623
1	0.001667	13	0.001555
3	0.001662	15	0.001552
5	0.001662	17	0.001546
7	0.001662	19	0.001546
9	0.001653	23	0.001546

This experiment was repeated several times. The initial and final values were identical in each case; and, after the major change in conductivity began, the change was completed in practically the same time. In some cases, however, a longer time elapsed than that shown in Table II before the drop in conductivity began; in no case did this occur before the lapse of seven minutes after mixing. It seems then that there is some unstable compound present which changes over into another form comparatively rapidly when once started. All these solutions were stirred vigorously and continuously, so that temperature conditions and concentration was constant throughout the solution under observation.

Since an appreciable time elapsed before this drop in conductivity occurred, an attempt was made to separate the liquid phase from the precipitate before the change occurred. Such was accomplished by filtering by suction through a hardened filter on a Buchner funnel. The filtrate was perfectly clear. After standing for about thirty minutes this filtrate became cloudy from the formation of a precipitate, probably of tricalcium phosphate. This shows that the observed change in conductivity is at least partly caused by a precipitation reaction, and not entirely by the action of the supernatant solution upon the precipitated tricalcium phosphate, such as would accompany the formation of dicalcium phosphate either by hydrolysis or by a reaction similar to that indicated by Equation 1b.

While there is no direct evidence in support of the conclusion, it appears probable that the phenomenon described may be due to the temporary formation of monocalcium phosphate along with the tricalcium phosphate, in accordance with Equation 1a given above. This salt is, as shown by Cameron and Seidell,¹ unstable in dilute solution, being easily hydrolyzed. This monocalcium phosphate, temporarily formed, would be converted into tricalcium phosphate in accordance with the equation,

If we combine Equations 1a and 4 we obtain Equation 3, which, as has been shown, represents conditions after equilibrium is reached.

¹ *Loc. cit.*

Discussion of Results.—All solutions of dipotassium phosphate to which calcium nitrate had been added with formation of a precipitate showed an acid reaction to phenolphthalein and to litmus, due to the presence of the monopotassium phosphate formed according to Equation 3. Congo red showed the presence of free acid in no case, nor did the conductivity titrations performed later give any indication of the presence of free acid, either nitric or phosphoric. It seems that the absence of free acid could have been predicted from purely chemical considerations. Free nitric acid acts upon dipotassium phosphate in dilute solution with the formation of monopotassium phosphate and potassium nitrate, while phosphoric acid gives only monopotassium phosphate. In either case, any acid formed by the progress of the imaginary reaction would finally convert all of the dipotassium phosphate into the more acid salt. Furthermore, monopotassium phosphate does not form a precipitate even with an excess of calcium nitrate.

Part 2. Experimental.

The liquid phase in contact with the phosphate precipitates in the various mixtures evidently contains varying quantities of dipotassium phosphate and monopotassium phosphate, together with potassium nitrate, and if added to the mixture in excess, calcium nitrate also. A knowledge of the relative proportions of mono- and dipotassium phosphate present in the various mixtures would, if obtained, lead to a confirmation of one of the several reactions given previously in this discussion. It might be mentioned at this point that the evidence obtained from such analytical results confirms the existence of the reaction expressed by Equation 3 as representing conditions at the end of 48 hrs. On account of the short duration and instability of the first step in the interaction of the two salts, for which we suggest Equation 1a, no analytical results could be obtained to prove its existence with certainty.

In order to investigate with the greatest possible accuracy the composition of the liquid phase, we have made use of some of the principles found in the work of Berthelot¹ on the basicity of phosphoric acid, and in the work of Thiel and Roemer² on the same subject.

Berthelot found that, when a solution of potassium or sodium hydroxide is added in increasing amounts to a given quantity of dilute phosphoric acid, the conductivity decreases regularly until sufficient alkali is added to form the primary salt. Here there is a sharp break in the curve, which proceeds regularly with increasing conductivity values until sufficient alkali is added to form the secondary salt. At this point there was a decided change in direction of the curve again, although not so sharply defined as the first break. There was no break observed corresponding

¹ *Compt. rend.*, 113, 851 (1891).

² *Z. physik. Chem.*, 63, 711 (1908).

to the formation of the normal salt. Thiel and Roemer¹ observed that the position of these breaks in the curve depended to some extent on the concentrations employed, and that, for very dilute solutions approached most nearly to the theoretical value. We have found that this method may be used for quantitatively determining the amount of phosphoric acid and dihydrogen phosphate present in a dilute solution. Furthermore, we have originated a somewhat similar method for determining the amount of dipotassium phosphate present, *e. g.*, by the addition of increasing quantities of nitric acid to the phosphate solution. There is a very sharp break corresponding to the transformation of the dipotassium into the monopotassium salt. Dutoit¹ gives similar curves, obtained by adding to a phosphate solution uranyl nitrate according to the well-known analytical practice.

Conductivity Titration of Phosphoric Acid.—This proceeds according to the equation:

Fig. 3 shows the character of the curve obtained. At this dilution it is very similar to the ordinary neutralization curve of a strong acid. This is given merely for the sake of completeness, since no free acid was observed in the course of the analyses.

Fig. 3.

Conductivity Titration of Dihydrogen Phosphate.—This takes place according to the equation,

Fig. 4 shows the character of the conductivity curve obtained. While Berthelot¹ and Thiel and Roemer¹ did observe a more or less noticeable break at this point, they did not suggest that such was decided enough

¹ *Loc. cit.*

for use in a quantitative determination of dihydrogen phosphate. Since the present investigation is concerned with concentrations which vary within comparatively narrow limits, it has been found practical to use this break for the accurate determination of this form of phosphoric acid when present in dilute solutions, such as heretofore described.

Fig. 4.

It was necessary, however, to apply corrections which were directly proportional to the total phosphate present in solution. The break was found to occur in all cases at a point beyond the theoretical addition of alkali. The excess of monopotassium phosphate, calculated from the curve, amounted to 11.8% of the total phosphate present in the solution, both being measured as grams of PO_4 per liter. In order to verify the existence of this break beyond the theoretical point indicating the completion of Equation 6, potassium hydroxide was added in varying amounts to a similar quantity of dipotassium phosphate. A break in the conductivity curve, identical in its nature, was observed when alkali corresponding to 11.8% of the total phosphate had been added. This proof was regarded as conclusive.

Conductivity Titration of Monohydrogen Phosphate.—This is possible on account of the fact that the equation,

goes to completion in dilute solution, or practically so. The conductivity curve is shown in Fig. 5. In contrast to the titration of dihydrogen phosphate, the present procedure requires a smaller amount of acid than the theoretical, the difference between the observed and calculated quantities being again proportional to the total amount of phosphate in the solution. This correction of the observed value for monohydrogen

Fig. 5.

phosphate under our experimental conditions amounted to 5.0% of the total phosphate present.

Results of Conductivity Titrations.—It has been assumed that the breaks in the conductivity curves obtained by adding either potassium hydroxide or nitric acid are not sufficiently affected by the amounts of potassium nitrate, initially present in the mixtures, to appreciably alter the results obtained. In those cases where calcium nitrate had been added in excess, it was not possible to determine the amount of dihydrogen phosphate present without the formation of a precipitate of tricalcium phosphate at the point where enough potassium hydroxide had been added to render the solution alkaline. It is possible, however, that even in such cases there is a break

corresponding to the amount of dihydrogen phosphate present.

Since in all solutions investigated the total phosphate was made up only of mono- and dihydrogen phosphate, the total phosphate was first approximately determined as being equal to the sum of the uncorrected values of the two latter forms. Using this value of total phosphate for calculating the magnitude of the corrections to be applied, as described above, new values were obtained for the amounts of mono- and dihydrogen phosphate. This furnished a more nearly correct value for total phosphate than the one first used. Three successive approximations were sufficient.

Determinations, by means of the methods and apparatus described, of H_2PO_4 , HPO_4 , and total PO_4 were made upon six solutions representing various points in the reaction between calcium nitrate and dipotassium phosphate. The results are given in Table III, together with the theoretical values which should obtain if we consider that Equation 3 represents the reaction which occurs. The results are represented graphically in Fig. 6. The dotted lines in this figure represent the theoretical values. All values in the table and figure represent percentage of original PO_4 (0.5455 g. per liter).

TABLE III.—COMPOSITION OF LIQUID PHASE.

150	1.37	0.00	..	5.00	..	5.00

Discussion of Results.—The results of the conductivity titrations, given in Table III and shown graphically in Fig. 6, bring to light some interesting points. In the first place, there is close agreement between

the observed and theoretical values for dihydrogen phosphate throughout the range of solution mixtures investigated. The observed values, however, for monohydrogen phosphate and total phosphate exceed the theoretical by amounts which increase with increasing quantities of

Fig. 6.

calcium nitrate, up to a point corresponding to the completion of the reaction expressed by Equation 3. Beyond this point further addition of calcium nitrate diminishes slightly the amount of monohydrogen phosphate present.

These data indicate that the principal reaction to be considered is, as has been proposed previously in this article, expressed by Equation 3. Furthermore, the tricalcium phosphate formed in accordance with this equation appears to be so hydrolyzed that a portion dissolves as monohydrogen phosphate, the resulting calcium oxide probably forming a solid solution with the remainder of the unhydrolyzed tricalcium phosphate. There are no indications to show that dihydrogen phosphate is formed by the hydrolysis of tricalcium phosphate under the conditions of these experiments. An examination of Table III will show that the extent of this hydrolysis, which is measured by the excess of the observed value of monohydrogen phosphate above the theoretical, increases with increas-

ing amounts of calcium nitrate, and is approximately proportional to the amount of the latter. This may be considered as due to the progressive formation of dihydrogen phosphate in accordance with Equation 3, and the resulting increase in the hydrogen ion concentration.

Finally we can conclude that an excess of calcium nitrate diminishes slightly the hydrolysis of tricalcium phosphate.

Summary.

1. A conductivity study of the reactions between calcium nitrate and dipotassium phosphate in dilute solution has been made. A constant concentration of dipotassium phosphate (0.5455 g. PO_4 per liter) has been employed, with amounts of calcium nitrate varying from 0 to 500 mg. N as calcium nitrate per liter.

2. From the occurrence of a break in the conductivity curve representing the addition of 120 mg. N as calcium nitrate per liter, the conclusion is drawn that the reaction which obtains at the end of 48 hrs. (for practical purposes, at the end of one or two hours) can be represented by the equation

3. Evidence is presented to show that for a short while after mixing there occurs some reaction, probably

This is an unstable condition, however, and persists for a short while only (about seven minutes in the case investigated). After this short interval has elapsed, there occurs a reaction which is characterized by further precipitation of tricalcium phosphate and which results in a condition shown by the equation immediately preceding. This reaction establishes a stable condition. It proceeds very rapidly at first, more slowly finally. The unstable condition is never reached when an excess of calcium nitrate is added, or else persists for an exceedingly short time. In this case the stable condition is reached immediately.

4. In order to further verify the occurrence of the equation,

the liquid phase of a number of solution mixtures was analyzed at the end of 48 hrs. by means of a method of conductivity titration. These mixtures represented various steps in the progress of the reaction. A comparison of the observed values for mono- and dihydrogen phosphate and total phosphate with the theoretical values was then made.

5. The amount of dihydrogen phosphate in the liquid phase was determined by means of the break in the conductivity curve obtained on adding increasing amounts of dilute potassium hydroxide solution. While the occurrence of this break has been recorded by previous investigators, its location does not seem to have been hitherto utilized for a quantitative analysis of an unknown solution.

The amount of monohydrogen phosphate in the liquid phase was determined by means of a similar break obtained on adding increasing amounts of dilute nitric acid. In this case both the principle involved and its application to physico-chemical volumetry are given here for the first time.

6. The results of the conductivity titrations further verify the equation given in paragraph 2 above.

7. Furthermore, the deviation of the observed values of monohydrogen phosphate from the theoretical shows that the precipitated tricalcium phosphate undergoes partial hydrolysis, in such a way as to appear in the liquid phase as monohydrogen phosphate.

8. The extent of this hydrolysis is roughly proportional to the concentration of the dihydrogen phosphate present, and is slightly diminished by excess of calcium nitrate.

NORTH CAROLINA AGRICULTURAL EXPERIMENT STATION,
WEST RALEIGH.

THE BEHAVIOR OF CERTAIN HYDRAZINE SALTS ON DECOMPOSITION BY HEAT.¹

By J. W. TURRENTINE.

Received December 14, 1914.

In 1899 Sebanejeff² described a method for the preparation of hydronitric acid depending upon the action of nitric acid on hydrazine sulfate. It was observed that when hydrazine mononitrate was treated with concentrated sulfuric acid at ordinary temperature, nitric oxide was evolved, a reaction which did not occur at -15° . On heating with dilute sulfuric acid, hydronitric acid was produced and was given off.

The hydrazine dinitrate, which proved to be much less stable than the corresponding monocompound, was decomposed under three sets of conditions and its decomposition products were studied—(1) at 80° to 85° ; (2) on a water bath, with a limiting temperature of 100° ; (3) at ordinary temperatures over sulfuric acid.

On warming this compound to 80 to 85° , this author found that the nitrate decomposed and yielded the volatile products, hydronitric acid, nitric acid, nitrogen and water, and the nonvolatile products, the neutral mononitrate and ammonium nitrate. Upon heating on the water bath, at 100° , the decomposition of the dinitrate occurred very much as it did at the temperature of 80 – 85° , except that the decomposition was more complete, yielding a residue containing only ammonium nitrate.

When the hydrazine dinitrate was allowed to stand at ordinary temperature in a desiccator over sulfuric acid, there occurred a continuous evolu-

¹ A chapter from the thesis submitted by the author to the Faculty of Cornell University, May 1908, for the degree of Doctor of Philosophy.

² *Z. anorg. Chem.*, 20, 21 (1899).

tion of hydronitric acid accompanied by a disintegration of the crystals. The residual powder on analysis proved to be ammonium nitrate and hydrazine mononitrate.

Within the last few years¹ it has been shown in this laboratory that hydronitric acid may be obtained by the action of a number of different oxidizing agents in acid solution on hydrazine sulfate. With a view to determining whether hydrazine salts of acids, the action of whose other salts upon hydrazine sulfate have been previously studied, would yield hydronitric acid as one of their decomposition products, the investigation to be described in the present chapter was undertaken. The results obtained are classified under the following headings:

Decomposition of: (1) hydrazine monochlorate; (2) hydrazine dichlorate; (3) hydrazine monoperchlorate; (4) hydrazine diperchlorate; (5) hydrazine monosulfate; (6) hydrazine disulfate.

Decomposition in Solution.

The apparatus used for the decomposition of solutions consisted of a 200 cc. distilling flask and an ordinary condenser, the lower end of which was connected by means of a long-stemmed adapter with a receiver containing a few cubic centimeters of distilled water for the absorption of the hydronitric acid.

The procedure followed consisted in the careful distillation of a measured volume of the solution under consideration and in the cautious heating of the residue (in case any was obtained) until no further action was observed to take place. The distillate was divided into several fractions, each of which was treated with three drops of a 5% solution of ferric chloride. From the intensity of the color produced some idea was obtained of the relative amounts of the acid present.

Decomposition of a Solution of Hydrazine Monochlorate.—Salvadori,² anticipating us in our work on the chlorates and perchlorates, while the work was still in progress in this laboratory published in complete form a description of the methods of preparation and properties of the monochlorate and the monoperchlorate of hydrazine. His interest in, and study of these compounds, however, was in connection with their explosibility. He found that the chlorate crystallizes in unstable, hygroscopic, laminated crystals and, when placed in hydrochloric acid, evolves chlorine. In concentrated sulfuric acid it explodes; if the sulfuric acid has been warmed to 80° explosion occurs with a loud report and a terrific local effect. A study of the decomposition products formed when the decomposition occurs explosively led the author to the conclusion that

¹ Browne, *THIS JOURNAL*, 27, 551 (1905); *Ber.*, 38, 1825 (1905); Browne and Shetterly, *THIS JOURNAL*, 29, 1305 (1907); 30, 53 (1908); 31, 221, 783 (1909); *Ber.*, 40, 3953 (1907).

² *Gazz. chim. ital.*, 37, 32 (1907).

the intramolecular oxidation took place as indicated by the equation

In these experiments the explosions were induced by percussion.

Preparation of Hydrazine Monochlorate.—To prepare 5 g. of hydrazine monochlorate, 6.8 g. of barium chlorate were added to 5.6 g. of hydrazine sulfate; to this were then added 6.4 g. of barium hydroxide, $\text{Ba}(\text{OH})_2\cdot 8\text{H}_2\text{O}$, the precipitated barium sulfate was removed by filtration and the solution was allowed to concentrate by spontaneous evaporation in the open air, at room temperature. All attempts made to crystallize the salt in mass, even at low temperatures over sulfuric acid, resulted in the spontaneous decomposition of the compound with the evolution of chlorine. When evaporated in small bulk on the stage of a microscope, laminated crystals made their appearance, only to decompose at once with the evolution of gas. A slight residue was left which, on examination, proved to be hydrazine chloride.

Experiments 1-4.—A solution of hydrazine monochlorate, prepared as described above, 1 cc. of which contained 0.035 g. of the salt, was treated in accordance with the procedure outlined. The 5 cc. portions, together with 30 cc. of water, were introduced into the distilling flask and the resulting solution was distilled.

On examining the distillate, no indication of the presence of hydronitric acid in any fraction was obtained.

Experiments 5 and 6.—Conditions identical with those of the preceding experiments were chosen except that in each of these cases 0.5 cc. of concentrated sulfuric acid was added. The distillate was caught in each experiment in 5 cc. fractions, in each of which the presence of hydronitric acid was clearly demonstrated. The amounts of acid increased as the distillation progressed until the last fraction was reached, in which no indication of the presence of the acid could be obtained.

Decomposition of a Solution of Hydrazine Dichlorate.—A solution of hydrazine dichlorate was prepared by treating 3.2 g. of hydrazine sulfate with 7.9 g. of barium chlorate. The solution was filtered and was concentrated by evaporation at room temperature until 1 cc., as shown by analysis, contained 0.05 g. of hydrazine dichlorate. Treatment of small portions of the solution with sulfuric acid and with barium chloride, respectively, gave no indications of the presence of appreciable quantities of barium or of sulfuric acid.

In concentrated solution this compound likewise proved so unstable that it rapidly decomposed. Crystals could be obtained when small amounts of the solution were evaporated to dryness under the microscope, but their disintegration was so rapid that they could not be subjected to an examination. Here, also, a slight, solid residue, consisting of a chloride of hydrazine, remained from the destruction of the compound. The main products of the decomposition of hydrazine dichlorate, as is also true of the monochlorate, are gaseous.

Experiment 7.—A 5 cc. portion of the above solution, with 30 cc. of H_2O , was distilled and collected in 5 cc. fractions. Appreciable quantities of hydronitric acid were formed, the most distinct indications of its presence being obtained in the sixth fraction.

Experiment 8.—The conditions prevailing in Expt. 7 were closely duplicated except that 0.5 cc. of concentrated sulfuric acid was added to the solution. Hydronitric acid was found to be present in the successive fractions of the distillate in increasing amount up to the fifth fraction. The last fraction, containing other products of the reaction, gave no indications of the presence of the acid.

Decomposition of a Solution of Hydrazine Monoperchlorate.—This substance was prepared by Salvadori¹ and by the author independently. Salvadori ascribed to it the formula $N_2H_4ClO_4 \cdot \frac{1}{2}H_2O$, a formula upheld by his analytical results. The salt readily can be crystallized from water on the water bath, which fact bespeaks for its remarkable stability. It is nonhygroscopic, soluble in water and alcohol and insoluble in ether, carbon disulfide, benzene and chloroform. It melts at $131-132^\circ$. Like the chlorate, hydrazine monoperchlorate on heating and on being subjected to percussion is violently explosive.

A solution of this compound was obtained by treating 3.3 g. of hydrazine sulfate with 4.3 g. of hydrated barium hydroxide and 4.3 g. of barium chlorate, in solution. After the barium sulfate had been removed by filtration, the solution of hydrazine monoperchlorate was evaporated until the compound crystallized out. As a check upon the purity of the compound so obtained, the percentage of nitrogen was determined by the method of Rimini.²

Per cent. nitrogen: calculated for $N_2H_4ClO_4 \cdot H_2O$: 11.17%; found (av. of two): 10.51%.

Determinations of so-called water of crystallization by desiccation methods shown in Table I, made before the appearance of Salvadori's work, had led us to the belief that the monoperchlorate crystallized with one molecule of water of crystallization.

TABLE I.

No.	$N_2H_4 \cdot HClO_4 \cdot H_2O$ Weight taken.	Loss.	Theory.	
			$\frac{1}{2} H_2O$.	1 H_2O .
1.....	0.2737	0.0175	0.0128	0.0196
2.....	0.5194	0.0335	0.0193	0.0372

In Experiment 1 the sample was dehydrated to constant weight over sulfuric acid; in Experiment 2 the sample was heated at 100° on a water bath until its weight became constant. These results show that the water is quite readily removed from the monoperchlorate, both by desiccating agents and by heat. No attempt is here being made to refute the statements of Salvadori.

Experiments 9 and 10.—A volume of 25 cc. of a solution of hydrazine monoperchlorate containing 0.004 g. per cc. was distilled until the solution came to dryness. Collected in 5 cc. fractions. No test for hydronitric acid was obtained in any fraction. On coming to dryness, the residue exploded. From the products of the decomposition remaining in the flask, after being dissolved in water, were obtained, by means of the usual tests, indications of the presence of hydrochloric acid and hydrazine. The last fraction of the distillate gave an acid reaction and emitted the odor of chlorine.

Experiments 11 and 12.—In these experiments the conditions which obtained in Experiments 9 and 10 were observed as closely as possible, with the single exception that 0.5 cc. of concentrated sulfuric acid was added to the solution before the distillation. No test for hydronitric acid was obtained in any fraction. The last portions of the distillate gave an acid reaction with litmus. Some sulfur dioxide was produced. The residue in the flask consisted of hydrazine sulfate and gave no tests for chlorine ions.

Decomposition of a Solution of Hydrazine Diperchlorate.—To prepare 10 g. of hydrazine diperchlorate, 13.5 g. of $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ were neutralized with perchloric acid which had been freed from hydrochloric acid by precipitation with a solution of silver perchlorate, prepared by dissolving silver carbonate in perchloric acid. To the solution of barium perchlorate thus formed was added the theoretical amount, 5.56 g., of hydrazine sulfate. After removing by filtration the precipitated barium sulfate, the clear solution was evaporated to dryness over steam coils and with the aid of a blast of dry air.

Experiments 13-16.—Distillation of the unacidified (Expts. 13 and 14) and the acidified (Expts. 15 and 16) solutions, respectively, gave no detectable amount of hydronitric acid. The residue from the former showed the presence of hydrazine and of chloride; that from the latter, hydrazine sulfate.

Decomposition of Solids.

The apparatus used for the decomposition of the solid substances consisted essentially of three parts, which, in the order in which they were connected, were (1) a carbon dioxide generator, especially constructed with a view to furnishing very pure, air-free gas, (2) an ignition tube, containing a thermometer, in which the substance under examination was heated, and (3) an absorption apparatus, designed for the subsequent detection of hydronitric acid.

The absorption apparatus, connected with the farther end of the ignition tube, consisted of two large test tubes, each of which contained a few cubic centimeters of distilled water. These were so connected by means of glass tubes and stopcocks that the current of gas could be passed either through the two tubes in series, or through the farther tube only. By this device it was possible to prevent the contamination of the solution to be tested for hydronitric acid by other products formed at certain stages of the decomposition. After the current of gas had passed through the two tubes it entered the third, the inside wall of which were fastened several strips of filter paper impregnated with manganous sulfate.

By moistening one of these slips with a few drops of potassium hydroxide solution, introduced through a small separatory funnel, it was possible to detect the presence of oxygen in the tube at any time. To facilitate the successive application of this test without dismantling the apparatus, the stem of the separatory funnel was bent at right angles. By slightly turning the funnel, the end of the stem could be brought into contact with successive strips of the paper.

The gas finally passed through a short tube into a eudiometer filled with a solution of potassium hydroxide.

Procedure Followed.—When the air in the entire apparatus had been displaced by carbon dioxide, as indicated by the failure to obtain a brown coloration on the manganous sulfate paper, heat was applied slowly to a weighed sample of the hydrazine salt contained in a porcelain boat, which previously had been introduced into the ignition tube. A slow stream of carbon dioxide was passed through the apparatus throughout the decomposition of the salt and until all decomposition products had been swept into the absorption apparatus. When it became evident in any case that products of decomposition capable of interfering with the detection of hydronitric acid were being formed in any considerable quantity, the current of gas which previously had passed through both absorption tubes was directed so as to pass through the second only. By this means the hydronitric acid, which seemed ordinarily to be formed in the early stages of the decomposition, was not contaminated by the products of the final stages.

The acid was identified by the usual method. The unabsorbable, gaseous products of decomposition were collected in the eudiometer and, whenever it seemed desirable, were subjected to further examination.

Decomposition of Hydrazine Monoperchlorate. Experiment 17 (and duplicate, 18).—A sample of hydrazine monoperchlorate of 0.10 g. was treated as outlined under "procedure." The salt first melted, then began to boil slowly, giving off gas and water vapor. At this stage of the decomposition, as shown by the reddening of the ferric chloride in the first of the absorption tubes, hydronitric acid was produced.

When the visible evolution of gas from the substance undergoing decomposition had ceased, as marked by the cessation of the formation of bubbles, the course of the stream of gas through the apparatus was diverted into the second absorption tube. On further heating then, the substance in the boat exploded, emitting light, and filling the apparatus with fumes (H_2O and HCl ?) which soon condensed. It was subsequent to this violent stage of the decomposition that a nonabsorbable gas appeared in the eudiometer. A slight, white residue was left.

The solution from the second absorption tube, on examination, showed the presence of chlorine ions with silver nitrate in the presence of nitric acid; of hydrogen ions, with blue litmus; of chlorine, with potassium iodide and carbon disulfide and, perhaps, of nitrates. Water was a further product of the decomposition. The gas accumulated in the eudiometer at the end of the run proved to be 14.0 cc. of nitrogen, and 7.6 cc. of oxygen. The presence of oxygen was indicated also by the manganous sulfate paper.

Decomposition of Hydrazine Diperchlorate. Experiment 19 (and duplicate, 20).—Following the procedure already described for preceding experiments, a portion of hydrazine diperchlorate of 0.057 g. was decomposed and its decomposition products studied. These proved to be hydronitric acid in considerable quantities; oxygen, chlorine, and chlorine and hydrogen ions, as determined by the usual tests. The unabsorbed gases proved to be 9.0 cc. of nitrogen, and 8.0 cc. of oxygen.

This substance in decomposing behaved very much as did the monopерchlorate in that the decomposition at first was gradual and was accompanied by a slow bubbling. After this had ceased an explosion occurred which filled the tube with a yellow-green gas of chlorine or of chlorine peroxide, or both. The odor indicated chlorine peroxide. It was subsequent to the explosion, also in this case, as in the preceding instance, that the nitrogen and oxygen made their appearance in the gas collector, a fact which would indicate that they were liberated at the time of the explosion. A white residue, presumably of ammonium chloride, remained.

Action of Potassium Perchlorate upon Hydrazine Sulfate. A Correction.—In connection with their study of the oxidation of hydrazine,¹ Browne and Shetterly found that potassium perchlorate (Baker and Adamson, "C. P."), when used in comparatively large quantities, oxidized hydrazine in sulfuric acid solution, with formation of both hydronitric acid and ammonia. The former product, under most favorable conditions, was obtained in exactly the same amount, 22.4%, with potassium perchlorate, as with potassium chlorate² as oxidizing agent. The possible significance of this fact was overlooked until the attention of one of the authors was directed to the matter by Dr. H. H. Willard, who has done extensive work with the perchlorates.³ Dr. Willard very kindly furnished a liberal sample of the very pure potassium perchlorate prepared during the course of his investigations.

In a series of additional experiments performed by Dr. Shetterly under conditions similar to those prevailing in the earlier work, except that the very pure potassium perchlorate, which was found to be entirely free from chlorates, was used, no indication whatever of the oxidation of the hydrazine was obtained. The tests for both hydronitric acid and ammonia gave negative results. Examination of two samples of the Baker and Adamson perchlorate used in the earlier work showed that this product contained a considerable quantity of potassium chlorate (KClO_3 , found, (1) 4.22, (2) 4.23%). It may, therefore, be concluded that chlorate-free potassium perchlorate is without action upon hydrazine sulfate under the conditions of the experiments, and that the oxidizing action noted in the earlier experiments was due to the presence of potassium chlorate in the perchlorate used.

This conclusion is of particular interest when considered in connection with the results obtained in the decomposition of the perchlorates of

hydrazine. The formation of hydronitric acid in this decomposition in the dry way suggests the query: Is this formation not due to the action of the chloric acid radical on the hydrazine instead of the perchloric radical? It may be regarded as possible that the decomposition of the perchlorate takes place in such a way that its initial stage is marked by the liberation of oxygen, yielding chlorate, a decomposition characteristic of the more stable perchlorates, and that the chlorate in turn reacts intramolecularly to form hydronitric acid. The presence of free oxygen in the gaseous products of the decomposition may be interpreted to indicate such a liberation. The freedom from chlorate of the hydrazine perchlorates dealt with is suggested by the absence of hydronitric acid from the products obtained from these when decomposed in the wet way, a suggestion borne out by their analysis.

Decomposition of Hydrazine Monosulfate.—Hydrazine monosulfate was prepared by treating 2.28 g. of hydrazine disulfate in solution with a solution of barium hydroxide containing 2.76 g. of $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ transposition taking place analytically according to the equation

After filtering, the clear solution was evaporated over steam coils. A clear syrup, or gum, resulted which, on being touched with spatula or rod, rapidly became an opaque mass of white crystals, the crystals growing out in fronds from the point of the surface to which the rod had been touched. The analysis of the dry substance gave the following:

N calc. for $(\text{N}_2\text{H}_4)_2 \cdot \text{H}_2\text{SO}_4$: 34.52; found (av. of 4): 33.45%. S calc.: 19.76; found (av. of 2): 19.76%.

Experiment 21.—A portion, 0.2 g. in weight, when heated gradually, melted at $70-80^\circ$ and at 120° began to decompose, as evidenced by the appearance of a white sublimate on the cooler portions of the combustion tube. It was not until a temperature of 160° was reached, however, that the decomposition became so rapid as to produce frothing. The sublimate then became yellow, revealing its identity as sulfur. When the temperature had been raised to 180° the visible activity had ceased. There was a free evolution of water and hydrogen sulfide. No test for hydronitric acid, on account of the presence of hydrogen sulfide, could be obtained. A white residue remained which, qualitatively, proved to be hydrazine sulfate.

Experiment 22.—Experiment 21 was duplicated with modifications designed to test successive portions of the gaseous products of the decomposition, still yielding negative results with respect to hydronitric acid.

It was noticed that as the condensed moisture on the inside of the tube was driven out by re-evaporation, a white crystalline substance remained. On examination, this substance was shown to be ammonium carbonate.

Decomposition of Hydrazine Disulfate. Experiments 23 and 24.—Hydrazine disulfate in 1 g. portions, finely pulverized, was subjected to decomposition under the conditions shown above. Once the temperature of incipient decomposition had been reached, the intramolecular oxidation became self-propagating. There ensued a lively evolution of gas accompanied by a bubbling of the melted mass. Sulfur was evolved and formed an abundant white sublimate, deepening to a yellow color where the sub-

limate was thickest, over the interior of the apparatus. Water was formed. And among the gaseous products of the decomposition were found volumes of hydrogen sulfide and sulfur dioxide.

No hydronitric acid was found in any experiment with the disulfate.

Sulfurous acid gives a reaction with both silver nitrate and ferric chloride which superficially resembles and effectively masks that of the hydronitric acid with these reagents—namely, a white precipitate with silver nitrate, which gives a red coloration when treated with ferric chloride, and a red coloration direct with ferric chloride, due to the formation of ferric sulfite. Practically the only differences which easily are shown between the reactions of sulfur dioxide and hydronitric acid with these two favorite reagents for the detection of hydronitric acid are that silver trinitride is readily and violently explosive, while silver sulfite is not and that the color obtained from ferric chloride and hydronitric acid, due to ferric trinitride, slowly fades, while that due to ferric sulfite fades more rapidly. The change of color in solution of ferric sulfite is brought about by the reduction of the ferric iron to the ferrous by the sulfite and the oxidation of the sulfite to the sulfate by the ferric iron. Ferrous sulfate results.

It is necessary, therefore, if one is to test for hydronitric acid in the presence of sulfur dioxide, first to eliminate the sulfur dioxide. The method as applied in the following paragraphs is recommended.

A Test for Hydronitric Acid in the Presence of Sulfites.

To 10 cc. of a standard solution of hydronitric acid were added 100 cc. of a 5% solution of sodium hydroxide, 10 cc., 10% sodium sulfite solution and 15 cc. of a 3% solution of hydrogen peroxide. This solution was boiled until effervescence had ceased upon which it gave negative tests for both hydrogen peroxide and sulfites with the potassium iodide and potassium iodate tests, respectively. The solution was then transferred to a distilling apparatus and, after acidification, it was distilled until a few drops of the distillate gave no test for hydronitric acid. To the distillate were then added 10 drops of ferric chloride and the solution was diluted with distilled water to a definite volume. Another portion of 10 cc. of the standard solution of hydronitric acid was then treated with the same amount of ferric chloride and was diluted to an equal volume. The two solutions were then compared in comparison cylinders and their color intensity was found to be equal, showing that no hydronitric acid was oxidized by hydrogen peroxide in alkaline solution.

The solution from the absorption apparatus, which contained the decomposition products of the hydrazine disulfate, was then treated with 10 cc. of a 5% solution of sodium hydroxide, and 10 cc. of a 3% solution of hydrogen peroxide. The resulting solution was placed in a distilling apparatus and boiled until effervescence had ceased. The cessation of the effervescence in this case was taken as an indication of the complete

removal of the excess of hydrogen peroxide. The solution was then acidified with 1 : 1 sulfuric acid and was distilled. The distillate gave no tests for hydronitric acid with ferric chloride.

Summary.

The decomposition of hydrazine monochlorate, by heat, in neutral, aqueous solution yielded no hydronitric acid; in (H_2SO_4) acid solution hydronitric acid resulted. The corresponding di-salt yielded hydronitric acid both in the presence and absence of sulfuric acid. The mono- and diperchlorate of hydrazine yielded no hydronitric acid in either acidified or unacidified solution. When the dry crystallized salt was decomposed by heat in a stream of carbon dioxide, hydronitric acid was produced from the latter, but not from the former. Both liberated gaseous chlorine, nitrogen and oxygen, and chloride and hydroxide ions. The mono- and disulfates of hydrazine, under similar conditions, gave off water, hydrogen sulfide, sulfur dioxide and sulfur, but no hydronitric acid. A method is described for the detection of hydronitric acid in the presence of sulfur dioxide.

CORNELL UNIVERSITY, ITHACA, N. Y.

ELECTROCHEMICAL OXIDATION OF HYDRAZINE SULFATE AND AMMONIUM HYDROXIDE.¹

By J. W. TURRENTINE AND J. M. OLIN.

Received December 15, 1914.

Szarvasy² has shown that hydrazine, on electrolysis, yields nitrogen at the anode and hydrogen at the cathode in the ratio in which these two elements exist in the hydrazine molecule, namely, $\text{N}_2 : 2\text{H}_2$. These results were obtained from the electrolysis of solutions of hydrazine hydrate, sulfate and chloride at varying concentrations of solution, current densities and temperatures. The hydrazine cations, he explains, are oxidized at the anode by the discharge anions, oxygen, chlorine, with the formation, respectively, of water and hydrochloric acid, evolving nitrogen; and at the cathode "the free base reacts with two molecules of water, the hydrate being re-formed and hydrogen liberated." Under the conditions of his experiments, as his figures indicate, the hydrazine cation was oxidized at the anode quantitatively to nitrogen without any indication of a reduction at the cathode.

These experiments show conclusively that oxygen and chlorine liberated by electrolysis, under the conditions named, do not oxidize hydrazine in the alkaline solution of the hydrate or in the neutral or weakly acid solution

¹ In part a chapter from the thesis submitted by the author to the Faculty of Cornell University for the degree of Doctor of Philosophy, May, 1908.

² "Electrolysis of the Nitrogen Hydrides and of Hydroxylamine, *J. Chem. Soc.*, [1] 11, 603 (1900).

of the sulfate or chloride¹ to an intermediate oxidation product as ammonia or hydronitric acid, but, as stated above, directly to nitrogen.

The investigation here described was undertaken by the present writer to discover if, under more widely varying conditions than those which obtained on the work of the investigation quoted, reactions could not be induced by electrolysis, as the primary agent, which would yield as a product other hydronitrogens such as ammonia, and more particularly, hydronitric acid.

Looking upon the action of the current at the anode as nothing more than that of an agent whose function it is to liberate in that area some oxidizing agent such as oxygen, chlorine, etc., and wishing to simulate as closely as possible a weak oxidizing agent, as one would conclude from the complete oxidation of the hydrazine directly to nitrogen in the experiments of Szarvasy that the conditions there were such as to yield too strong an oxidizing agent, the electrolysis was conducted, in our earlier experiments, between a large anode and small cathode and with a very low current density at the anode. The small cathode was employed to cut down the reduction in its region.

The electrolysis of the hydrazine sulfate was conducted in strongly acid solutions, since, as observed by Browne and Shetterly² in their work on the oxidation of hydrazine, the production of hydronitric acid and ammonia is always most noticeable in strongly acid solution. Moreover, to remove readily the hydronitric acid from its aqueous solution, it is quite advantageous to acidify strongly before distillation. It was hoped thus by acidification and heating to drive off the acid, if formed, from the electrolytic bath as rapidly as produced, as it has been shown³ that hydronitric acid itself is decomposed electrolytically at the anode.

Experimental.

Experiment 1.—A solution of hydrazine disulfate, saturated in the cold, containing 5% by volume of concentrated sulfuric acid, was electrolyzed at its boiling point between platinum electrodes and contained in the apparatus described as follows:

A 250 cc. beaker contained as anode a sheet of platinum foil of 60 cm. square, on a face, curved so as to fit against the walls of the beaker, and a platinum wire cathode extending horizontally to the center of the beaker and then perpendicularly down. The beaker rested on a sand bath and was covered as tightly as possible by an evaporating funnel. From the top of the funnel extended a Reitmeier bulb to return any acid spray. From this a narrow glass tube extended downward to the bottom of a test

¹ The author makes no mention in connection with the chloride and sulfate of hydrazine as to whether he dealt with the neutral, monosalt or the acid disalt.

² "On the Oxidation of Hydrazine, I," *THIS JOURNAL*, 29, 1305 (1907); II, *Ibid.*, 30, 53 (1908); III, *Ibid.*, 31, 221, 783 (1909).

³ Szarvasy, *Loc. cit.*; Peratoner and Oddo, *Gazz. chim. ital.*, 25, II, 13; 30, II, 95.

tube containing a few cubic centimeters of an aqueous solution of ferric chloride. The test tube was closed by means of a two-hole rubber stopper and was connected in turn through a suction flask, to a Bunsen pump. This complication in the apparatus was introduced to make it possible, by drawing a rapid stream of air into the funnel from the edges of the beaker and on through the test solution of ferric chloride, to catch and detect any hydronitric acid distilled from the solution during the electrolysis. The liquid from the condensed vapors was conducted from the collecting rim of the funnel likewise to a test tube containing a test solution of ferric chloride.

The solution of above composition was poured into the electrolytic cell until it covered the entire anode and submerged 1.5 cm. of the wire cathode; its temperature was then raised to its boiling point and there maintained throughout the electrolysis. Distilled water was added from time to time to prevent too great concentration. The current density at first was regulated so that only the slightest evolution of gas was visible at the anode. Under these conditions no indication of the presence of hydronitric acid could be found in either test solution.

The current density was subsequently raised, but with only negative results.

Experiments 2, 3 and 4.—The concentration of the sulfuric acid in the solution undergoing electrolysis was increased successively to 10%, 15% and 20%, respectively, in these experiments, but only negative results as regards the formation of hydronitric acid were obtained. No tests were made for ammonia.

These negative results made it appear improbable that the direct oxidation of the hydrazine cation by the oxygen set free by the current could be made to yield readily the less highly oxidized products of hydrazine as hydronitric acid and ammonia. Oxygen, in its active condition as evolved from the anode, apparently is too strong an oxidizing agent, carrying the oxidation to the extreme of removing all the hydrogen atoms from the union with nitrogen atoms in the hydrazine molecule. The conditions of the experiments were then so altered as to permit of the formation in the electrolytic bath of oxidation products which would escape from the sphere of action less readily than the oxygen. The oxidation products could then, by secondary reactions, subsequently, or during the electrolysis, oxidize the hydrazine.

The oxidation products formed from the electrolysis of solutions in which $\text{SO}_4^{''}$ ions predominate are ozone (H_2O_3) and persulfuric acid. These are produced in largest amounts at high current densities. Accordingly, a long, thin, platinum wire anode, encircling the cup and exposing an active surface for about 10 cm. of its length, was substituted for the large sheet anode in the electrolytic cell, as described in Experiment 1.

In every other respect the cell was allowed to remain as originally described.

Experiment 5.—A saturated solution of hydrazine sulfate, $\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$, containing 10% by volume of concentrated sulfuric acid, was electrolyzed with a current of 1.5 amperes. As the electrolysis continued, the solution became heated. Ozone was evolved.

Hydronitric acid soon made its appearance both in the gases and distillate from the cell and continued to come over during the electrolysis. Strong tests were obtained with solutions of ferric chloride and silver nitrate.

Experiment 6.—This experiment was a duplicate of Experiment 5, with the modification that the temperature of the solution in the cell was maintained at the boiling point from the beginning of the electrolysis. Both the gases and distillate products contained hydronitric acid, though only in small amounts.

It was feared that under the conditions of this experiment the hydronitric acid might be oxidized in its vaporious form by the ozone evolved with it,¹ thus accounting for the low yield of the acid. It seemed desirable, therefore, to conduct the electrolysis at so low a temperature that the acid would remain in solution. The experiment was designed, also, with a view to determining whether hydronitric acid was produced at low temperatures and, as indicated by Experiment 5, continuously during the electrolysis.

Experiment 7.—A solution of the same composition as that used in the previous experiments was electrolyzed in the cell as described, its temperature being maintained during the electrolysis, by means of an ice bath, at 0° and below. The presence of the acid in the gases drawn from the cell could not be detected. There was a free evolution of ozone.

The electrolysis was then discontinued, and to test the cold solution for the presence of hydronitric acid the solution was transferred to a 500 cc. distilling flask. Through the mouth of the flask to the bottom extended a glass tube. The side arm of the flask was connected to a condenser, the lower end of which was joined, by means of an adapter, to a suction flask which in turn was connected with a Chapman pump. In the suction flask was held a small test tube containing the test solution of ferric chloride into which dipped the elongated tube of the adapter. Air was then drawn through the cold solution and was caused to bubble through the ferric chloride solution in the test tube, thus sweeping the hydronitric acid from the acid solution through the test solution.

While a distinct test was obtained, only a small amount of hydronitric acid was thus detected. The solution was then heated to boiling, the dis-

¹ It may be questioned and remain undetermined whether the ozone could escape from the solution at the temperature at which the electrolysis was conducted without undergoing instantaneous decomposition.

tillate was caught in 5 cc. fractions and each tested with 6 drops of ferric chloride. A series of strong tests for hydronitric acid was thus procured.

The foregoing experiments tended to show that hydronitric acid was produced in the electrolytic bath during the electrolysis either directly, *i. e.*, by the direct oxidation of the hydrazine cation by oxygen, which seemed impossible in the light of previous experiments, or by secondary reactions with other anode products.

So far only qualitative determination had been made of the yield of acid. To obtain quantitative measurement Experiment 8 was performed.

Experiment 8.—In the apparatus and under the same conditions of temperature as described under Experiment 7 a solution of the disulfate containing exactly 1.00 g. of the salt in 150 cc. H_2O and 50 cc. concentrated H_2SO_4 was electrolyzed for six hours with a current which varied from 0.5 to 1.5 amperes.

For the ferric chloride solution, formerly placed in the test tube to catch and detect vapors of hydronitric acid in the gaseous products of the electrolysis, was substituted a few cubic centimeters of a solution of silver nitrate containing sodium acetate, prepared by adding to 2 cc. of a 10% solution of $AgNO_3$, 2 cc. of a 10% solution of sodium acetate, and sufficient water to completely dissolve the silver acetate formed. During the course of the experiment a slight precipitate of silver trinitride appeared in this tube. At the end of the electrolysis the solution was transferred to the distilling apparatus mentioned under Experiment 7. The tube of the adapter dipped beneath the surface of a solution of $AgNO_3$, prepared as above, so that both liquid and vapor products of the distillation could be recovered. A copious, white precipitate of AgN_3 was formed in the receiver. When the distillate no longer showed the presence of hydronitric acid, when subjected in small amounts to the ferric chloride test, the solution was again made up to 200 cc. with distilled water, and two 2 cc. portions, each equal to 0.01% of the total sample, were withdrawn for analysis. The average of the two analyses gave 0.00729 g. of $N_2H_4.H_2SO_4$ in 2 cc., making the value of the total solution 0.729 g. $N_2H_4.H_2SO_4$. This value, subtracted from the total amount (1.00 g.) started with, gave the weight of the salt oxidized as 0.271 g. of $N_2H_4.H_2SO_4$. The silver trinitride was filtered on a Gooch filter, quickly washed with small amounts of distilled water, dried at 110° and weighed. Weight of $AgN_3 = 0.0464$ g. = 0.0130 g. HN_3 .

Experiments 9 and 10.—The solution that remained from Experiment 8 was subjected to two successive treatments as described under Experiment 8, the electrolysis in each case being prolonged for a period of three hours, with a current of 1.0 to 1.5 amperes. After each distillation the solution was made up again carefully to its original volume and samples were withdrawn for analysis. The silver trinitride also was determined

in both cases as above. The results of these two experiments, with those of two others, are given in Table I.

TABLE I.

For the sake of comparing these results with those obtained in the purely chemical oxidation, the yields of hydronitric acid have been calculated on the basis of the equation:

During the oxidation of hydrazine by purely chemical means ammonia seems invariably to be formed under the conditions favorable to the production of hydronitric acid. In order to ascertain whether this same general principle is applicable to the electrolytic oxidation of hydrazine, a portion of the residual solution from which all the hydrazine and hydronitric acid had previously been eliminated, as described above, was made alkaline with potassium hydroxide and distilled in the usual way, the ammonia being caught in a measured excess of standard hydrochloric acid. By titrating back with standard alkali, it was found that about 0.05 g. of NH_3 had been formed during the decomposition of about 1.5 g. $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$, corresponding to a yield of about 51% of NH_3 on the basis of the above equation.

The electrolysis of the hydrazine salt in the latter experiments was conducted under conditions chosen with a view to the production of more permanent oxidizing agents than the oxygen evolved from the anode. The fulfilment of our prediction and the success of our efforts indicate from the start that the oxidizing agent which one knows to be formed as anode products under these conditions are the agents which yield HN_3 and NH_3 . Only three oxidizing agents are possible, namely, the oxygen evolved from the anode, the ozone evolved from the anode and dissolving in the solution, and the persulfuric acid also dissolved in solution, both of the latter two being inevitable products of electrolysis under the conditions maintained. The early experiments in this work as well as those of Szarvasy are sufficient to lead one to dismiss oxygen, though no direct proof has been adduced to show that under the conditions of very high current density the hydrazine cation might not be oxidized to other hydro-nitrogens.

Chattaway¹ observes that phenylhydrazine in a liquid film on filter

¹ "Oxidation of Hydrazines by Oxygen," *J. Chem. Soc.*, 91, 1323 (1907).

paper, when exposed to the action of oxygen confined in stoppered bottles, rapidly absorbs oxygen with the production of heat and evolves a volume of nitrogen greater than that of the oxygen absorbed.

The chemical action of ozone on hydrazine has not been studied as yet, but the slight tests for HN_3 obtained from the cold solutions through which ozone, as well as oxygen, had been passing would indicate that neither of these two acted as the oxidizing agent to any great extent.

Browne and Shetterly¹ have shown that persulfates in hot, acid solutions oxidize hydrazine salts, yielding N_2 , HN_3 and NH_3 . The present writer, in his attempts to prepare hydrazine persulfates, has found that persulfates do not oxidize hydrazine readily in the cold. It was only necessary, therefore, to analyze the cold solution before and after the distillation to show whether the major portion of the oxidation had occurred during the electrolysis or during the distillation. That some oxidation occurred during the electrolysis in both hot and cold solution has already been shown. The following experiment was designed to reveal to what extent oxidation occurred during the distillation.

Experiment 11.—A solution which contained 0.50 g. $\text{N}_2\text{H}_4\cdot\text{H}_2\text{SO}_4$, to 50 cc. of concentrated H_2SO_4 and 150 cc. H_2O , was electrolyzed under the same conditions of time, current, etc., as those which obtained in Experiments 9 and 10. After the electrolysis aliquot portions were analyzed for hydrazine; the results of the analysis showed that 0.1976 g. had been decomposed during the electrolysis, leaving in the solution 0.3024 g. unoxidized. The solution was then distilled until all HN_3 had been removed, was diluted again to a known volume and aliquot portions again analyzed. The results showed that all the remaining hydrazine had been consumed during the distillation.

These facts point conclusively to the persulfuric acid as the oxidizing agent, and explain why a stronger test for HN_3 can be obtained from a warm solution during the electrolysis than from the refrigerated one.

These conclusions fail to take into consideration the possible action of ozone and persulfuric acid on HN_3 . Until such a time when we shall understand the chemistry involved in a possible interaction of these substances, we can not say that HN_3 is not a product of the electrolytic oxidation of hydrazine in much greater amounts than indicated in our experiments, and that it is not destroyed almost as fast as formed by ozone or even by the persulfates.

It has been shown² in this laboratory that the oxygen evolved by the decomposition of persulfuric acid, theoretically and experimentally is both analogous and similar to that evolved against an insoluble anode in the electrolysis of a sulfate. Why the oxygen from the anode oxidizes hy-

¹ *Loc. cit.*

² Turrentine, *J. Phys. Chem.*, **11**, 623 (1907).

drazine to N_2 and that from the decomposition of persulfates oxidizes it only to hydronitrogens may be explained on the basis of the principles of mass action. The oxygen evolved against an anode is necessarily in contact with only the merest film of solution containing the oxidizable cations. The migration of the cations away from the anode would tend further to decrease their concentrations in this film. The conditions resulting are those of relatively high concentration of the oxidizing agent and low concentration of the substance oxidized, conditions suitable for complete oxidation. On the other hand, with persulfates in solution in low concentration and more slowly evolving oxygen and hydrazine in high concentration and with its concentration uninfluenced by migratory tendencies incited by the current, the conditions are the reverse of those existing at the anode—the oxidizing agent is present in low concentration and the reducing agent in relatively high concentration, thus affording conditions suitable for mild or incomplete oxidation.

The Electrochemical Oxidation of Ammonia to Hydrazine.¹

Raschig² obtained hydrazine as a product of the chemical oxidation of ammonia when he treated ammonium hydroxide, in 20% solution, with sodium hypochlorite, in normal solution, in the presence of glue. The proportions taken in a typical experiment were, 200 cc. of ammonium hydroxide, 100 cc. (normal) sodium hypochlorite, with 5 cc. of 1% glue solution.

Attempts were made to induce analogous reactions electrochemically by electrolyzing under various conditions solutions of ammonium hydroxide with ammonium or sodium chloride, and glue. The proportions taken were 200 cc. 25% ammonium hydroxide, 100 cc. normal ammonium chloride or sodium chloride, with 5 cc. 2% glue, a solution not widely differing from that employed by Raschig. The strength of the electrolyzing current was varied between 4.5 amperes and 0.3 ampere, the temperature between that of ice and of the boiling point of the solution, and the concentrations of the ammonium hydroxide and glue from zero to that indicated by the above statement of concentrations. These conditions, with either ammonium or sodium chloride, yielded no hydrazine detectable by Fehling's solution. Finally, with sodium chloride, when that solution was added slowly during the electrolysis, the formation of hydrazine took place. The conditions obtaining were as follows: Current strength, 0.3–0.4 ampere; temperature, 100°; strength of solution, that cited above. The sodium chloride solution was added gradually until it totaled 310 cc. To replace the ammonia lost through volatilization, additional volumes of the solution, likewise, were poured in from time to time, until its volume

¹ Experimentation by J. M. Olin.

² *Ber.*, 40, 4580–8 (1907); D. R. P. 198,307.

also totaled 310 cc. The experiments were repeated and the above observations duplicated.

Summary.

Hydrazine, in saturated solution of the sulfate, containing 10% by volume of concentrated sulfuric acid, is oxidized electrochemically to hydronitric acid when a high current density is maintained at the anode. The yield in hydronitric acid is greater when the solution undergoing electrolysis is held at a low temperature (0°). Since these are the conditions favoring the formation of persulfates, it is believed that the oxidation is the product of a secondary anode reaction, the action of the persulfate ion, a product of a primary anode reaction, on the hydrazine ion. The degree of oxidation has been determined.

Ammonium hydroxide, in the presence of sodium chloride and glue and with low current density, is oxidized electrochemically to hydrazine, provided the solution of sodium chloride is added in small amounts at intervals during the electrolysis.

A DESCRIPTION OF THE NEW COMPOUND, HYDRAZINE DIPERCHLORATE.¹

By J. W. TURRENTINE (with crystallographic notes by A. C. GILL).

Received November 14, 1914.

While perchloric acid is perhaps the most stable of the oxyacids of chlorine, yet it is a sufficiently strong oxidizing agent, especially in concentrated solution, to lend especial interest to a compound which it can form by union with so unstable and easily oxidizable a base as hydrazine. In even greater degree is this true of the salt formed from chloric acid and the base, hydrazine.

Actuated by such considerations, a research was undertaken in this laboratory, which was originally intended to embrace an investigation of the methods of preparation and the properties of the series of hydrazine salts, the mono-, and dichlorates, and the mono-, and diperchlorates. The work had progressed to a satisfactory stage, all four substances having been prepared and studied in varying degree and the two more stable ones, the perchlorates, having been purified and analyzed, when Salvadori² announced his complete research in an article replete with data on the more stable of both of the chlorates and perchlorates, the mono-salts. No further work has been done in this laboratory, therefore, on either of the compounds studied by him, though our probably more casual observations in some minor details do not coincide with those of the author referred to.

¹ A chapter from the thesis of the author submitted to the Faculty of Cornell University, May 1908, for the degree of Doctor of Philosophy.

² *Gazz. chim. ital.*, 37, 32 (1907).

Salvadori prepared hydrazine monochlorate by treating a solution of chloric acid of known concentration with such a volume of a solution of hydrazine hydroxide as contained an amount of the base equivalent, molecule per molecule, to the chloric acid. After evaporation to an oily consistency over sulfuric acid, the salt was precipitated from the solution by the addition of alcohol and was washed with absolute alcohol. Laminated crystals were obtained. These were shown to be soluble in water, less soluble in alcohol and insoluble in ether, benzene, and chloroform. The salt proved to be instable and easily explosive on being subjected to a percussion.

The monopерchlorate of hydrazine was obtained in crystalline form directly from evaporation on the water bath. It crystallizes from water with one-half molecule of water of crystallization. It melts at $131-2^{\circ}$; at 13° water dissolves 67.56% by weight of the salt. The compound was further studied with a view to its explosibility, its rate of decomposition being determined. The explosion of this compound, when induced by percussion, is said to be equal to that of the perchlorate in violence.

Hydrazine Dichlorate.—This compound was prepared by treating a solution of hydrazine disulfate with the theoretical amount of barium chlorate in solution, the reaction taking place in agreement with the equation,

The barium sulfate was removed by filtration. The filtrate was subjected to qualitative tests for both sulfate and barium and was found to be free from these two most probable impurities. Portions of this solution were then evaporated *in vacuo* over concentrated sulfuric acid, the temperature of the solution being maintained most of the time at 0° , or below. On the appearance of crystals in the concentrated solution, decomposition began to occur with the evolution of chlorine gas and continued with accumulating rapidity, finally resulting in the entire destruction of the hydrazine compound present. When the crystallization was allowed to take place under the microscope, a similar decomposition took place so that the compound could not be further studied there. Attempts to study the crystallized compound were not made.

Hydrazine Diperchlorate.—Hydrochloric-acid-free perchloric acid was obtained on treating a solution of perchloric acid contaminated with hydrochloric acid, a decomposition product, with a solution of silver perchlorate. The latter was prepared by dissolving silver carbonate in perchloric acid; it was added titrimetrically to the impure acid until the last drop produced no further precipitation of silver chloride. By means of the purified acid a solution containing 13.5 g. of barium hydroxide, $\text{Ba}(\text{OH})_2 \cdot \text{H}_2\text{O}$, was neutralized and was then treated with the theoretical amount of hydrazine sulfate, 5.56 g. $\text{N}_2\text{H}_4 \cdot \text{H}_2\text{SO}_4$, in solution to form

hydrazine diperchlorate. After filtering to remove barium sulfate and after testing the solution for traces of sulfate and barium, the solution was evaporated to crystallization.

In the earlier part of this work the solutions of the diperchlorate were evaporated in desiccators over concentrated sulfuric acid and under reduced pressure. But when it was found that the substance was so stable as to permit it, the evaporations were conducted more expeditiously on the water bath, or on steam coils with the aid of an air blast. When evaporated in this way until crystallization begins to take place and then cooled the entire mass becomes solid with laminated crystals. If evaporated more slowly, beautiful, brilliant plates may be obtained.

Hydrazine diperchlorate crystallizes with two molecules of water of crystallization. This was determined by desiccating *in vacuo* over sulfuric acid, until there was no further change in weight, a carefully weighed sample of the crystals which previously had been allowed to come to constant weight in the open air of a dry, steam heated room. Table I gives the figures obtained.

TABLE I.

1.....	0.1065	0.0136	12.77	13.35
2.....	0.1499	0.0190	12.65	13.35

Upon dehydration the crystals effloresced. The effloresced salt, however, did not regain its water of crystallization when again exposed to the open air of the laboratory. It is probable, therefore, that the low results were due to a partial dehydration of the crystals before they were transferred to the desiccators.

Analysis.—The nitrogen content of the diperchlorate was determined by the method described by Rimini.¹ The samples for analysis were dissolved in about 25 cc. of water in tall, narrow mouthed Erlenmeyer flasks. An excess of a standard solution of potassium iodate was then run in from a buret. After boiling off the liberated iodine, the solution was cooled and was mixed with 15 cc. 1 : 4 sulfuric acid. Sufficient potassium iodide in crystalline form was then added to completely decompose the excess of iodate and also to dissolve readily the liberated iodine; thereupon the free iodine was rapidly titrated, with starch solution as indicator, with a standard solution of sodium thiosulfate.

Chlorine was determined in the perchlorate by the following method: A weighed sample of the salt was transferred to a platinum crucible and was intimately mixed with ten times its weight of pure, chlorine-free sodium carbonate. On account of the difficulty of mixing the dry crystals of the salt with the sodium carbonate and the danger of an explosion on grinding the salt in a mortar, the crystals, after being transferred to the crucible, were dissolved in a drop of warm water and the sodium carbonate was added all at once so as to absorb immediately all the solution and thus prevent any loss of it by the rapid effervescence which took place on adding the carbonate to the acid perchlorate solution. The carbonate with the absorbed perchlorate could then be mixed easily with a stirring rod. After covering the crucibles tightly, they were heated on a sand bath for several minutes to drive off the excess moisture from the contained carbonates and were gradually heated to bright redness over Bunsen flames. The crucibles and fused mass, while still hot, were plunged into cold water in a beaker, to loosen the mass from the crucible and were heated on the sand bath until the fused substance had completely dissolved. The resulting solutions were then made slightly acid with nitric acid, the chlorine was precipitated with silver nitrate in slight excess, more nitric acid was added, and the solutions were boiled. The silver chloride was filtered, dried and weighed on a Gooch filter. In Table III are given the results obtained, calculated on the basis of the hydrated salt containing two molecules of water of crystallization.

Analyses were also made of the anhydrous salt. These are shown in Table IV.

These results established a formula for hydrazine diperchlorate as $N_2H_4 \cdot 2HClO_4 \cdot 2H_2O$.

Hydrazine diperchlorate is not only efflorescent but is also deliquescent. In moist air it takes up water rapidly and dissolves in it. A portion of 0.079 g. exposed to the open air, gained in three and one-half hours 0.48 g. in fifteen and one-half hours, 0.53 g. of absorbed water.

Its solubility is indicated by the following figures determined without

the use of the more refined methods: At 29° , 100 parts of water dissolve 102 parts of the hydrated salt. Solution in water takes place with an absorption of heat. In absolute alcohol, 2.8 parts are soluble in 100 parts of the solvent; in ether, about 1 part is soluble in 100 parts of the solvent. It was not determined whether the salt which crystallized from absolute alcohol was the anhydrous or the hydrated diperchlorate, or the monoperchlorate.

Considerable difficulty was encountered in determining the true melting point of hydrazine diperchlorate. When this operation was conducted in capillary melting point tubes, incipient fusion took place at 95° . But so gradual was the change from the solid to the liquid condition, and so marked was the decomposition before the distinctly molten condition had been reached, that it is not safe to say at what temperature the pure salt actually melts.

Crystalline Structure.—Professor A. C. Gill, of the Department of Geology, Cornell University, has had the very great kindness to make a crystallographic examination of both the mono- and the diperchlorate of hydrazine.

The diperchlorate forms colorless, tabular crystals which are shown by their optical behavior to be orthorhombic.

The acute bisectric emerges exactly normal to the large faces, and extinction is parallel to the longer sides. The substance is optically negative with an optical angle of 30° to $40^{\circ}(?)$ and remarkably strong dispersion of the optical axes.

On attempting to extend and verify these observations two or three weeks later, only crystals of the monacid salt could be found. (As the platinum wire with which they were taken out had also been used with the monacid salt, it is possible that the change may have been in a measure induced by the presence of that compound.) An examination of the crystals of the monoperchlorate showed that they were probably monoclinic. The somewhat elongated tablets showed the oblique emergence of one axis of a negative biaxial interference figure, with large optical angle. The plane of the optical axis is the clinio-pinacoid. Like the diacid compound, the double refraction is strong, but the dispersion is not marked. In the prism zone, the following angles were observed (in the sequence given), starting from the large tabular face: $49^{\circ} 10'$, $57^{\circ} 20'$, $38^{\circ} 50'$, $19^{\circ} 30'$, and $15^{\circ} 10'$.

Other Properties.—The diacid salts of hydrazine exhibit strong acid properties. Bach¹ has shown that the dichloride of hydrazine produces the inversion of cane sugar in the same way as does hydrochloric acid in the presence of a chloride. This salt in dilute solutions yields 4 ions.

¹ *Z. physik. Chem.*, 9, 258 (1892).

Stolle¹ suggests the use of the disulfate for standardizing solutions of caustic alkalis. On titration, the disalts go over into the monosalts, as indicated by the equation,

Curtius² makes use of this fact to determine titrimetrically hydrazine hydrate with standard sulfuric acid. His statement of the reaction by the equation,

however, is manifestly incorrect, as Stolle's work, as well as numerous titrimetric determinations of hydrazine hydrate in this laboratory, show. The hydrazine disulfate, being largely hydrolyzed in aqueous solution, indicated as the final product in the reaction represented in Curtius's formula, must needs give an acid reaction to indicators. One must, then, necessarily regard this error in the paper of Curtius's as simply an oversight, especially as, when one examines his calculations, it is seen that actually they are not based on this equation, but rather on the equation,

which is the correct one.

In Table V are given the results of a comparison of the methods of Curtius and Rimini when applied to the analysis of anhydrous hydrazine. These analyses were made incidentally in a different research and are used here in substantiation of the preceding statements. The figures in Col. 1 are arrived at from calculations based on Curtius's equation, those in Col. 2, on the corrected equation as given above, and those in Col. 3, are obtained from calculations based on Rimini's iodate method. Each sample of the anhydrous hydrazine served for two analyses. The weighed samples of the anhydrous substance were dissolved in water and titrated with standard acid. On the same solution was then conducted an analysis by the method of Rimini.

¹ *J. prakt. Chem.*, [2] 66, 332-8 (—).

² *Ibid.*, 42, 521 (1890).

An examination of the hydrazine dichloride, dichlorate and diperchlorate revealed the fact that these salts also are susceptible of titration with solutions of alkali, methyl orange being used as indicator, and of being thereby quantitatively determined, as was shown by Stolle to be the case for the disulfate. Hydrazine diperchlorate also dissolves carbonates with the evolution of carbon dioxide. The dichloride on heating to 180° gives up quantitatively one molecule of its acid,¹ thus resulting in the monochloride. The diperchlorate probably possesses the same property, this surmise being founded on the observation that in a vacuum desiccator and over sulfuric acid the diperchlorate exhibits a marked vapor pressure of perchloric acid, the desiccator becoming filled with the vapor of this acid.

While the pure and dry hydrazine diperchlorate seems to be quite stable, the impure salt, after standing for several months at room temperature, deteriorates, and becomes discolored, assuming a yellow hue. In solution a gradual loss of perchloric acid occurs and crystals of the monoperchlorate form.

The substance, on being struck with a metal hammer, explodes with a loud report.

A METHOD FOR THE TITRATION OF SMALL AMOUNTS OF HALIDES.

BY FRANKLIN C. MCLEAN AND DONALD D. VAN SLYKE.

Received March 5, 1915.

The accuracy, convenience, and wide applicability of the Volhard method for titration of halides has made its use nearly universal. The fact that 1 drop, or about 0.05 cc., of 0.1 *N* solution is required to give the color change satisfactorily at the end point, however, makes it necessary to have under ordinary conditions at least 0.5 milligram molecule of halide, equivalent to 5 cc. of 0.1 *N* silver nitrate, in order that the accuracy of the titration may be within 1%.

The necessity for an accurate means of determining chlorides in small amounts has forced us to seek a titrimetric method with a more sensitive end point, so that less material than is required by the Volhard method may be analyzed with equal percentage accuracy. An iodometric method, with a manipulation almost identical to that of the Volhard titration, proved thoroughly practicable. Like the Volhard, it permits titration in an acid solution, and requires the use only of stable standard solutions, while because of the more sensitive color change it permits one to use

¹ Curtius, *J. prakt. Chem.*, [2] 39, 27 (1889).

0.02 *N* or 0.01 *N* standard solutions and still obtain the end point with one drop. Without sacrificing the accuracy or convenience of the Volhard method, it therefore reduces by about 80% the amount of material required for analysis.

Iodometric determination of chlorides appears to have been first attempted by Pisani,¹ who used a dilute starch-iodine solution to titrate the excess of silver left after precipitation of the chloride with standard silver nitrate solution. Starch-iodine is not stable, however, and consequently the method does not appear to have proven practical. Bang² overcame this disadvantage by utilizing, in place of the starch-iodine, a standard solution of potassium iodide containing a small proportion of potassium iodate. The chloride was precipitated with an excess of standard silver solution containing free nitric acid, the filtrate treated with an excess of the iodide-iodate solution (of about 0.01 *N* conc.), and the excess titrated back with more of the standard silver. A disadvantage of this method is that one can titrate accurately in only one direction; an excess of the iodide-iodate mixture must be added, so that the iodine of all the iodate and of a corresponding amount of iodide is transformed into free iodine ($\text{HIO}_3 + 5\text{HI} = 6\text{I} + 3\text{H}_2\text{O}$). If in titrating one adds the iodine mixture to the silver, the proportion of iodate that is decomposed before the iodide is precipitated depends somewhat on the manner in which the iodine mixture is added, *i. e.*, rate of addition, manner of shaking, etc. It is therefore a drawback that the oxidizing agent used to liberate the iodine of the iodide contains in its own molecule iodine which may also be liberated in the elementary condition. Another drawback to the utilization of the method as described by Bang is the device used to render possible the filtration of the colloidal silver chloride formed in the high dilutions used. The solution containing the precipitate is shaken with kaolin, which adsorbs the silver chloride and gives a clear filtrate. Unfortunately, however, it also adsorbs part of the excess of silver nitrate present. The error introduced by this action was recognized by Bang, who made a correction for it, based on the average amount of silver adsorbed in blank experiments. The necessity for this correction, however, which is not an exact one, makes it impossible to class the method with Volhard's for accuracy. A third disadvantage of Bang's method lies in the titration in the presence of quite concentrated nitric acid, which interferes with the formation of the starch-iodine, and therefore obscures the end point.

The method described below was developed as the result of an attempt to utilize Bang's method. It is similar in principle to the latter (titration with iodide in the presence of an oxidizing agent) but free from the three weaknesses pointed out in the preceding paragraph.

¹ Quoted by Bang, *Biochem. Ztschr.*, 1913, XIX, 33.

² *Loc. cit.*

1. Nitrous, instead of iodic acid, is utilized to free the iodine from the iodide added, so that the possibility of error resulting from incomplete decomposition of iodic acid is eliminated, and one can titrate in either direction. This enables us to simplify the procedure by the elimination of one step, *viz.*: addition of excess of iodide after precipitating the unknown amount of chloride or bromide. As we can now titrate, adding iodide solution to silver, as well as *vice versa*, we need only to filter off the silver bromide or chloride, and titrate the excess of silver in the filtrate directly with standard iodide solution.

2. The use of kaolin or any other adsorbent to make the silver chloride filterable has been rendered unnecessary by utilization of caprylic alcohol to cause coagulation of the colloidal precipitate. This alcohol has a remarkable ability to reduce the surface tension of aqueous solutions, and has been used for some years in this laboratory to prevent foaming of solutions in various operations. Ether has a similar effect of reducing surface tension, although to a less marked extent, and Rothmund and Burgstaller¹ showed that shaking a solution of colloidal silver chloride with ether accelerated the coagulation in the Volhard procedure. Ether did not prove practicable in our case, for its presence interfered with the sensitiveness of the end reaction. Caprylic alcohol, however, is even more efficient, and does not interfere. One adds two or three drops of the alcohol to the solution containing freshly precipitated silver chloride or bromide and shakes vigorously for a few seconds. This treatment coagulates the precipitate to such an extent that it can be collected on an ordinary folded filter, and gives a perfectly clear filtrate. The first few drops that pass through a dry filter are sometimes cloudy, but if they are passed through a second time a clear filtrate is obtained. In fact the filtrates we usually obtained from a silver chloride coagulated with caprylic alcohol were so clear that the turbidity determined with Richard's nephelometer exceeded to a barely detectable degree that of the silver nitrate solution in the dilution used.² In control tests with the nephelometer we could detect 0.1 mg. of NaCl added to a slight excess of silver solution in a liter of water.

3. The addition of a "buffer salt" is utilized in order to give the slight degree of acidity necessary for the sharpest end point. In most cases it is convenient or necessary to precipitate the silver halide in nitric acid solution. When the excess of silver is titrated back with iodide, the presence of free nitric acid in even moderate concentration seriously interferes with the end point. The starch does not, until a considerable excess of iodine is present, combine appreciably with it in strongly acid

¹ *Z. anorg. Chem.*, **63**, 330 (1909).

² Caprylic alcohol can also be used to advantage in gravimetric determination of chlorides to facilitate coagulation of the silver chloride.

solution, and consequently the end point obtained is the yellow-brown color of free iodine, which is much more difficult to detect than the blue of the starch compound. The difficulty is obviated by adding an amount of trisodium citrate, equivalent to the free nitric acid present, before the titration is begun. The amount added may vary 10% above or below an exact equivalent without affecting the end point. A solution containing one molecule of potassium acetate to three of acetic acid may also be used, but the citrate solution appears to give the clearer end point.

Description of the Method.

The halide is precipitated in the presence of a known amount of free nitric acid, preferably about one gram, with an excess of 0.04 *N* or 0.02 *N* standard silver nitrate solution. In the case of bromides and chlorides the silver halide is removed by filtration, after coagulation of the colloid precipitate has been accomplished by shaking the mixture for a few seconds with one or two drops of caprylic alcohol. In case a dry filter is used it may be necessary to pass the first portion of the filtrate through a second time in order to make it perfectly clear.

In either the entire filtrate, washed through the filter, or in an aliquot part, passed through a dry filter, the excess of silver is titrated with 0.02 *N* or 0.01 *N* potassium iodide, which has been standardized against the silver solution.¹ Just before titration one adds from a buret for each gram of free nitric acid present (one gram approximately, or 16 mg. molecules, is contained in 1 cc. of nitric acid of 1.42 specific gravity) 4 cc. of the following solution:

Trisodium citrate, $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 + 5\frac{1}{2}\text{H}_2\text{O}$	446.0 g.	{ 5/4 gram-molecules or 15/4 equivalents
Sodium nitrite.....	19.0	
Soluble starch.....	2.5	
Water to.....	1000.0 cc.	

One cc. of this solution contains four milligram-equivalents of sodium. The solution, because of its nitrite, serves to liberate iodine; the citrate regulates the acidity of the titrated solution; and the starch is present for the end reaction. Under the above conditions one obtains, with one drop of 0.02 *N* iodide, a very sharp color change, that can be seen in 150 cc. of solution, and is, of course, still more striking in a smaller volume. It is preferable, though not necessary, to keep the volume of the filtrate to be titrated within 50 cc.

The removal, by filtration, of silver chloride or bromide before titrating back with iodide is necessary, because iodine forms a much more insoluble silver salt than either of the other halogens. It reacts with their precipi-

¹ The accuracy of the silver nitrate solution can be checked by titration against 0.01 *N* or 0.02 *N* hydrochloric acid prepared from redistilled acid by the method of Hulett and Bonner, *THIS JOURNAL*, 31, 390 (1909).

tates ($\text{AgCl} + \text{HI} = \text{AgI} + \text{HCl}$) so rapidly that the slight amount of iodine necessary to give the end point is removed from solution in a few seconds by freshly precipitated silver chloride or bromide. This is true for both chlorides and bromides in strongly acid solution. When the acidity is depressed by the addition of sodium citrate as described above, the change still occurs so rapidly with chlorides that no end point with iodide can be obtained. In the case of bromides a sharp end point is obtained that persists for a short time. The amount of iodide necessary to produce this end point is slightly in excess of the correct amount, so that in order to obtain exact results filtration of the bromide precipitate also is necessary (Tables III and IV). When, in either case, the titration is performed after removal of the silver halide precipitate, the end point produced with one drop of excess of iodide lasts for hours, and in fact seems to intensify with time. For reasons similar to the above, *i. e.*, the relative insolubility of silver thiocyanate compared with silver chloride, it is necessary to remove the silver chloride in the Volhard titration in order to obtain the most satisfactory results.¹ Filtration is, of course, unnecessary in the determination of iodides by our method.

Experimental.

Our standard solutions were based on: (1) the constant boiling hydrochloric acid described by Hulett and Bonner² and (2) special "Reagent" metallic silver, which was dissolved in a slight excess of nitric acid. Hulett and Bonner claim a composition constant within one part in 10,000 for the acid distilled by their method, and we have in several years' use of it never found an appreciable variation from their values. The solution used in this case was distilled at 760 mm. atmospheric pressure, so that, according to Hulett and Bonner's table, 180.17 g. contained one gram molecule of HCl .³ The standard solutions made by weight from this acid and from the "Reagent" silver foil checked each other within one part per thousand when titrated by Volhard's method, with filtration of the silver chloride.

The bromide solutions were made by weight from pure potassium bromide, and standardized by careful titration against the silver solution by Volhard's method. As there was no detectible impurity, the salt was not recrystallized.

The potassium iodide solution used was of $M/58.5$ concentration. It was prepared originally for determination of sodium chloride (1 cc. $M/58.5$ $\text{NaCl} = 1$ mg.) and standardized by titration against the silver solutions.

² *Loc. cit.*

³ Gravimetric determinations gave the following results: 2.1802 g. HCl solution, 1.7350 g. AgCl ; 2.1792 g. HCl , 1.7348 g. AgCl ; g. HCl solution calculated to contain 36.46 g. of HCl , 180.17 and 180.12.

For the determinations of Tables I and III the precipitated and coagulated chloride or bromide was washed several times by decantation, then several times on the filter, with water at room temperature, and the entire filtrate was titrated. For Table II aliquot parts were taken, as indicated.

4.00	2.00	2.10	2.593	2.668	—0.075	—2.8
5.00	2.00	1.58	3.305	3.335	—0.030	—0.9
5.00	2.00	1.58	3.305	3.335	—0.030	—0.9
10.00	4.00	3.18	6.580	6.670	—0.090	—1.35
10.00	4.00	3.20	6.555	6.670	—0.115	—1.70
25.00	7.00	2.10	16.250	16.690	—0.440	—2.6
25.00	7.00	1.92	16.500	16.690	—0.190	—1.1

From inspection of Tables I, II and III it will be seen that the titration error exceeds 0.05 cc. (1 drop) of the *M*/58.5 KI solution, equivalent to 0.03 mg. Cl or 0.07 mg. Br, only when the amounts titrated are so large that this error falls within or near the 1 pro mille limit. In most cases where small amounts were analyzed, the results indicate that the absolute error was within half a drop.

The percentage error ranges from a maximum of 3% in analyses of the smallest amounts, 0.7 mg. Cl and 2.6 mg. Br, down to 0.1% towards the other end of the scale, where amounts up to 70 mg. of Cl and 33 mg. of Br were determined.

Summary.

A method for titration of halides is described which permits utilization of the starch-iodine color for the end point. Because of the sensitiveness of the color change under the conditions ascertained, and the simplicity of the manipulation, amounts of halide no greater than 0.5 mg. molecule can be determined with an accuracy of one part per thousand.

THE OXIDATION OF SULFIDES WITH POTASSIUM IODATE.

By REGINALD S. DEAN.

Received February 22, 1915.

L. W. Andrews¹ has shown that in solutions containing 50% by volume, or more, of concentrated hydrochloric acid at the end of the titration, potassium iodate may be used as an oxidizing agent, and that under such conditions the iodine, which is at first liberated by the reduction of iodate, is finally completely converted into iodine chloride, ICl, and the end of the titration can be shown by the disappearance of the iodine color in

¹ THIS JOURNAL, 25, 756 (1903).

some chloroform which is mixed with the liquid to be titrated. This method has been applied to the determination of copper,¹ antimony,² mercury,³ hydrazine⁴ and lead peroxide.⁵ Not the least striking of the advantages of the method is its applicability in the presence of solid material and organic matter such as filter paper. This made it seem not improbable that the method could be extended to the determination of sulfides, especially where the sulfide is easily washed without oxidation, as is the case with arsenic and antimony. We would expect the reaction to proceed according to one of the following equations:

we have found that the amount of iodate solution required for the oxidation of cadmium, zinc and lead sulfides does not correspond to either of these equations, but instead, $\frac{1}{3}$ of the sulfur is oxidized to sulfuric acid, while $\frac{2}{3}$ is liberated as free sulfur in accordance with the equation

When a smaller proportion of hydrochloric acid is present, however, the amount of iodate corresponds more nearly to the first equation.

Experimental.

(a) **Cadmium.**—Cadmium sulfide was chosen to work with since it is comparatively easy to wash without oxidation and is easily soluble in hydrochloric acid. Ten cc. of 0.1 molar cadmium sulfate solution was precipitated with H_2S , the precipitated sulfide was filtered and washed free from H_2S and then the filter and contents were placed in a bottle containing nearly the required amount of iodate and hydrochloric acid. The liberated iodine was titrated with iodate, using chloroform or carbon tetrachloride as indicator. If an excess of iodate was used it was titrated back with standard iodide. The results were as follows:

Cadmium sulfide used was 0.144 g. = 1 millimol.

Concentration of HCl (% by vol.)	10	15	30	40	75	75	75	80
Cc. 0.05 M KIO_3	10	10.1	14.2	17.5	19.8	20.0	20.1	19.9
Concentration of HCl (% by vol.)	80	96						
Cc. 0.2 M KIO_3	4.95	5.00						

The acid concentrations are calculated on the volume after titration.

From the above results we see that, in solutions containing 10–15% concentrated acid, the reaction proceeds as represented in Equation 1; below this concentration difficulties are encountered in dissolving the sulfide

¹ Jamieson, Levi and Wells, *THIS JOURNAL*, 30, 760 (1908).

⁴ Jamieson, *Ibid.*, 33, 349 (1912).

⁵ R. S. Dean, *Chem. News*, 111, 2 (1915).

and in the hydrolysis of the iodine chloride; with increasing concentration of acid, the consumption of iodate increases and reaches a maximum when the ratio of iodate to sulfide is 1:1, as represented by Equation 3, according to which only one-third of the sulfur is oxidized to sulfuric acid.

In order to test this last assumption, four solutions from the above titrations, two of 75% acid, and one each of 80% and 96% acid, were filtered from the filter paper, sulfur, etc., and, after boiling off the HCl and ICl, were precipitated with barium chloride, the barium sulfate being weighed and calculated to sulfur. The results were as follows:

Cadmium sulfide used = 0.1444 g. = 0.0321 g. sulfur.

Concentration of HCl (% by vol.).	75	75	80	96
Sulfur found as H ₂ SO ₄	0.0106	0.0110	0.0103	0.0109

It will be noticed that the sulfur oxidized to H₂SO₄ is, within the experimental error, exactly one-third of the total sulfur.

(b) **Zinc.**—We would expect zinc sulfide to oxidize exactly as the cadmium and we find that such is the case; only two concentrations of acid were used. The zinc was precipitated from a formic acid solution and treated exactly as the cadmium. The zinc solution used was of such strength that, oxidizing according to Equation 1, 25 cc. of 0.05 molar iodate would be required, while oxidizing according to Equation 3, 50 cc. would be required. The results were:

Concentration of HCl (% by vol.).....	15	15	15	65	65	65	65
Cc. 0.05 M iodate.....	25.4	25.2	24.8	49.8	50.2	50.5	49.8

(c) **Lead.**—Lead sulfide was precipitated from a solution of known strength, filtered, washed, and titrated in the same manner as the zinc and cadmium. The concentration of acid used was about 75%. The sulfide was of such an amount that if oxidized according to Equation 3, 24.0 cc. of 0.05 M iodate would be required. The results were 23.9, 24.0, 24.0, 24.2, respectively.

(d) **Antimony.**—Antimony was chosen as a representative of the sulfides, in which the metal shows two states of oxidation. From our work on cadmium we would expect that antimony would be oxidized at low concentrations according to the equation

while with increasing concentration it would approach and finally reach the reaction represented by the following equation:

That the above gives the correct ratio is shown by the following results:

The antimony was precipitated from 10 cc. of a 0.1 molar solution of potassium-antimonyl tartrate and treated exactly as was the cadmium; the reaction proceeding according to Equation 4 would require 25 cc.

0.05 molar iodate while according to (5) it would require 40 cc. The results were as follows:

Conc. of HCl (% by vol.).....	26	31	36	40	60	65	70	90
Cc. 0.05 <i>M</i> KIO ₃	26.2	28.2	29.6	32.2	40.4	39.9	40.2	40.0

The above results show, as with the cadmium, that with maximum oxidation only one-third of the sulfur is oxidized to sulfuric acid; they do not show the minimum found with cadmium, as the insolubility of antimony sulfide makes it inconvenient to work in the less concentrated solution.

(e) **Arsenic.**—As L. W. Andrews explicitly states, with higher concentrations of hydrochloric acid no oxidation of arsenic takes place. We would naturally predict then that only the sulfur from the arsenious sulfide would be oxidized, thus:

The results with arsenious sulfide showed, however, only $\frac{2}{3}$ of the iodate called for by this equation; no satisfactory explanation has been found for this result.

10 cc. of an 0.08 *M* solution of arsenious chloride was precipitated as sulfide and titrated with 0.05 *M* iodate with about 80% concentrated acid. The iodate required according to Equation 6 would be 24.0 cc. The iodate consumed was 16.0, 16.0, 16.3, 16.0, respectively. Whether this apparently exact ratio of 2 iodate to 1 arsenic sulfide is accidental or not we have not determined, because the insolubility of the sulfide limits the applicable concentration to practically pure acid.

This work was done under the direction of Prof. U. H. Gottschalk.

MISSOURI SCHOOL OF MINES,
ROLLA, MO.

THE DETERMINATION OF BORON IN IRON.

By J. M. LINDGREN.

Received March 12, 1915.

The present work has had to deal with the determination of small percentages of boron in iron. Two procedures have been tried. First, the well-known method of Gooch,¹ which consists in the formation of methyl borate and distillation of the ester in a properly arranged apparatus, with recovery of the boron in the form of calcium borate. The complications involved in this method are accentuated by reason of the large quantity of iron oxide and the fact that distillation must be repeated at least six times.

The other method made use of is that proposed by Wherry² which involves titration with alkali of the boric acid in the filtrate obtained

¹ *Am. Chem. J.*, 9, 23 (1887).

² *THIS JOURNAL*, 30, 1687 (1908).

after precipitating the iron. The application of this method to the present problem made it necessary to determine whether it is possible to recover the relatively small amounts of boric acid in the presence of large amounts of ferric hydroxide. After considerable experimentation this was found to be entirely feasible without departing in any marked degree from the principles involved in the method as set forth by Wherry. The details of the procedure are as follows:

Two to three grams of iron are dissolved in a round-bottomed Jena flask of about 800 cc. capacity, using 10 cc. each of nitric acid (sp. gr. 1.4), hydrochloric acid (sp. gr. 1.2), and water. When the action is completed the solution is cooled to room temperature and the iron precipitated by use of C. P. calcium carbonate. If not properly carried out this precipitation may result in the formation of colloidal hydrate. It will be noted that the volume of the solution is approximately 30 cc. If to this solution there is added, all at one time, approximately double the amount of dry calcium carbonate necessary for complete neutralization, and the mixture is stirred by vigorous agitation, a pasty or solid mass results, which, upon the addition of hot water, yields ferric hydroxide in the form of a dark brown and very granular precipitate. Two hundred and fifty to three hundred cc. of carbon-dioxide-free water are added and the mixture is boiled under a reflux condenser for at least 30 minutes to assure entire absence of carbon dioxide or bicarbonate.

Before filtering, and in order to still further open up the precipitate to admit of thorough washing, there is now added a considerable quantity of asbestos fiber which has been well washed. A good method for preparing the asbestos is to digest over night on the steam bath a considerable quantity in dilute hydrochloric acid. This should be well washed and suspended in boiling water. The fiber is added wet to the precipitated iron, the amount needed in each process being approximately 50 cc. in bulk, sufficient to thoroughly impregnate the precipitated iron. After boiling the mixture for a few minutes the precipitate is filtered at once by suction through a Büchner funnel, about 15 cm. in diameter, having a double thickness of filter paper carefully fitted over the bottom. A splash trap is connected to the receiving flask. The precipitate should be washed 8 or 10 times with boiling hot water. The funnel is then removed and replaced by a solid rubber stopper. By renewal of the suction, further ebullition is produced in the flask without addition of more heat. The solution is then cooled and titrated as follows with 0.1 *N* alkali (free from carbonate). After addition of a few drops of phenolphthalein, alkali is added until a pink color appears. One gram of mannite is next added, and the titration continued until a permanent pink color is obtained.¹ Familiarity with the end point is attained by practice. A blank should

¹ For details of the reactions see *THIS JOURNAL*, 30, 1699 (1908).

be carried through using pure iron and following the process exactly as described.

In testing the accuracy of the method, 0.1 *N* solution of boron was prepared by dissolving 3.5 g. of B_2O_3 in one liter of CO_2 -free water. The B_2O_3 was prepared by fusing pure boric acid in a platinum dish. When titrated in the presence of mannite, 8.68 cc. of this B_2O_3 solution required 8.75 cc. 0.1 *N* KOH. Known quantities of this boric acid solution were added to a solution of iron free from boron and the operations were carried out as indicated. Contrary to the experience of Wherry, when the precipitation by use of calcium carbonate was properly carried out, it was found possible to wash the iron entirely free from boric acid and recover the full amount in the filtrate. The use of the boric acid solution made up of the pure fused material as above described also served admirably as a medium for standardizing the alkali used in the titrations.

URBANA, ILL.

CHEMICAL REACTIONS AT LOW PRESSURES.¹

BY IRVING LANGMUIR.

Received March 31, 1915.

In the course of investigations into the causes of the blackening of tungsten lamps,² the effects produced by the introduction of low pressures of various gases have been studied in considerable detail.

It had been previously known³ that the vacuum in a lighted tungsten lamp normally improves during the life of the lamp, but it was thought that this removal of the residual gases⁴ was brought about by electrical discharges in much the same way as that commonly observed in Geissler and Roentgen ray tubes. These experiments have shown, however, that a highly heated tungsten filament will cause the disappearance or clean-up of nearly any gas introduced into the bulb at low pressure, and that this action, in the great majority of cases, is purely chemical in nature.

The experimental methods that have been employed in these investigations are relatively simple. A bulb containing one or more short filaments, usually of tungsten, was sealed to an apparatus consisting essentially of a mercury Gaede pump, a sensitive McLeod gage for reading the pressures, and an apparatus for introducing small quantities of various

¹ Paper presented before the New York Section of the American Chemical Society, March 5, 1915.

² *Trans. A. I. E. E.*, **32**, 1913 (1913).

³ *THIS JOURNAL*, **35**, 107 (1913).

gases into the system and for analyzing the gas residues obtained in the course of the experiments.

By means of the pump, the pressure in the system could be lowered to 0.00002 mm. of mercury. The McLeod gage gave a reading of one millimeter on the scale for a pressure of 0.000007 mm. of mercury. By means of the apparatus for analyzing gas, a quantitative analysis of a single cubic mm. (at atmospheric pressure) of gas could be carried out, determining the following constituents: hydrogen, oxygen, carbon dioxide, carbon monoxide, nitrogen and the inert gases.

The apparatus by which this has been accomplished has been in almost daily use for over five years, and during that time a very large number of reactions have been studied by its aid. In a typical experiment, after having thoroughly exhausted the whole apparatus, a small quantity, usually 5-20 mm. of gas, is introduced and the filament is electrically heated to a definite temperature, while readings of the pressure are taken at regular intervals (usually one minute). By plotting the pressure readings against the time, a curve is obtained which clearly shows how the rate of clean-up varies with the pressure.

A series of such curves are prepared with different filament temperatures and with various other changes in the conditions which I shall describe later.

In this way we have studied the clean-up phenomena with many different gases and several different kinds of filaments. Most of the work has been done with tungsten filaments, but, in order to get a broader outlook over the field of low-pressure reactions, filaments of carbon, molybdenum, platinum, iron, palladium, and other metals have also been tried. The principal gases studied have been oxygen, nitrogen, hydrogen, carbon monoxide and dioxide, chlorine, bromine, iodine, methane, cyanogen, hydrochloric acid, argon, phosphine, and the vapors of many substances, such as mercury, phosphorus pentoxide, sulfur, etc.

With each of these gases, conditions can be found, under which a heated tungsten filament will cause the clean-up of the gas. The curves obtained in the course of the experiments have furnished very complete data for a study of the kinetics of the reactions involved.

It has long been generally recognized that the kinetics of gas reactions afford the best, if not the only means of studying the mechanism of reactions, and the literature of recent years shows that the velocities of many reactions have been investigated with this end in view.

Very few experimenters, however, have realized that by working with gases at extremely low pressures the experimental conditions may be enormously simplified and the velocity of the reaction is then much more intimately related to the behavior of the individual molecule than it is at higher pressures.

In fact, by working continually with gases at these low pressures, one soon acquires an entirely new view-point and sees almost daily fresh evidences of the atomic and molecular structure of matter. The kinetic theory of gases then becomes the great guiding principle. According to this view-point, the velocity of a reaction is a matter of statistics. The question becomes: Out of all the gas molecules which strike the surface of heated filament, what fraction enter into reaction with it?

This statistical view-point has become prevalent among physicists within the last few years. Without it, the tremendous advances in our knowledge of radioactivity, electric conduction through gases, applications of the quantum theory, etc., would have been impossible.

In the field of chemistry, however, only a very small beginning has been made. Chemistry was the first of the sciences to make use of the atomic theory, and, in fact, the history of chemistry in the last century shows that the great advances in both inorganic and organic chemistry were largely dependent on this theory.

The development of physical chemistry, however, took place along rather different lines. The remarkable progress which occurred from 1870 to 1900 was, in a large degree, based upon the applications of thermodynamics to chemistry. Gradually, the idea became prevalent that the atomic theory was only a working hypothesis and might perhaps profitably be dispensed with entirely. The energy relations of reactions, on the other hand, were considered to be of the most fundamental importance. Just about the time that the majority of physical chemists had been won over to this view-point the physicists began to discover absolute proofs of the existence of atoms and molecules and soon showed what remarkable results could be obtained by the applications of statistical methods.

As yet, apparently, very few chemists have awakened to the wonderful opportunities that lie open to them on all sides when they attack the problems of chemistry by the new methods which the physicists have developed. The physicist, on the other hand, is gradually beginning to extend his investigations into the field of the chemist and we may hope, if the chemist will but meet him half way, that there will result a new physical chemistry which will have an even more far-reaching effect on our ordinary chemical conceptions than has the physical chemistry of the last decades.

Perhaps the most noteworthy of the recent attempts to apply statistical methods to chemical changes is the work of J. J. Thomson on positive rays.

Strutt¹ has studied the statistics of a few gas reactions, in some of which his active modification of nitrogen (atomic nitrogen) takes part. Although his experimental methods are quite different from those we have

¹ *Proc. Roy. Soc., (A)* 87, 302 (1912).

used in studying the clean-up of gases, his results are closely related to some of those we have obtained, and I shall therefore have occasion to refer again to this work of Strutt's.

An excellent example of the study of chemical reactions, by statistical methods, and this time by a chemist, is to be found in the work of S. C. Lind¹ on the nature of chemical action brought about by radioactive bodies.

The reactions which we are to consider this evening are for the most part reactions between gases and heated filaments; that is, they are heterogeneous reactions involving a solid and gaseous phase. The kinetics of reactions of this type have not received the attention which has been accorded to homogeneous reactions. For example, in Jellinek's recent book on the "Physical Chemistry of Gas Reactions," 34 pages are devoted to the kinetics of homogeneous reactions, but only half of one page to the kinetics of heterogeneous reactions.

It was at first thought that the law of mass action could be applied to heterogeneous reactions just as to homogeneous reactions. Experiments soon showed, however, that other factors than purely chemical ones usually determined the velocity of these reactions. Noyes and Whitney² studied the rate of solution of solid substances in liquids and concluded that the velocity was dependent entirely on the rate at which the dissolved substances could diffuse out through the thin layer of liquid next to the solid. Stirring the liquid had the effect of thinning this layer and so increased the rate.

Nernst extended this idea and suggested that the velocity of heterogeneous reactions in general was limited by the rate of diffusion of the reacting substances through a "diffusion layer," which he considered, under ordinary circumstances, to be of constant thickness. Thus he reasoned that the velocity of these reactions, in practically all cases, should be proportional to the concentration of the reacting substances. In other words, the reactions should follow the laws of monomolecular reactions. Nernst pointed out, however, that it was wrong to draw conclusions as to the mechanism of heterogeneous reactions from measurements of their velocity.

Fink,³ as a result of his study of the kinetics of the sulfur trioxide contact process, developed a theory of the mechanism which marked a new step in our conceptions of the mechanism of heterogeneous reactions. Bodenstein and Fink⁴ successfully applied this theory to a large number of other catalytic reactions.

¹ *J. Phys. Chem.*, 16, 564 (1912).

² *Z. physik. Chem.*, 23, 689 (1897).

³ *Dissertation*, Leipzig, 1907; see also Bodenstein and Fink, *Z. physik. Chem.*, 60, 1 (1907).

⁴ *Z. physik. Chem.*, 60, 46 (1907).

This theory differs essentially from Nernst's, in that the reaction velocity is assumed to be limited by the rate of diffusion of the reacting bodies through an *adsorbed film of variable thickness*. Thus, in the case of the reaction

in contact with platinum it is shown that there is present on the platinum an adsorbed layer of SO_3 . The theory assumes that the thickness of this layer is at all times proportional to the square root of the concentration of SO_3 in the gas phase; in other words, that there is an adsorption equilibrium. The reaction is assumed to take place only at the boundary between the adsorption film and the platinum. The oxygen and sulfur dioxide must therefore diffuse through the film before being able to react. In this way the theory indicates that the velocity of the reaction should be inversely proportional to the square root of the concentration of SO_3 and should be proportional either to the concentration of oxygen or to that of the sulfur dioxide (not to both), depending upon which is in excess at the surface of the platinum.

This theory seems to have met with general favor and has been applied to the kinetics of many heterogeneous reactions.

The experiments on gas reactions at low pressures which I shall describe this evening, have shown that this theory must be modified and that we must consider the reaction velocity to be limited, not by the rate of diffusion through the adsorbed film, but rather, by the rate at which the surface of the metal becomes exposed by the evaporation of single molecules from an adsorbed layer one molecule deep. We shall see that the statistical view-point will lead us very much further in the understanding of all reactions of this type.

In interpreting the experimental results, we shall need to make use of some of the fundamental principles of the kinetic theory. I should therefore like to spend some time in discussing these and in showing their relation to the phenomena we shall have to consider.

We shall refer frequently to low gas pressures, and it will be well at the outset to say a word as to the unit of pressure which we shall use throughout. It has been customary to measure pressures in mm. of mercury, but this is really a very arbitrary and inconvenient unit for such work as this. Professor Richards, last year at Cincinnati, made a strong appeal to chemists to use the C. G. S. unit of pressure, the *bar*, or the megabar, and enumerated many good reasons for doing so. The *bar* is defined as a pressure of one dyne per sq. cm. and the megabar is a million times this. The megabar is almost exactly 750 mm. of mercury and is really more nearly average atmospheric pressure than the 760 mm. usually adopted as standard. A bar is therefore one millionth of an atmosphere, or just three-fourths of a thousandth of a mm. of mercury.

This unit is particularly convenient for our purpose, for the pressures we shall deal with are usually from 1 to 100 bars.

According to the kinetic theory, the pressure of a gas on the walls of the containing vessel is due to the impact of the rapidly moving molecules against the surface. The average velocity (Ω) of the molecules is

$$\Omega = \sqrt{8RT/\pi M} \quad (1)$$

where T is the absolute temperature, M the molecular weight, and R the gas constant (83.2×10^6 ergs/degree). If we substitute the numerical value of R in this equation we find

$$\Omega = 14550 \sqrt{T/M} \text{ cm. per sec.} \quad (2)$$

We see that the velocity is proportional to the square root of the temperature and inversely proportional to the square root of the molecular weight. For oxygen at room temperature ($T = 293$; $M = 32$), the average velocity of the molecule is 44000 cm. per second, or nearly half a kilometer per second (about 30% greater than the velocity of sound). The pressure of the gas being produced by the impact of the molecules, is proportional to the velocity of the molecules as given above and also to the total mass of all the molecules striking the surface per second. If we let m represent the number of grams of gas molecules which strike a unit surface per second, then it can be shown that the pressure p is equal to

$$p = \frac{1}{2} \pi m \Omega. \quad (3)$$

From this and (1), we find m to be

$$m = \sqrt{M/2\pi R T} p. \quad (4)$$

We shall find that this is an equation of very fundamental importance in the theory of the kinetics of heterogeneous reactions. It enables us to calculate the exact rate at which the gas can come into contact with a given surface. Substituting the numerical value of R , etc., the equation becomes

$$m = 43.74 \times 10^{-6} \sqrt{M/T} p. \quad (5)$$

Here m is expressed in grams per sq. cm. per second and p is in bars.

For air ($M = 29$) at atmospheric pressure (10^6 bars) and room temperature ($T = 293$), this gives $m = 13.8$ g. per sq. cm. per second. This mass of air corresponds to about twelve liters.

Let us pause a moment to consider what this means. In each second, the total number of molecules striking a single sq. cm. of surface is as great as is the number contained in twelve liters of air. Of course, under ordinary conditions, the same molecules strike the surface a vast number of times each second. As the pressure is lowered, the number of molecules striking the surface decreases, but so does the number contained in a given volume. Thus we see that no matter what the pressure, the number of molecules which strike a single square centimeter of surface in a second is the same as that contained in twelve liters. ▴

According to Millikan's recent accurate determinations, there are 2.488×10^{19} molecules in a cubic centimeter of any gas at 20°C. and one megabar pressure. The lowest pressures that have been produced and measured are about 0.001 bar, or 10^{-9} megabars. Even in this remarkably good vacuum, there are still 2.5×10^{10} molecules per cubic centimeter. However, when we consider that the average distance between the molecules under these conditions is about 0.02 mm., a distance about equal to the diameter of the filament of a small tungsten lamp, we realize that the gas must behave very differently from a continuous medium.

For many calculations the number of molecules per g. molecule is a very convenient number. According to Millikan's data, this is 6.062×10^{23} . For example, from this figure we can calculate (by Equation 5) the number of molecules of a gas which strike a sq. cm. of surface per second. We find this number to be

$$n = 2.652 \times 10^{19} p / \sqrt{MT}. \quad (6)$$

Very little is known about the diameter of molecules. The question itself probably has little meaning, for molecules are certainly not spheres, but are complex structures of electrons having no definite geometrical shape which can be adequately characterized by a single dimension. We do know, accurately, however, the distances between adjacent molecules in crystals, and in gases we know approximately how close the centers of molecules can approach during collisions. For oxygen, this distance, which, for convenience, we may call the diameter, has been found to be 2.7×10^{-8} cm. If we assume that these molecules are arranged in a single layer on a surface, much as the cells in honeycomb are arranged, it can be readily shown that the total number required to cover a square centimeter is 1.6×10^{15} .

The area covered by each molecule is the reciprocal of this, or 6×10^{-16} sq. cm. We already know, by Equation 6, how many molecules strike a sq. cm. per second, so to find how many molecules from the gas strike a given molecule on the surface we need only to multiply by 6×10^{-16} . We thus find, for the case of oxygen at room temperature and at a pressure of one bar, that an oxygen molecule on the surface would be struck by 170 molecules from the gas every second. Similarly, if the surface were originally free from oxygen and every oxygen molecule striking the surface should stick, it would take approximately only $1/170$ of a second to cover the surface with a layer one molecule deep. Even at 0.001 bar pressure, the lowest pressure that has been measured, it would require only about 6 seconds to form such a film. This explains the difficulty of preparing surfaces in vacuum which are not contaminated by gas.

A very fundamental conception is that of evaporation. By means of Equation 4 we may obtain a relation between the vapor pressure of a substance and its rate of evaporation. When a substance is in equilibrium

with its saturated vapor the vapor is condensing on the substance at the same rate as the latter is evaporating. Now if we assume that every molecule of the vapor striking the surface condenses, then Equation 4 gives us the rate (m) at which the vapor must condense. This must be equal to the rate at which the substance evaporates.

Let us now consider the essential differences between the conditions in our low pressure experiments and those that would prevail if higher pressures were used.

At pressures as high as atmospheric pressure, convection currents set up by the filament introduce very serious complications. At pressures of a tenth of a megabar or less, convection currents become negligible for most purposes, but the problem is still complicated by the sharp temperature gradients that occur in the gas around the wire. At ordinary pressures, unless the velocity of the reaction is extremely small, the rate of reaction will be determined largely, if not wholly, by the rate at which the reacting substances can diffuse to the surface and the products diffuse out. Under these circumstances, we should expect Nernst's theory to apply in general, but in this case we are really not measuring the velocity of a chemical reaction at all; we are merely measuring a diffusion coefficient in a gas.

On the other hand, at pressures as low as 10 bars, diffusion may be considered as practically infinitely rapid. At this pressure the average free path of the molecules of most gases is very close to 1 cm. This is so large, compared to the diameter of the wire, that it is evident that the molecules leaving the wire can in no way interfere with those approaching it. Under these conditions the gases don't need to diffuse through each other in the ordinary way.

At such low pressures as these we may, in fact, look upon the gas as consisting of a swarm of molecules which are independent of one another. The velocity of the molecules around the filament is then determined by the temperature of the bulb and is entirely independent of that of the filament. There is thus no temperature gradient in the gas around the filament. The average velocity of the molecules striking the filament is definitely known and, in case two or more gases are present, the relative numbers of each kind of molecules striking the filament are also known, no matter how rapid the reaction may be.

An interesting feature, possible only with reactions at very low pressures, is the fact that the temperature of the molecules striking the filament is different from that of the filament itself. At ordinary pressures, because of the heat conductivity of the gas, the molecules striking a solid body are, of course, always at the same temperature as the body itself. This opens up new possibilities in studying the kinetics of reactions. The effect of separate variation in the temperature of two reacting sub-

stances can thus be studied. If it is the impact of the gas molecules against the surface of the filament which determines the velocity of the reaction, then this velocity should depend much more on the temperature of the bulb than on that of the filament, since the impact depends on relative velocity, and the velocity of the heavy tungsten atoms, even at high temperatures, is much less than that of ordinary gas molecules at room temperature. On the other hand, if the reaction velocity is determined rather by some condition of the surface of the filament, then the effect of bulb temperature will usually be negligible.

Another result of the use of low pressures is that the molecules of the products of a reaction, when they leave the filament, do not return again until after having made many collisions with the bulb. If the substance formed is a nonvolatile solid, or can be condensed by cooling the bulb in liquid air, it is thus possible to make certain that the reaction does not take place as the result of two collisions, but necessarily occurs in one. In this way also it should be possible to produce many compounds which are very unstable at the temperature of the filament.

At sufficiently low pressures (about 1 or 2 bars) the molecules leaving the filament travel directly to the bulb without striking any other molecules on the way. Naturally, they have no chance of giving up any energy on the way to the bulb, and therefore (if we can speak of the temperature of a single molecule) reach the bulb with the same temperature as that with which they left the filament. This must produce the most sudden cooling possible, and there is then the minimum chance for the decomposition of the product formed if it happens to be unstable at some temperature between that of the filament and that of the bulb.

Another important advantage in working at low pressures is that the velocity of even the most rapid reactions in this way can be slowed down sufficiently so that they can be studied quantitatively. The heat liberated by the reaction on the filament is usually so small that it is not noticeable, or at any rate is not so large but that isothermal conditions may be maintained.

The theories of the mechanism of reactions that I will describe in connection with the experiments have been gradually developed during the last three or four years. To-night I shall discuss only the purely chemical evidence, but I should like to point out that the idea that the reaction velocity depends not upon the thickness of the adsorption layer, but upon the extent to which the surface is covered by it, was based upon experiments on the electron emission from heated tungsten wires in high vacuum. The evidence of the existence of such monomolecular layers in these experiments was very striking and the electron emission was found to depend entirely upon the extent of the uncovered part of the

surface. A preliminary account of this work was published in 1913.¹ I expect later to publish the results of the more recent experiments and to show that in the measurement of the electron emission from heated wires there is opened up a powerful method of studying the properties of films so thin that they only partly cover the surface with a layer one molecule deep.

We are now in a position to consider more in detail the reactions which occur when a gas is "cleaned-up" by a heated filament. These reactions may be divided into four distinct classes, which we shall consider separately. The four types of reaction are those in which:

1. The filament is attacked by the gas.
2. The gas reacts with the vapor given off by the filament.
3. The filament acts catalytically on the gas, producing a chemical change in the gas without any permanent change in the filament.
4. The gas is chemically changed, or is made to react with the filament by means of electrical discharges through the gas.

Direct Attack of the Filament.

1. **Clean-up of Oxygen by a Tungsten Filament.**²—The action of oxygen on a tungsten filament is one of the best examples of this type of reaction. In air at atmospheric pressure tungsten begins to oxidize at about 400–500° C. and becomes coated with an iridescent film much as steel does. At higher temperatures the oxidation becomes rapid and a scale of the yellow oxide WO_3 forms on the metal. At temperatures above 1500° K. the oxide volatilizes so rapidly that it forms a dense, white smoke. Under such conditions the rate of oxidation evidently depends on the rate at which the oxygen can diffuse up to the surface of the metal through the nitrogen and through the layer of oxide on the surface. Such a large number of factors is involved that it would seem very difficult to derive much information as to the mechanism of the chemical reaction from experiments at these high pressures.

The case is quite different, however, when we study the action of a heated tungsten filament on oxygen at a pressure as low as, say, 100 bars. We then find that at temperatures above about 1200° K. the tungsten is attacked, producing the yellow oxide WO_3 , but that this distills off as fast as it is formed, leaving the surface clean and bright.

The pressure of oxygen decreases in the manner shown in Fig. 1. The rate of clean-up is initially high, but gradually becomes smaller as the oxygen pressure becomes less. It is found that the slope of this curve at any point is proportional to the pressure at that point. In other words, the velocity of the reaction is proportional to the pressure. This is the law according to which a monomolecular reaction proceeds, and is also

¹ *Phys. Rev.*, 2, 450 (1913).

² *THIS JOURNAL*, 35, 105 (1913).

the law which Nernst found to hold for reactions in which the velocity was limited by the rate of diffusion.

By Equation 5 we can calculate the rate at which the oxygen at a given pressure comes into contact with the filament. We can then compare this rate with the rate found experimentally for the same pressure. By dividing the two, we find what fraction of all the molecules that strike the filament react with it. Let us call this fraction ϵ . Of course this fraction must be less than unity, for the reaction cannot possibly take place more rapidly than the rate at which the molecules can come

Fig. 1.—Typical curve for the clean-up of oxygen.

into contact with the surface. Experimentally, we have shown that the rate of clean-up is proportional to the pressure. Since the rate at which the molecules strike the filament is also proportional to the pressure by (5), it is evident that ϵ is the same at all pressures in the range covered by the experiments. Table I shows the values obtained for ϵ from experiments at different filament temperatures. We see that ϵ is always less than unity, as of course it must be, but at the highest temperatures it seems to be approaching a limit which is below unity. At the lowest temperatures ϵ has a very large temperature coefficient, much higher than if we were dealing with a reaction of the types studied by Nernst with a diffusion film of constant thickness.

TABLE I.—RATE OF CLEAN-UP OF OXYGEN.

Temp.....	1070° K.	1270	1470	1570	1770	2020	2290	2520	2770
ϵ	0.00033	0.0011	0.0053	0.0094	0.0255	0.049	0.095	0.12	0.15

Experiments were made with the bulb cooled by liquid air and also heated to 300° in an oven. The rate of reaction was found to be independent of the bulb temperature.

Let us now examine these experimental data and see what conclusions can be drawn as to the mechanism of the reaction.

Since the oxide formed is WO_3 , it is evident that at least two molecules of oxygen must react with each atom of tungsten.

There are two possibilities to consider. Either both the oxygen molecules simultaneously strike a single tungsten atom or else an oxygen

atom or molecule must already be present on the surface at the point where the second molecule strikes.

We have already seen that the number of oxygen molecules striking the surface per second within an area of molecular dimensions is $170 \times p$. The velocity of the molecule is 44,000 cm. per sec. If we consider a molecule which strikes the surface and rebounds, the length of time it remains within molecular dimensions of the surface is the time taken to travel twice the diameter of the molecule, or 5.4×10^{-8} cm. In other words, the duration of a collision is only 1.2×10^{-12} seconds. Since there are $170 \times p$ collisions per second, the total time in each second during which molecules are present at a given point is $170 \times 1.2 \times 10^{-12} p$ or $2.1 \times 10^{-10} p$. This gives us directly the probability that a molecule striking a given point on the surface will find a molecule of oxygen already present. Thus, if we had to depend on simultaneous collisions we see that ϵ could not exceed $2.1 \times 10^{-10} p$. This is vastly less than the values of ϵ actually observed. At a pressure of 10 bars this would give for ϵ a value of only 2×10^{-8} , whereas at the higher temperatures we have found values as high as 0.15. A further objection to the hypothesis of simultaneous collisions is that it would lead to values of ϵ which are not independent of the pressure. With this hypothesis, the reaction velocity would be proportional to the square of the pressure (bi-molecular reaction).

We must therefore conclude that the oxygen molecule striking the surface reacts with those already present. There is thus definite proof that some sort of film containing oxygen is present on the surface.

This film, however, cannot be in equilibrium with the space around it, as was assumed in Bodenstein and Fink's theory. Since the oxide formed travels directly to the bulb and condenses, there is no possibility that any appreciable number of molecules of oxide return to the filament.

On the other hand, it is not possible to assume that each molecule of oxygen striking the filament remains there a short but indefinite time before distilling off. In this way it would be possible to account for any given value of ϵ , but the velocity of the reaction would then be proportional to the square of the pressure rather than the first power.

From another point of view, we also must conclude that there is a film on the surface which determines the velocity of the reaction. We have seen that at the lower temperatures only a small fraction of the molecules which strike the filament react. According to the ordinary conception of a reaction in a homogeneous system, it is the relative velocity of two molecules with respect to each other at the moment of contact which largely determines whether or not they will react. The higher the relative velocity, the greater the chance of reaction is supposed to be. The experiments in the present case have shown that the rate of reaction does

not depend on the relative velocity of the molecules, since changing the temperature of the bulb had no effect. What is it, then, that determines whether a given oxygen molecule shall react or not? It must be something that depends solely on the condition of the surface of the filament.

We have just seen that the older theory, which supposes that it is the thickness of an adsorption film which determines the velocity, leads us into difficulties. Let us now look upon the problem from the point of view of the new theory, according to which the adsorption film is only one molecule thick.

Since the experiments have shown that ϵ is independent of the pressure, it is natural to assume that the condition of the surface responsible for determining the reaction velocity, is also independent of the pressure. This requirement would be met if we assume that the surface film covers the surface nearly completely and consists of two kinds of molecules in thermal equilibrium with each other. One of the kinds of molecules is to be regarded as capable of reacting directly with the oxygen striking the surface, while the other is incapable of so doing. The conclusion that the surface must be nearly completely covered with an adsorption film of oxide is based largely on experiments on the electron emission, where it is found that a pressure of oxygen even as low as 0.01 bar cuts the electron emission from tungsten at 1900° K., down to less than 1% of its value in the absence of oxygen.

In formulating the above theory more precisely we may proceed as follows:

Let us assume that of all the oxygen molecules striking the bare surface of tungsten, the fraction α is absorbed or sticks to the surface, the fraction $1 - \alpha$ being reflected or rebounding from the surface. Only a very small fraction of the surface, however, is bare and we may assume that the oxygen molecules striking a surface already covered, are not absorbed in this way. If we let θ represent the fraction which is bare, then of all the oxygen molecules striking the whole surface only the fraction $\alpha\theta$ is absorbed. Now the rate at which the oxygen molecules strike the surface is given by Equation 5 and we see that it is proportional to the pressure. We thus see that the rate at which oxygen is absorbed by the surface is

$$\alpha \theta p$$

if we neglect for convenience the constant factor in Equation 5.

To form a more concrete picture of the mechanism of the reaction, let us assume that the oxygen on the surface is at first in the form of the compound WO_2 , but that this reacts with the tungsten in contact with it to form 2WO , and that this reaction is reversible and that equi-

librium prevails between the two compounds.¹ According to the law of mass action, the surfaces covered by the two compounds will have to fulfill the relation

$$\theta_1 = K\theta_2$$

where K is the equilibrium constant and θ_1 is the fraction of the surface covered by WO_2 and θ_2 is the surface covered by WO .

It is now natural to assume that if oxygen striking the surface collides with a WO_2 molecule, no reaction takes place, but that when the oxygen strikes a WO molecule it reacts to form WO_3 , which distills off. Of all the O_2 molecules striking the WO we may, for the sake of generality, assume that only the fraction ϵ_2 reacts.

From these considerations it is easy to state the problem mathematically as follows:

$$\alpha \theta p = \frac{1}{2} \theta_2 \epsilon_2 p \quad (7)$$

$$\theta_1 = K\theta_2 \quad (8)$$

$$\theta + \theta_1 + \theta_2 = 1 \quad (9)$$

The first equation states simply that the rate at which the oxygen is adsorbed is equal to the rate at which it is removed by the reaction. The coefficient $\frac{1}{2}$ is necessary because each molecule of oxygen striking the filament only removes one atom ($\frac{1}{2}$ molecule) of oxygen from it in forming WO_3 . The second equation merely expresses that equilibrium exists between the WO_2 and the 2 WO , and the third equation states that the bare surface is equal to that which is not covered by the WO_2 and the WO . For a more general solution of the problem we may also take into account the fact that the WO_2 and the WO are probably evaporating or dissociating to some extent and that the WO_3 that is formed requires some time before it evaporates. The equations obtained in this way are more complicated than those above, but can easily be worked out. The results in the present case are not essentially different from those we obtain by the above equations.

From the three equations above we may eliminate θ , θ_1 and thus obtain

$$\theta_2 = \frac{2\alpha}{\epsilon_2 + 2\alpha(K + 1)} \quad (10)$$

The rate R at which the oxygen is converted into WO_3 is

$$\frac{3}{2} \epsilon_2 \theta_2 p$$

or

¹ This assumption of the existence of the compounds WO and WO_2 on the surface is made only to form a picture of a possible mechanism. It is much more probable that the oxygen atoms are chemically combined with tungsten atoms which form the surface of the filament and which are part of the "space lattice", of the tungsten crystals.

$$R = \frac{3\alpha\epsilon_2 p}{\epsilon_2 + 2\alpha(K + 1)} \quad (11)$$

This shows that the rate of clean-up by this theory is proportional to the pressure, in agreement with the experiments. If every oxygen molecule which struck the filament reacted, the rate of clean-up would be p (neglecting the same constant factor as before) and hence the value of ϵ which we determined from the experiments and have given in Table I, would be

$$\epsilon = \frac{3\alpha\epsilon_2}{\epsilon_2 + 2\alpha(K + 1)} \quad (12)$$

This is independent of the pressure. It is probable that ϵ_2 and α are nearly independent of the temperature and that the large temperature coefficient of ϵ is due to that of K . Thus, at low temperatures, K must be very large, which means that the amount of WO in equilibrium with the WO_2 is very small. As the temperature rises, K decreases and ϵ therefore increases, but finally reaches a limiting value,

$$\epsilon_{\max.} = \frac{3\alpha\epsilon_2}{\epsilon_2 + 2\alpha} \quad (13)$$

which is always less than unity. This is in splendid agreement with the experiments. In order that $\epsilon_{\max.}$ may be as large as 0.2, the value estimated from Table I, it is necessary that ϵ_2 shall be greater than 0.2 and that α shall be greater than 0.1. That is, at least 0.2 of the O_2 molecules, colliding with WO molecules must react and at least 0.1 of the oxygen molecules striking the bare surfaces must be absorbed or react to form WO_2 .

By this theory it may be predicted that with still higher filament temperatures ϵ will begin to decrease when a point is reached at which the WO_2 and WO evaporate or dissociate so rapidly that only a small fraction of the surface is covered. For similar reasons it may be predicted that ϵ cannot remain independent of the pressure down to the lowest pressures. There is excellent experimental evidence that the last prediction is in accord with the facts. It is found that an extremely low pressure, probably less than 0.001 bar, of oxygen in a tungsten lamp not only does not perceptibly attack the filament, but actually prevents the tungsten which evaporates from discoloring the bulb. This action is probably due to the dissociation of the WO on the filament producing atomic oxygen which, traveling to the bulb, reacts with the deposited tungsten even at room temperature, to form WO_3 . In a later paper I hope to take up this point in more detail and consider the phenomena quantitatively from the view-point of the theory I have outlined this evening.

I have spent much more time on this reaction between tungsten and

oxygen than its experimental importance warrants, but I wished to illustrate by it in some detail the application of the theory of molecular films.

2. Reactions between Chlorine and Tungsten.—Chlorine at low pressures attacks tungsten, forming WCl_6 . The velocity of the reaction reaches a maximum at about 1500°K. and becomes extremely small at higher temperatures. This is undoubtedly to be explained by the dissociation of some of the intermediate products which are necessary steps in the formation of WCl_6 . The chlorine leaving the filament is largely dissociated into atoms under these conditions and produces some extremely interesting effects which I shall discuss more in detail a little later.

3. Reactions between Carbon and Oxygen.—It has long been a disputed question whether carbon monoxide is a direct product of the oxidation of carbon or whether it is formed only by the interaction of carbon with carbon dioxide produced as a primary product.

By heating a carbon filament in oxygen at very low pressures in a bulb immersed in liquid air, a definite answer to this question is readily obtained. If carbon dioxide is produced and leaves the filament, it must travel directly to the bulb and there be condensed at the low temperature of liquid air where the vapor pressure of carbon dioxide is barely measurable. The filament therefore never comes in contact with carbon dioxide.

The first experiments showed that the phenomena involved in the oxidation of carbon are very complex as compared with those of the oxidation of tungsten. With tungsten the results were always accurately reproducible, but with the carbon filaments the rate of clean-up depended entirely upon the previous history of the filament.

In the experiments metalized carbon filaments were used. These consist of a highly graphitized carbon of the highest attainable purity (ash about 0.01%). After mounting in the lamp the filament was heated in a high vacuum for several hours until it ceased giving off measurable quantities of gas. Small quantities of oxygen at a pressure about 5–10 bars, were admitted and the rate of clean-up with different filament temperatures was noted.

With the filament at 1220°K. the oxygen began to disappear very rapidly, but soon slowed down to a rather uniform slow rate. At this temperature the whole of the oxygen gradually disappeared and CO_2 , without a trace of CO , was formed. The amount of CO_2 , however, was considerably less than the equivalent of the oxygen which disappeared. On adding a second supply of oxygen the rate of clean-up was very much slower than the first time. After three or four treatments the rate of clean-up finally became reproducible. On raising the filament temperature to 1700°K. the rate of clean-up increased again, but gradually

decreased as before. In the first treatment, at 1700°K. , all the oxygen disappeared and no CO was formed, but in subsequent treatments at the same temperature there began to be formed increasing amounts of CO. After five or six runs in oxygen, pumping out the residues of CO each time, the pressure would decrease only 10 or 20% when the filament was lighted in a fresh supply of oxygen, and would then increase until finally a residue of pure CO would remain, having a volume usually about 30% greater than that of the oxygen used.

If the filament was now heated in vacuum, it gave up CO extremely slowly at 1700°K. , but at 2200°K. the evolution was much more rapid, although even at this temperature from half an hour to an hour was required before the evolution ceased. The total amount of CO so obtained usually amounted to 3-5 cu. mm. After having thus heated the filament in vacuum, the first run in oxygen with the filament at 1700°K. gave nothing but carbon dioxide, but the runs following this gave, as before, an increasing amount of carbon monoxide.

With the filament at 2100°K. in oxygen, there was always a large quantity of carbon monoxide produced, even in the first run.

These experiments seem to show that when oxygen acts on carbon at, say, 1200°K. , part of the oxygen reacts to form CO_2 , but another part forms an adsorption layer of some sort on the surface which retards the velocity of the reaction. This adsorption layer is probably chemically combined with the carbon, presumably as an extremely stable solid oxide of carbon.

At higher temperatures the rate of formation of this adsorption layer increases rapidly. When a sufficient quantity has accumulated this compound begins to decompose, forming carbon monoxide, the higher the temperature the more rapid being the formation of this gas.

Judging from the great stability of this adsorption layer, which enables it to be heated for half an hour at 2200°K. in the highest vacuum without being completely decomposed, a plausible guess as to its constitution is that it consists of oxygen atoms chemically combined with the carbon atoms which form the surface of the filament. According to our recent knowledge of the structure of solid bodies, we have the best of reasons for believing that the atoms of solid bodies are held together directly by chemical forces and that a crystal must be looked upon as a single molecule. The carbon atoms in the filament must thus be considered as forming endless carbon chains with each other. It is probably due to the great stability of these carbon chains that carbon has such a low vapor pressure and such a high melting point. In the present case, if we consider the oxygen atom to be chemically combined with one of the outer carbon atoms, we have a structure that could be represented by the formula

This hypothesis would seem to afford an unforced explanation of the extraordinary difficulty of removing oxygen and hydrogen from carbon.

Experiments were also made to study the action of the heated carbon filament on carbon dioxide and monoxide.

With carbon dioxide at 1220° K. no change occurred, but at 1700° K. carbon monoxide was formed at first slowly, and then gradually more rapidly. The total volume, however, usually remained nearly constant, showing that the reaction was not

but was rather

On the other hand, at temperatures up to 2400°, there was never any perceptible change in volume when the filament was heated in carbon monoxide, showing that the adsorbed compound is not formed by adsorption of carbon monoxide.

These results should be looked upon merely as preliminary results, and I hope to be able to present further details of the experiments with carbon and oxygen at a later date.

II. Reactions with Vapor from Filament.

Clean-up of Nitrogen by a Tungsten Filament.¹—When a tungsten filament is heated to 2700 or 2800° K. in nitrogen at low pressure, the nitrogen slowly disappears at a rate which is independent of the pressure.

Fig. 2 gives a good example of the way the pressure decreases in a typical experiment. At the high temperatures employed in these experiments it has been found that the filament evaporates fairly rapidly. A comparison of the amount of nitrogen cleaned up with the loss of weight of the filament, showed that the ratio was the same as

Fig. 2.—Typical curve for the clean-up of nitrogen.

¹ THIS JOURNAL, 35, 931 (1913).

that in a compound of the formula WN_2 . This ratio still held if the temperature of the filament was raised several hundred degrees, where the rate of clean-up was over four hundred times more rapid. Measurements showed that the rate of loss in weight of the filament in low pressure nitrogen was the same as in vacuum, so it was evident that the nitrogen did not attack the filament.

In these experiments the tungsten does not collect on the bulb as the usual black deposit, but was of a clear, brown color. On opening the bulb and admitting moist air the brown color disappeared and a strong smell of ammonia was observed.

It is evident that the nitrogen in this case combined with the tungsten vapor as fast as it is given off. By working at such low pressures that only a few of the tungsten atoms collided with nitrogen molecules on the way to the bulb it was proved that practically every collision between the nitrogen molecules and tungsten atoms resulted in the formation of the compound. In other words, the coefficient ϵ is unity. We are here dealing then in reality with a bimolecular homogeneous reaction of maximum possible velocity.

The true reaction velocity is independent of the temperature. What is measured in the experiment is only the rate at which the tungsten evaporates.

Recent experiments have shown that the rate of clean-up of the nitrogen at higher pressures is the same whether the bulb is heated to 300°C . or is cooled in liquid air. But at lower pressures an interesting difference occurs, which is shown by the dotted curve in Fig. 2. With the bulb at room temperature the curve departs from the straight line at the lower pressures because the nitrogen molecules become so scarce that a large fraction of the tungsten atoms strike the bulb without colliding with nitrogen molecules. From the agreement between the calculated and observed curves at the lowest pressures, it was reasoned (in the paper on the nitrogen clean-up) that the tungsten atoms striking the glass deposit as such, do not combine with nitrogen. This suggested that few, if any, nitrogen molecules are present on the glass at room temperature. The more recent experiments now prove that when the bulb is cooled in liquid air the tungsten atoms do combine with nitrogen even if the pressure is so low that they do not strike them on the way to the bulb. The shape of these curves at low pressures proves that the glass surface, or rather that of the tungsten nitride layer on the glass, at liquid air temperature is covered by an adsorbed film of nitrogen, but at room temperature it is not. This method can even be used to calculate quantitatively the fraction of the surface that is covered by the nitrogen at any given temperature.

Clean-up of Nitrogen by a Molybdenum Filament.—Molybdenum evaporates much more readily than tungsten, and it was thought that

nitrogen would therefore be cleaned up more easily by a molybdenum than by a tungsten filament. This was not found to be the case. On further investigation it was found that the molybdenum lost weight at the same rate as in vacuum and that the rate of clean-up was independent of the pressure, as in the case of tungsten, but that the amount of gas cleaned up was only about one-tenth of that which would have been observed if every molybdenum atom combined with a nitrogen molecule.

Under these conditions we should expect that the rate of clean-up would vary with the pressure, for the higher the pressure the more collisions the molybdenum atoms must make with the nitrogen molecules before striking the bulb. In order to account for the fact that the rate of clean-up is independent of the pressure, it is necessary to assume that if combination does not take place during the first collision it does not take place at all. The question arises: What is the difference between the first and the subsequent collisions which can account for the different behavior in the two cases? Since the nitrogen molecules are the same in both cases, the difference must lie in the molybdenum atoms. Now, according to our ordinary conceptions, atoms can differ from each other only in respect to their translational velocity.¹ Since the velocities of the molybdenum atoms leaving the filament are higher than those after collision with nitrogen molecules, it would seem that this could readily explain the fact that combination can occur only on the first collision.

If this were the case, then raising the temperature of the filament should increase ϵ ; that is, the percentage of successful collisions. Actually, however, the reverse was found. By lowering the filament temperature 100° , ϵ increased from 0.11 to 0.33, and by raising it 100° , ϵ decreased to 0.05. The effects of varying the bulb temperature were still more striking. With the bulb in liquid air, ϵ became about 0.4 and by heating the bulb to 270° C. ϵ became 0.01.

In other words, the reaction velocity has a very marked negative temperature coefficient; there is thus a much larger fraction of successful collisions if the relative velocities of the nitrogen molecules and molybdenum atoms are small at the moment of collision.

This, however, makes it still more difficult to explain why the reaction can occur only at the first collision, for it would seem that if the first collision were unsuccessful the subsequent collisions would be more likely to result in combination because the velocities would then be lower.

I think the solution of this difficulty is to assume that the first collision always results in a union of the nitrogen and molybdenum so that they travel together to the bulb, but that this union may occur in one of two ways, depending upon the relative velocity of the molecule and atom at

¹ Experiments show that neither the nitrogen nor the molybdenum is electrically charged.

the moment of their collision. If the relative velocity is high, the union is so weak that the two components fall apart when the unstable molecule strikes the bulb. On the other hand, if the relative velocity at the moment of contact is small enough, actual chemical combination occurs.

This may seem a rather far-fetched theory, but there is a very large amount of experimental evidence in its favor which I have not time to go into this evening. A paper describing these results in more detail is now nearly ready for publication.

The striking fact that the velocity of the actual chemical reaction has a large negative temperature coefficient will be considered again in connection with other experiments. It must be pointed out, however, that this effect is only noticed because of our analysis of the reaction into its separate partial reactions. If the temperature of the gas and filament varied together and if the function of the molybdenum vapor were not known, the effect would never be noticed, for the large positive temperature coefficient of the rate of evaporation of molybdenum would completely mask that of the true chemical reaction.

In these experiments the molybdenum deposit which collected on the bulb had very remarkable properties. It adsorbed large quantities of nitrogen, but not hydrogen, if cooled by liquid air. But, at room temperature and above, it could slowly dissolve large quantities of hydrogen which it would slowly give up again at 300° C. Although it contained a large amount of nitrogen, none of this gas could be driven off by heating it at 360°; but if it was heated in nitrogen at 250° C. it apparently combined with the nitrogen, for this gas was absorbed and was not liberated by heating at 360° C. in a vacuum.

Another characteristic of this deposit was that it reacted rapidly at room temperature with water vapor, producing hydrogen, most of which remained dissolved and was liberated on heating.

Molybdenum deposited on the bulb in high vacuum does not exhibit any of these characteristics. It seems that the molybdenum described above, is in an atomic state of division as a result of being deposited atom by atom by the decomposition of the unstable compound formed in the "unsuccessful collisions."

Clean-up of Carbon Monoxide by Tungsten.—With the bulb at room temperature this gas behaved exactly like nitrogen. In fact, with the filament at a given temperature, the curves obtained first with nitrogen and then with carbon monoxide proved to be identical. This proved that each atom of tungsten combined with one molecule of CO, presumably to form a compound WCO. The coefficient ϵ must have been unity as in the case of nitrogen.

Since with nitrogen and molybdenum ϵ was found to vary with the tem-

perature, it was of interest to see if ϵ with carbon monoxide and tungsten might not vary also.

Raising the bulb temperature to 300° gave a value of ϵ distinctly less than at room temperature, so that the expected effect was present and in the same direction as with the Mo-N₂ reaction.

When a similar experiment was tried with the bulb in liquid air, the surprising result was obtained that on lighting the filament the gas cleaned up about five times as fast as with the bulb at room temperature. Further experiments showed that the filament under these conditions lost weight about five times as fast as in a vacuum, so that the filament was clearly being attacked by the carbon monoxide. The rate of clean-up, however, was still linear; in other words, was independent of the pressure. Evidently, the compound formed was of approximately the same composition as that formed by interaction with the vapor, namely WCO.

There is apparently no escape from the conclusion that the attack of the filament by CO is a reaction which takes place more rapidly when the velocity (or at least kinetic energy) of the CO molecules is small. We thus again have a case of negative temperature coefficient.

The simplest explanation of the fact that the rate of attack is independent of the pressure, seems to be that the velocity of the reaction is so great that the rate of evaporation of the compound formed determines the rate of reaction.

Thus we assume that the surface is practically completely covered with a film (1 molecule deep) of WCO. As fast as molecules of this distil off, the surface of tungsten is exposed to the attack of the CO.

If this explanation is correct, then as long as the bulb temperature is low enough to cause the formation of a film of WCO, it is evident that a further lowering of the bulb temperature should cause no further increase in rate. Another conclusion may be drawn. At a bulb temperature so high that the supply of WCO is barely sufficient to keep the surface covered, we should expect that the rate of clean-up at the lower pressures would be less than at higher. In other words, there should be certain intermediate temperatures at which the rate of clean-up is no longer linear.

The experiments made to test these points have yielded results in quantitative agreement with the theory. Thus it was found that the rate of clean-up at -78° C. (solid CO₂) was the same as at -190° C., and on the other hand the rate at -20° was the same as at $+20^{\circ}$. But at -40° the rate was intermediate between that at -78° and that at -20° , and, furthermore, the curve was no longer straight, but was in splendid agreement with a calculated curve which was based on the assumption that the rate of formation of WCO on the *exposed surface* of tungsten was proportional to the pressure of CO.

I think this case is an excellent illustration of the general applicability

of what I might call the molecular film theory of heterogeneous reactions.

In this case also I hope soon to publish quantitative data with a more completely developed theory.

Clean-up of Oxygen by Platinum.—A platinum filament at temperatures above about 1600° K. gradually causes the clean-up of low pressures of oxygen. With pressures less than 100 or 200 bars the rate is independent of the pressure. The filament loses weight at the same rate as in vacuum. Quantitative measurements show that the oxygen combines with the platinum atoms as fast as they evaporate from the filament and form the compound PtO_2 which collects on the bulb as a brown deposit. At higher pressures the oxygen also begins to attack the platinum at a rate dependent on the pressure.

III. Catalytic Reactions.

Dissociation of Hydrogen into Atoms.¹—It has been shown that when a wire of tungsten, platinum, or palladium is heated to a temperature above 1300° K., in hydrogen at very low pressure (1–20 bars), a portion of the hydrogen molecules which strike the filament is dissociated into atoms. This atomic hydrogen has remarkable properties. It is readily adsorbed by glass surfaces at room temperature, although more strongly at liquid air temperatures; but only a very small amount (a few cu. mm.) can be so retained because the atoms evidently react together to form molecular hydrogen as soon as they come in contact, even at liquid air temperatures. The atomic hydrogen reacts instantly at room temperature with oxygen, phosphorus and many reducible substances such as WO_3 , PtO_2 , etc.

When a tungsten wire is heated to very high temperatures (above 2000°) in hydrogen, the dissociation of the gas in contact with the wire causes the absorption of a very large quantity of heat. The atomic hydrogen produced diffuses out from the wire and as soon as it reaches a cooler region recombines to form molecules and liberates the heat of the reaction. The result is that the heat conductivity of hydrogen, at temperatures where dissociation occurs, is several times larger than it would otherwise be.

Recently, Mr. Mackay and I have made a series of measurements on the heat losses from tungsten wires at pressures ranging all the way from 10 bars up to atmospheric pressure and at temperatures up to the melting point of tungsten. From these data I have been able to show that the dissociation of the hydrogen does not occur in the space around the wire, but takes place only among the hydrogen molecules which have been absorbed or dissolved by the metal. The mechanism is as follows:

¹ *Trans. Am. Electrochem. Soc.*, 20, 225 (1911); *THIS JOURNAL*, 34, 860 (1912); 34, 1310 (1912); 35, 927 (1913); 36, 1708 (1914); 37, 417, (1915); *Z. Elektrochem.*, 20, 498 (1914).

All the hydrogen atoms striking the surface of the wire and about 70% of all the molecules striking the wire are absorbed by it. The velocity of the reaction between the molecules and atoms of hydrogen absorbed is so great that equilibrium prevails among them at all times. The rate of dissociation of the hydrogen by the wire can thus be calculated from the dissociation constant of the hydrogen and from Equation 5, which gives us the rate at which the gas comes into contact with the wire. By reversing this process it has been possible to determine the degree of dissociation of hydrogen at all temperatures and pressures and to calculate the heat of dissociation. At 2000°K. , hydrogen is 0.33% and at 3000°K. , 13% dissociated at atmospheric pressure.

Dissociation of Chlorine into Atoms.—By heating a tungsten filament for a short time to 3000°K. in a high vacuum a sufficient quantity volatilizes to form a black deposit on the bulb. If, now, a low pressure of chlorine be admitted to the bulb, this does not perceptibly attack the deposit on the bulb nor the filament, even if the bulb is heated to 200°C. However, if the filament is now heated to a high temperature, while the bulb is kept cool, the tungsten deposit on the bulb soon disappears. The chlorine has evidently been activated or dissociated by the filament and the atoms formed travel at these low pressures directly from the filament to the bulb without having any chance to recombine on the way.

The experiment is more striking if two filaments be placed side by side in the same bulb containing a very low pressure of chlorine. If one of the filaments be heated to a high temperature it is found that the other one, which remains cold, is gradually eaten away on the side facing the hot filament until it finally disappears completely. The hot one does not lose at all in weight, but may even become heavier, by having tungsten deposited on it by the decomposition of the chloride formed by the attack of the cold filament.

Dissociation of Oxygen into Atoms.—In connection with the clean-up of oxygen by a tungsten filament I have already spoken of some of the evidence for the dissociation of oxygen into atoms at extremely low pressures. Still better evidence has been obtained in some experiments on thermionic currents in which the bulb containing the filaments is immersed in liquid air. Under these conditions an active form of oxygen can be collected on the glass which is slowly given off and reacts even at liquid air temperatures with tungsten. The phenomena are in many ways similar to those observed with hydrogen. A further quantitative study of the formation of this active oxygen is being undertaken.

Reaction between Carbon Monoxide and Oxygen in Contact with Platinum.—In all the reactions I have spoken of, thus far, there has been only one gas in contact with the filament. The case where the filament is brought into contact with two gases is an important one and

warranted special study. For this purpose a short filament of fine platinum wire was mounted in the center of a four-liter bulb. Pressures of carbon monoxide and oxygen up to a total of about 30 bars were admitted and the filament was heated to such a temperature that the reaction proceeded at a convenient rate. A large tube extended from the lower part of the bulb and was kept immersed in liquid air, so that the molecules of carbon dioxide produced in the reaction were condensed before they had any opportunity of striking the filament.

The results were very striking. The rate of clean-up was found to be directly proportional to the pressure of oxygen, but *inversely proportional* to the pressure of carbon monoxide. Reference to the literature showed that Bodenstein and Ohlmer,¹ in their study of the reaction between these gases on quartz glass surfaces, had found these same relations at about atmospheric pressure. Subsequently, Bodenstein and Fink² suggested tentatively that the explanation of this peculiar behavior might be that the surface of the quartz is covered with an adsorbed film of carbon monoxide of a thickness proportional to the pressure of this gas. If it was further assumed that the oxygen had to diffuse through the layer of carbon monoxide and come into contact with the platinum before it could react with the monoxide, then the reason for the reaction being directly proportional to the oxygen pressure and inversely proportional to that of the carbon monoxide was apparent.

There were serious objections to applying this theory in the present case, for in order that the thickness of a film could be proportional to the pressure over a wide range of pressures it would be necessary to have a film many molecules deep, and this seemed very improbable at the low pressures used in these experiments.

If, on the other hand, we apply the "theory of molecular layers," these difficulties disappear. Let us assume that, of all the CO molecules striking the surface, a certain fraction α , are condensed and that the CO layer thus formed distills off at a certain rate. Let us assume further that the reaction occurs when CO molecules strike oxygen on the surface, but does not occur when O₂ molecules strike CO molecules. We might picture the cause of this as being due to the carbon monoxide molecules on the surface arranging themselves with the carbon atoms in contact with the platinum, while the oxygen atoms cover these and thus protect the carbon from attack by the oxygen.

It is easy to state these assumptions mathematically and thus derive an equation giving the rate of the reaction in terms of the partial pressures of the gases. This relation is of the form:

¹ *Z. physik. Chem.*, 53, 166 (1905).

² *Ibid.*, 60, 46 (1907).

$$R = \frac{I}{\frac{ap_1}{p_1} + \frac{b}{p_1} + \frac{c}{p_2} + \frac{d}{p_1p_2}} \quad (14)$$

where p_1 is the partial pressure of CO and p_2 is that of the oxygen. The coefficients a , b , c and d all have a definite physical significance in this theory, but I will not go into this at present.

It is readily seen that at higher pressures the terms involving b , c and d become negligible compared to that involving a . The p_2 in this term goes into the numerator and we have

$$R = p_2/ap_1. \quad (15)$$

which is the law observed in the experiments I have described.

On the other hand, at lower pressures or at higher temperatures, the first term in the denominator becomes negligible and the fourth term still remains so and the relation becomes

$$R = \frac{I}{\frac{b}{p_1} + \frac{c}{p_2}} \quad (16)$$

At still lower pressures or higher temperatures the last term in the denominator would become the important one and the equation would reduce to

$$R = p_1p_2/d. \quad (17)$$

This theory thus suggested that if higher filament temperatures were used in the experiments the rate would no longer be in accord with Equation 15 but would follow Equation 16. Furthermore, the term containing d involved the rate of evaporation of the CO and O₂ from the surface in such a way that it must increase with the temperature. The velocity of the reaction would therefore decrease at higher filament temperatures.

To test this prediction it was necessary to use a filament of extremely short length (1 cm.) and very small diameter (0.003 cm.), so that the rate of clean-up would not be too rapid to measure. Under these conditions it was found that the rate of clean-up actually reached a maximum at a temperature below a red heat, and at a bright red heat the rate was only about one-tenth of that at the lower temperature.

By studying these data in the light of this theory, I am confident that it will be possible to calculate in detail the statistics of this reaction; for example, the rate of evaporation of each constituent, the proportion of the collisions between the CO and the oxygen which result in combination, etc.

Reaction between Hydrogen and Oxygen in Contact with Platinum.—This reaction proves at low pressures in absence of water vapor to be essentially similar to that between carbon monoxide and oxygen. At low

temperatures the rate of reaction is directly proportional to the pressure of oxygen and *inversely proportional to that of the hydrogen*. At higher temperatures the rate varies with the pressure as indicated by Equation 16, but in contrast to the behavior of oxygen and carbon monoxide, the velocity does not decrease when the temperature is raised even to the melting point of the filament.

Other Catalytic Reactions.—The theory here outlined would seem to be generally applicable to all heterogeneous reactions, even at atmospheric pressure. The many reactions studied by Bodenstein lend themselves admirably to testing out this theory.

There is every indication that the experimental results of Fink will be in at least as good agreement with equations derived by this theory as with those derived from the theory that involves diffusion through a film of variable thickness. For a given concentration of SO_2 the equations take the form

$$R = \frac{1}{\frac{b}{p_1} + \frac{c}{p_2}}. \quad (18)$$

When one constituent is in excess the reaction velocity is thus proportional to the concentration of the other. When there are equivalent proportions, then the velocity is proportional to the total pressure. These are the relations found by Fink, but here one equation fits all the results, whereas by Fink's theory two equations are necessary.

Theory of Adsorption.—The "theory of molecular layers" leads to a simple but quantitative theory of adsorption.

In every reaction we have studied we have found that of all the molecules striking a surface, a large proportion are absorbed. If the rate of evaporation is high the molecules will leave the surface very soon, while if the rate of evaporation is low they may remain a long time. The adsorption is due to the fact that a certain time must elapse between the condensation and the evaporation of a molecule.

In the case of strongly adsorbed bodies, or in all cases where the vapor is nearly saturated, we must take into account the condensation and evaporation in the second and subsequent layers. If we assume that the rate of evaporation in the first layer is different from that for the others, this theory, stated mathematically, leads to an equation of the form

$$Q = \frac{1}{\frac{a}{p} + b - cp} \quad (19)$$

where Q is the amount adsorbed at the pressure p .

This theory will be developed in detail in a subsequent paper.

IV. Reactions Caused by Electrical Discharges.

If a positive potential of a hundred volts or so is applied to an auxiliary electrode in a bulb containing a heated filament, electrons are given off from the heated filament and these, in passing through the gas, may produce ionization. The positive ions then are attracted to the hot filament and strike it with high velocity. Under these conditions reactions often occur which otherwise would not take place. For example, if the gas is nitrogen, these positive ions will combine with the tungsten filament to form the nitride WN_2 even at temperatures where there is normally no appreciable volatilization of the tungsten.

Similar effects are observed with hydrogen and carbon monoxide.

The effects are in general more complicated than those observed in the purely thermal reactions, and largely for that reason I shall not consider them further at present. The phenomena, however, are of very great interest and will probably be the subject of many further investigations.

General Considerations.

This evening I have attempted to present to you a rather new view-point by which we may regard heterogeneous chemical reactions. By working at very low pressures it has been possible to learn much about the mechanism of these reactions.

In each case we have seen that the velocity of the reaction has been limited by the rate at which the reacting molecules come into contact with each other.

With reactions occurring on the surface of the wire, only a small fraction of the surface was in condition suitable for the reaction. The rate of reaction in these cases was limited by the rate at which the gas molecules could strike that part of the surface where the reaction could occur. In no case was there any evidence that the reaction was limited by any diffusion process in the ordinary sense.

In the case of reactions where the gas combined with vapor from the filament, the rate was again limited by the rate at which the molecules came in contact. All those that made contact reacted.

Only in two cases was it possible to measure a velocity which was not limited by such purely physical factors. These cases were the combination of nitrogen with molybdenum vapor and the attack of tungsten filament by carbon monoxide with low bulb temperatures. It is remarkable that in both these cases the temperature coefficient of the reaction velocity was strongly negative. In all the other reactions the large positive temperature coefficient was due to the fact that the rate of evaporation of the filaments or of adsorbed materials on them increases so rapidly with temperature.

I do not mean to imply that all the truly chemical reactions must have negative temperature coefficients, but the results strongly suggest that

such chemical reactions are very common, and that their effects are masked by other physical factors having large positive temperature coefficients.

The number of chemical reactions previously known which have negative temperature coefficients is extremely small. Bodenstein cites one case, that of the reaction: $2\text{NO} + \text{O}_2 = 2\text{NO}_2$.

Strutt found that atomic nitrogen recombines to form molecules much more rapidly at low temperatures than at high, and he reasons that a high translational velocity of the molecule should in general hinder rather than hasten the reaction. He considers that rotational velocity of the molecules, on the other hand, favors the reaction and that this factor in the majority of reactions greatly outweighs that of the translational velocity. Thus reactions between atoms should always have negative temperature coefficients, since atoms cannot have rotational energy. The present work lends further support to Strutt's views.

The view-point developed as a result of this work with low pressure reactions is undoubtedly applicable to reactions at high pressures and also to reactions between solids and liquids. It is hoped that further work will lead in a similar way to a better understanding of the mechanism of homogeneous reactions.

In conclusion, the writer wishes to express his appreciation of the valuable assistance of Mr. S. P. Sweetser, who has carried out most of the experimental part of this work.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF THE STATE UNIVERSITY OF KENTUCKY.]

CUPROUS SALTS OF OXYGEN ACIDS AND A NEW METHOD FOR PREPARING CUPROUS SALTS.

[PRELIMINARY PAPER.]

By LLOYD C. DANIELS.

Received March 19, 1915.

The number of cuprous salts of oxygen acids is so small, and those that are known are so unfamiliar, that it is not surprising that the misstatement is often made in text-books, even in the larger number of the more modern ones, that such compounds do not exist.

The longest known and most familiar member of this class of compounds is red cuprous sulfite, $\text{Cu}_2\text{SO}_3 \cdot \text{H}_2\text{O}$, first prepared by Rojoski.¹ Bourson² gives, as the best method for its preparation, the addition of a concentrated solution of sodium bisulfite to a solution of cupric sulfate, filtration from the slight precipitate, and gentle warming of the filtrate. Sulfur

¹ *Jahresber.*, 1851, 366.

² *J. prakt. Chem.*, 25, 399 (1842).

dioxide is evolved and the red compound crystallizes out. Rammelsberg¹ believed this compound to be a cuprous-cupric sulfite, $\text{Cu}_2\text{SO}_3 \cdot \text{CuSO}_3 \cdot 2\text{H}_2\text{O}$, but Etard² declares that the original conception of it is correct. It is also known in the form of a white isomer (Etard³).

Berzelius⁴ recognized the existence of cuprous sulfate in solution as probable from the fact that cooling a mixture, made by passing sulfur dioxide into hot cupric sulfate solution, produces a slight precipitate of metallic copper on cooling. This precipitate he attributed to a decomposition in the sense of the equation: $\text{Cu}_2\text{SO}_4 \longrightarrow \text{Cu} + \text{CuSO}_4$. Two derivatives of cuprous sulfate were made before the mother-substance, itself, was isolated. Joannis⁵ prepared a carbon monoxide addition product, $\text{Cu}_2\text{SO}_4 \cdot (\text{CO})_4 \cdot \text{H}_2\text{O}$, by reduction of copper sulfate with copper in the presence of carbon monoxide. An ammoniated compound was prepared by Pechard⁶ by reduction of cupric sulfate in ammoniacal solution with hydroxylamine sulfate and precipitating with alcohol, by Bouzat⁷ by the action of ammonium sulfate on cuprous oxide in ammoniacal solution, and by Foerster and Blankenberg⁸ by electrolysis of an ammoniacal solution of cupric sulfate. It is a white crystalline compound of the formula $\text{Cu}_2\text{SO}_4 \cdot 5\text{NH}_3$. The free cuprous sulfate cannot be obtained by driving out the gaseous constituents of either of these derivatives; but it has been made by Recoura⁹ by the action of cuprous oxide on methyl sulfate:

It is described as a grayish white powder, stable in dry air and to heat (at least up to a temperature of 188° , since it was made by boiling with an excess of methyl sulfate), but it is quickly decomposed by moisture and in the sense supposed by Berzelius:

Acid cuprous thiosulfate, shining, golden needles, prepared by adding a solution of cupric sulfate to a solution of somewhat more than two mols of sodium thiosulfate, falls partly within this class. Its formula is $\text{Cu}_2\text{H}_4(\text{S}_2\text{O}_3)_3$. Cuprous metaphosphate in solid solution in excess of metaphosphoric acid was prepared by Auger.¹⁰ Cuprous acetate is briefly mentioned by Pechard⁸ as a white crystalline compound, $\text{Cu}_2(\text{C}_2\text{H}_3\text{O}_2)_2$,

resulting from reduction of cupric acetate in ammoniacal solution with hydroxylamine sulfate. Ammoniated cuprous formate, $\text{Cu}_2(\text{HCO}_2)_2 \cdot 4\text{NH}_3 \cdot 1/2\text{H}_2\text{O}$, and ammoniated cuprous benzoate, $\text{Cu}_2(\text{C}_7\text{H}_5\text{O}_2)_2 \cdot 5\text{NH}_3$, were prepared by Joannis¹ by the action of the ammonium salts of the respective acids on cuprous oxide—both reagents in liquid ammonia solution.

Experimental.

The cuprous salts of some organic acids were desired for purposes which, if accomplished, will be reported later, and an attempt was made to prepare the oxalate by reducing the cupric compound with sulfur dioxide in the presence of oxalic acid or of alkali oxalate. No change could be obtained, possibly on account of the very slight solubility of the cupric oxalate, but, when the latter was dissolved in ammonia and sulfur dioxide was passed in to acid reaction, some interesting color changes and precipitations took place, and there was left an insoluble mixture containing a brown substance now believed to be the desired salt. This procedure was not studied, since a new and simpler process was found.

Cuprous sulfite was sprinkled little by little into a hot solution of an excess of oxalic acid; the solid changed from bright red to brown and much sulfur dioxide was evolved. The precipitate was almost as fine and difficult to filter as calcium oxalate, but became coarser by continued warming. It was filtered off, washed with water and finally with alcohol and tested qualitatively, as follows:

1. Hydrochloric acid, diluted (1:2), was freed from dissolved oxygen by warming in a stream of carbon dioxide and a little of the compound was thrown into the hot acid while still protected from air by the stream of gas. Immediate solution took place, indicating absence of free copper and only a faint color was present, indicating absence of cupric salt.
2. The compound dissolved in concentrated ammonia with considerable blue color which rapidly increased in intensity; that there was no free copper in the substance was proven by the absence of insoluble residue.
3. Warm dilute (1:15) nitric acid used in small quantity decomposes the substance, forming copper and copper nitrate. The solution, freed from copper by hydrogen sulfide, showed the presence of oxalic acid in large quantity.
4. Decomposed with a few drops of concentrated nitric acid and dissolved in water, the solution gave no precipitate with barium chloride, showing absence of sulfur compounds.
5. With cold, very dilute, sulfuric acid the compound remains unchanged, but it decomposes instantly on warming to about 30° , giving cupric oxalate and copper.

¹ *Compt. rend.*, 138, 1499 (1904).

6. Dilute nitric acid (1:15) does not change it in the cold but oxidizes it to copper nitrate by heating.

7. A sample of about 2 g. was heated in a water-jacketed air bath (about 95°) for two hours and changed in color to a dull, dark gray. This substance, when thrown into cold dilute nitric acid, changed back to the brown without any green or blue color showing in the liquid or in the solid.

8. Heated alone in a crucible, the substance changes to gray, then to greenish gray giving off traces of water, and then decomposes suddenly, almost explosively, scattering so that no residue remains in the crucible. (Silver oxalate explodes if heated quickly.¹)

Quantitative determination of the copper was made by decomposing it in a crucible with a few drops of slightly diluted nitric acid, evaporating and igniting.

0.3393 and 0.3003 g. gave 0.2148 and 0.1911 g. CuO; found: 50.57 and 50.82% Cu; Calc. for $\text{Cu}_2\text{C}_2\text{O}_4$: Cu, 53.89%; for $\text{Cu}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$: Cu, 50.61%.

The gray sample mentioned above was analyzed with the results:

0.1132 and 0.1317 g. gave 0.0717 and 0.0872 g. CuO; found: 50.70% and 50.82% Cu.

From this, taken in connection with its behavior with dilute nitric acid, the gray substance is of the same composition as the brown.

Attempts were made to find the reducing value of the oxalic acid radical by suspending the substance in hot water, passing hydrogen sulfide through and gradually adding dilute hydrochloric acid. The excess hydrogen sulfide was removed from the filtrate by heating in a stream of carbon dioxide and the solution was titrated with permanganate. Sharp end points were obtained, but the results were very erratic, all of them, however, indicating much greater reducing power than calculated for the formula $\text{Cu}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$, or even for the anhydrous salt formula. The substance was then decomposed in the presence of an excess of calcium nitrate with dilute nitric acid, and calcium oxalate was precipitated with an excess of ammonia. The oxalate was then titrated as usual.

The factor for the permanganate was cc. $\times 1.0967 =$ cc. 0.1 N. 0.2339 and 0.2107 g. required 23.14 and 20.85 cc.; found: 47.53% and 47.55% C_2O_4 .

The complete analysis, as far as carried out, is Cu 50.69, C_2O_4 47.54; Calc. for $\text{Cu}_2\text{H}_2(\text{C}_2\text{O}_4)_4$: 51.14, 47.25.

A hot water extract of the salt was found to be acid to methyl orange, though this may have been due to hydrolysis rather than to acidity of the salt.

What is apparently the same substance can also be prepared by digesting cuprous oxide with a solution of two and one-half parts of oxalic

¹ Richter's "Organic Chemistry," 3^d Am. Ed., Vol. I, 433-4.

acid. A sample made by digesting 4 g. of the oxide with the acid for three hours was analyzed for copper:

0.2256 g. gave 0.1156 g. CuO; found: Cu 50.95%.

The reactions of many other organic acids on cuprous sulfite have been tried but, in all cases, more or less green coloration has indicated the formation of cupric compounds. Apparently, the solubility of the cuprous compound first formed is chiefly responsible for the success of the experiment. The appearance of the insoluble portions obtained in some of the experiments gives encouragement to the hope that they can be used for further transformations as cuprous salts.

Conclusions.

1. Attention has been called to an erroneous statement common in text-books of general chemistry.
2. A new method for the preparation of cuprous salts of oxygen acids has been devised, and the probable conditions of its applicability have been indicated.
3. A new compound of the class has been prepared, some of its properties described, and its probable formula determined.

LEXINGTON, Ky.

[HARRIMAN RESEARCH LABORATORY, ROOSEVELT HOSPITAL, NEW YORK CITY.]

A PRECIPITANT FOR AMMONIA. (A SUBSTITUTE FOR NESSLER'S REAGENT.)

By SARA STOWELL GRAVES.

Received March 3, 1915.

TABLE OF CONTENTS.—I. Introduction. II. The Reagent. III. Results with Reagent. IV. Directions. V. Applications. VI. Summary.

I. Introduction.

Nessler's reagent for ammonia, developed in the early part of the last century, was applied to water analysis in 1867. It has stood the test of time and has come into wide use, particularly in physiological work. But with the development of colorimetry, its disadvantages, as well as its value, have become apparent and innumerable modifications of the reagent have resulted. Its instability and tendency to produce a cloud in dilute solutions are the chief difficulties. Recently efforts have been made to apply the reagent in micro-Kjeldahl¹ work (without previous distillation) with varying degrees of success, the precipitate due to salts making the accurate matching of colors extremely hard.

A probable explanation of why the colored solution produced by Nessler's reagent becomes cloudy, especially in the presence of salts, may be found in the following considerations:

¹ Folin and Farmer, *J. Biol. Chem.*, **11**, 493 (1912); Gulick, *Ibid.*, **18**, (1914); Bock and Benedict, *Ibid.*, **20**, 47 (1914).

(a) Only the iodide complex of mercury and ammonia is highly colored and soluble.

(b) The other complexes of mercury and ammonia, like the chloride described in this paper, are colorless, insoluble compounds.

Therefore in the presence of other salts, the colored iodide complex is probably partially changed to, and in equilibrium with, the colorless complexes, such as the chloride or sulfate, and as only the color is estimated, appreciable error may result.

The idea of finding a precipitant for ammonia, was suggested by a research of Dr. W. G. Lyle as to the possibility of determining the non-protein nitrogen in blood, nephelometrically, and in the course of discussion, mercuric chloride was mentioned as a likely reagent.

Having in mind Nessler's solution and its disadvantages, an attempt was made to evolve an alkaline mercuric chloride solution which would be stable and colorless and which would form a white precipitate with ammonia, quantitatively. Since the salts, which interfere with the Nessler color, produce a white complex with mercury and ammonia, no probable error would be introduced by this proposed reagent.

II. Reagent.

Mercuric Chloride Complexes.—When a solution of mercuric chloride is made alkaline, immediately the yellow or red oxide forms, but it was found that by first adding sodium chloride, a complex was formed which was stable except in the presence of a large excess of alkali. As will be seen from the following equation, 2 molecules of sodium chloride unite with one of mercuric chloride:

This complex is readily soluble in water and while it has an appreciable dissociation into HgCl_2 and NaCl ,¹ with large amounts of sodium chloride, the dissociation is practically zero. It has the further advantage that chlorine compounds are more stable than those of the other halogens. Thus, the ammonium complexes of mercuric chloride are more stable than those of the bromide or iodide. The neutral iodine complex has a noticeable vapor tension of ammonia, which the analogous complex of chlorine has not.

Components of Reagent.—The reagent used consisted of mercuric chloride, sodium chloride, and lithium carbonate. The latter was chosen because of the low atomic weight of the cation and, therefore, but slight tendency to cause agglutination of suspensoids. Each component of the reagent was varied, in order to ascertain the most favorable conditions for the quantitative precipitation of ammonia.

¹ W. Richards and Archibald, *Z. physik. Chem.*, 40, 385 (1902); Le Blanc and Noyes, *Ibid.*, 6, 393 (1890).

50 cc. of a cold saturated solution of mercuric chloride and 50 cc. of water were chosen arbitrarily and the sodium chloride and lithium carbonate varied to the points at which mercuric oxide formed—with the following results:

TABLE I.—PRECIPITATION POINTS OF MERCURIC OXIDE.

Sat. sol. of HgCl ₂ . Cc.	H ₂ O. Cc.	NaCl. Grams.	Saturated Li ₂ CO ₃ solution. Cc.
50	50	5	5
50	50	10	30
50	50	15	50 plus
50	50	20	50 plus

50 cc. of mercuric chloride solution, 15 g. of sodium chloride, 35 cc. of saturated lithium carbonate solution, and 65 cc. of water were found to produce a satisfactory reagent. Experiments showed that it is fully as sensitive as Nessler's reagent, and it seemed likely that, owing to the sensitiveness of nephelometry, very small amounts of ammonia could be determined quantitatively more easily as a cloud than as a very faint color. The reagent precipitates ammonia from ammonium sulfate solutions as dilute as 1 part per million, producing a bluish white cloud which agglutinates in stronger solutions after a few minutes.

Before studying the reagent further it was necessary to find a protective colloid, to keep the precipitate in suspension long enough to make nephelometric readings (10–30 minutes). Soluble starch, when very dilute, proved satisfactory.

Two sets of experiments were accordingly carried out, using 10 cc. of ammonium sulfate solution (10.0 mg. per liter), 15 cc. of starch solution (5.0 mg. per liter) and 5 cc. of reagent, in which the mercuric chloride and lithium carbonate were varied. The clouds formed were compared with a fixed standard, in the nephelometer.

(1) **Mercuric Chloride.**—The mercuric chloride was varied from 25 to 75 cc. of saturated solution per 150 cc. of reagent. There was no appreciable change in the readings of the different solutions tested.

(2) **Lithium Carbonate.**—The amount of saturated solution of lithium carbonate (about 1%) was varied from 12.5 to 75 cc. 65 to 75 cc. produced mercuric oxide on standing. Solutions containing less than 65 cc. showed no marked difference in nephelometric readings.

Protective Colloid.—The effect of starch upon salt was studied in two connections: (1) When the reagent contained varying amounts of sodium chloride. (2) When the ammonia solutions contained varying amounts of potassium sulfate, thus allowing for any reasonable variation in the amount of ammonia as compared to salt found in micro-analysis.

(1) To 150 cc. of reagent, which already contained 15 g. of sodium chloride, more sodium chloride was added in varying amounts of 10,

20, 25, and 35 g., respectively. It was found that the solutions containing 20, 25 and 35 g. additional salt all allowed the use of a fairly large amount of starch. 25 g. were then decided upon, making a total of 40 g. of sodium chloride in 150 cc. of reagent. Later experiments show the effect of sodium chloride upon the constants of the reagent.

(2) The ammonium sulfate solutions were of three types: *A*, pure. *B*, with the amount of potassium sulfate found in normal Kjeldahl work. *C*, with four times the amount of salt found in normal Kjeldahl work.

Solution A contained 1.0 mg. of ammonium sulfate in 100 cc. or 2.57 mg. of ammonia per liter.

Solution B contained 1.0 mg. of ammonium sulfate, and 10 cc. of potassium sulfate solution (75 g. per liter), in 100 cc.

Solution C contained 1.0 mg. of ammonium sulfate, and 40 cc. of potassium sulfate solution (75 g. per liter) in 100 cc.

To solutions *A*₁, *B*₁, and *C*₁ (10 cc.) were added various amounts of starch, always diluting to 25 cc. at this point, and the time was determined from the moment the reagent (5 cc.) was added, until agglutinations were visible to the naked eye. At the same time it was observed that the nephelometric readings became slightly higher. The results obtained are seen in Table II, the minutes indicating the time during which the solutions are constant and suitable for nephelometric work, and the concentration of starch indicating the strength of the final solutions:

TABLE II.—TIME OF AGGLUTINATION.

Concentration starch. Mg. per liter.	<i>A</i> ₁ . Min.	<i>B</i> ₁ . Min.	<i>C</i> ₁ . Min.
0	14	11	5
2.5	27	15	6
5	37	25	10
10	48	40	14
15	60	60	20
20	28
25	32
40	50
50	60

It may be seen that the suspensions are fairly stable even without starch.

Completeness of Precipitation.—It was necessary to determine whether or not the completeness of precipitation was affected by the colloid.

To do this, solutions *A*₂, *B*₂, and *C*₂ were prepared containing 0.500 mg. of ammonium sulfate instead of 1 mg. as in *A*₁, *B*₁, and *C*₁. To 10 cc. of solutions *A*₂, *B*₂ and *C*₂ were added definite amounts of starch, diluting at this point to 25 cc. and finally 5 cc. of reagent were added with shaking, and the solutions compared with solutions *A*₁, *B*₁, and *C*₁, respectively, in the nephelometer. From the results the nephelometric constants (*k*) were calculated, using the formula¹

¹ For details as to nephelometric instrument, formula and manipulations, see Knabe, *J. Biol. Chem.*, 13, 490 (1913).

$$y = s/x - (1-x)sk/x^2$$

where y equals the reading of A_2

" s " " " " A_1

" x " " " ratio of A_1 to A_2 or 0.500.

Using the reagent containing 40 g. of sodium chloride per 150 cc., the following constants were obtained:

TABLE III.—EFFECT OF STARCH ON NEPHELOMETRIC CONSTANTS.

Concentration of starch. Mg. per liter.	A/k.	B/k.	C/k.
50	0.033	0.140	0.138
35	0.075	0.135	0.132
25	0.130	0.136	0.136
15	0.133	0.138	0.136
5	0.140	0.132	0.133

The above results show that in starch solutions containing 35 and 50 mg. per liter the precipitation of the pure solutions A, is retarded, but that in solutions containing less than 35 g. per liter the precipitation of the three solutions is apparently complete.

Table IV shows the effect of a reagent containing only 15 g. of sodium chloride per 150 cc. under similar conditions.

TABLE IV (Continuation of III).

Concentration of starch. Mg. per liter.	A/k.	B/k.	C/k.
15.0	Negative	Negative	0.077
5.0	0.090	0.180	0.173
2.5	0.164	0.154	0.166

Here it is evident that the precipitation is delayed in a starch solution containing 15 mg. per liter. The slightly higher constants with this reagent might be explained by the following equation:

According to the Law of Mass action the increased amount of sodium chloride would have a tendency to shift the equilibrium from the ammonium complex formation and therefore the reagent containing less sodium chloride might give more complete precipitation and thus slightly higher nephelometric constants.

III. Results with Reagent.

To test the precipitability of ammonia by the modified mercuric chloride reagent, three sets of ammonium sulfate solutions A, B, and C were made, as previously described, in which the amount of ammonium sulfate was varied from 10 to 5 mg. per liter.

Starch was added, the ammonia precipitated by the reagent, and the solution compared with a known standard in the nephelometer. From

Curve No. I.

the readings (usually 2) the accompanying curves were plotted. They are compared with the hypothetical or colorimetric curves. Curve No. I, with solutions A; Curve No. II, with solutions B; Curve No. III, with solutions C.

Solutions A contained 10 cc. of ammonium sulfate solutions containing 100, 90, 80, 70, 60, 50 mg. per liter, made up to 100 cc. with ammonia-free

Solutions B contained ammonium sulfate in the same amounts as solutions A, and in addition 10 cc. of potassium sulfate solution (75 g. per liter); the volume was then made up to 100 cc. with ammonia-free water.

TABLE V.—NEPHELOMETRIC READINGS.

(NH ₄) ₂ SO ₄ Mg. per liter.	Solutions A.		Solutions B.		Solutions C.	
	Readings. Mm.	Constant. k.	Readings. Mm.	Constant. k.	Readings. Mm.	Constant. k.
10.0	14.90	...	14.90	...	14.90	...
9.0	16.30	0.140	16.30	0.140	16.30	0.140
8.0	17.95	0.141	17.90	0.152	17.93	0.146
7.0	20.05	0.140	20.06	0.139	20.00	0.145
6.0	22.75	0.131	22.80	0.128	22.77	0.136
5.0	25.80	0.134	25.85	0.132	25.85	0.132
Average,		0.137			0.138	0.140

The hypothetical or colorimetric curve is obtained by assuming the readings to be inversely proportional to the concentration of the substance.

Solutions C were like solutions B except that they contained 40 cc. instead of 10 cc. of potassium sulfate solution (75 g. per liter).

To 10 cc. of solution were added 15 cc. of starch solution (30 mg. per liter) and finally, while shaking in a rotary fashion, 5 cc. of reagent were run in from a pipet. The strongest solution (10 mg. per liter) of a series was used as a standard, and the others of a series compared with it in succession. The preceding readings are the average of 2 or 3 readings.

From these results it seems probable that the precipitation is nearly complete, since:

(1) The curves are well below the hypothetical.

(2) The readings are consistent.

(3) The nephelometric constants are in close agreement.

Curve No. II.

IV. Directions.

A. Solutions: Ammonia-free Water.—Ammonia-free water must be used in making up all solutions which enter into the standard solution, just as with the Nessler standard. The usual recommendation is water which contains not more than 0.005 mg. of ammonia in 100 cc. This may be easily obtained by distilling tap water which has been made slightly acid with sulfuric acid.

Reagent.—To 80 g. of sodium chloride are added 130 cc. of water and 100 cc. of a cold saturated solution of mercuric chloride, with shaking. When the salt is practically all dissolved, 70 cc. of a saturated solution of lithium carbonate (1%) is added slowly while shaking, so that no

mercuric oxide forms on the sides of the flask. The solution is usually cloudy, owing to the ammonia in the reagents, but if well shaken with

Curve No. III.

talcum powder (3-5 g.) it is easily filtered clear. The solution may be used at once, or if carefully stoppered may be kept almost any length of time.¹ Filtering the reagent does away with errors due to impurities in its constituents.

Protective Colloid.

—A stock solution of starch is freshly made each day by boiling 1 g. of starch in ammonia-free water until clear and making up to 100 cc. with ammonia-free water.

Standard Solution.

—Ammonium sulfate prepared and purified according to Folin's² directions is used for a standard. The standard solution is made by taking 10 cc. of an ammonium sulfate

solution (100 mg. per liter), adding 10 cc. of potassium sulfate solution (75 g. per liter) and making up to 100 cc. in a volumetric flask with ammonia-free water. The amount chosen for a standard cloud is usually 10 cc. of this solution, ammonium sulfate (10 mg. per liter) to which is added 15 cc. of 0.003% starch and 5 cc. of reagent. Half or even one-fourth of the above amount is ample, the object in choosing a fairly strong standard being to lessen the percentage of error due to traces of ammonia in dust or water. In all experiments controls should be made on the water as well as on the reagents.

¹ Solutions have been kept several weeks without noticeable change.

² *Loc. cit.*

Potassium sulfate is added to the standard solutions in order to reproduce as far as possible the conditions found in all Kjeldahl work. Preceding data show that large or small amounts of salt do not affect the precipitation of ammonia with the reagents as given.

(B) Kjeldahl Nitrogen Estimation.

Catalyst.—It is necessary to use mercuric oxide instead of cupric sulfate as a catalytic agent, owing to the blue color developed by copper in alkaline solution.

Dilution.—After the usual heating the solutions containing the substance are diluted to 500 cc. and the blanks to 250 cc. These solutions may be designated as solutions A_x and A_y .

Neutralization.—5 cc. or more of solution A_x and 50 cc. or more of solution A_y are neutralized with sodium hydroxide, using litmus paper as indicator and each is made up to 100 cc. in a volumetric flask with ammonia-free water. Designation, solutions B_x and B_y .

To 5 cc. of solution A_x is added about 5 cc. 1 *N* sodium hydroxide and then 1 *N* sodium hydroxide drop by drop to the neutral point. To 50 cc. of solution A_y is added about 30 cc. of 15% NaOH and then 1 *N* NaOH drop by drop to the neutral point.

Care must be taken not to add a considerable excess of sodium hydroxide, or else mercuric oxide will form upon addition of the reagent. The small amounts of ammonia in the control can be readily estimated, if the control solution is not more than one-twentieth as dilute as the solution containing the substance. If the solutions B are cloudy because of the precipitation of alkaline earths, etc., they should be filtered through a dry filter after making up to volume.

Precipitation.—To 10 cc. of solution B are added 16 cc. of starch solution (30 mg. per liter) and 5 cc. of reagent with shaking, and the cloud produced compared with a standard ammonium sulfate cloud, by means of the nephelometer.

Calculation of Results.—From the readings of the standard solution and the unknown, by means of the formula $y = s/x - (1-x)sk/x^2$ the ratio of the concentrations of the solutions can be found and the amount of ammonia or nitrogen in the substance taken for analysis readily calculated, subtracting the amount of ammonia in the control. A more convenient form of the equation when solving for x is $x = \frac{s + sk + \sqrt{(s + sk)^2 - 4sky}}{2y}$ in which $(s + sk)$ is constant throughout any series of determinations. For this reagent k is about 0.138.

V. Applications.

The preceding method of making nitrogen estimations was tried on ammonium sulfate alone, and on ammonium sulfate with organic matter

(filter paper), as well as on uric acid and urine, with satisfactory results—which attest to the sensitivity of the reagent and its ability to precipitate ammonia quantitatively.

(1) 0.1001 g. of ammonium sulfate was digested with 5 g. of potassium sulfate and 20 cc. of sulfuric acid in the usual way. Duplicate estimations as well as duplicate controls were made. The solutions were diluted directly *without the usual distillation*, and the ammonia was determined according to the preceding directions, the standard solution containing 0.1001 g. of ammonium sulfate.

Solution.	Y.	S.	X.	Nitrogen found, g.	% Nitrogen found.	% Nitrogen theoretical.

		$\frac{1}{2}$ S				
Control ¹	24.00	14.00	0.503	0.00025

(3) 0.100 g. uric acid was digested in each of four experiments with 10 g. of potassium sulfate and 20 cc. of concentrated sulfuric acid in the usual way. Two controls were made at the same time.

Two of the uric acid digestions and one control were distilled by the aeration method² and the ammonia was estimated by titrating the distillate. The other two digestions and a control were treated as in Experiments 1 and 2.

PERCENTAGE OF NITROGEN IN URIC ACID.

VI. Summary.

A new reagent for ammonia has been found which:

- (1) Is more stable than Nessler's reagent in the presence of salts.
- (2) Is fully as sensitive as Nessler's reagent.
- (3) Will precipitate ammonia quantitatively.
- (4) Will give accurate results nephelometrically.
- (5) May be useful in water analysis.
- (6) May be directly applied to normal- and micro-Kjeldahl determinations, thus doing away with the tedium and errors of distillation.

I desire to express my gratitude to Mr. P. A. Kober, for the opportunity of working out this problem.

THE USE OF THE INTERFEROMETER FOR THE ANALYSIS OF SOLUTIONS.

By LEASON H. ADAMS.

Received March 29, 1915.

Chemists have long used the refractometer as an aid in analytical work, but have not made use of the interferometer to the extent that its precision and general convenience would warrant. The use of the ordinary forms of refractometer is limited by the circumstance that the change of refractive index with temperature is usually such as to require regulation of temperature to 0.01° in order to secure an accuracy of one unit in the sixth place in the measurement of refractive index. By means of the interferometer, on the other hand, it is a simple matter, requiring no special regulation of temperature, to secure an accuracy of one unit in the seventh place; this is possible because in the latter case we are comparing the refringence of one liquid (or gas) with that of another of very nearly the same composition and hence possessing almost the same temperature coefficient of refringence. In other words, with the refractometer one can determine the composition of a solution to 2 parts in 10,000 of solvent, but with the interferometer—provided that certain simple precautions be observed—to 2 parts in a million. The interferometer is adapted to the determination in any transparent mixture of a single varying component; this component may be solute or solvent, electrolyte or nonelectrolyte, indeed any substance which will not attack the

instrument. It is the purpose of the present paper to describe briefly a commercial interferometer which is convenient for chemical purposes, to discuss its mode of operation and to point out means of rendering it more generally useful. In the first place it is desirable, in the interest of a better understanding of the use of the interferometer, to recall some fundamental facts concerning the interference of light waves.

Principle of the Interferometer.—All interferometers, when reduced to their simplest terms, may be represented by Fig. 1. Light from a source, S , passes through two small openings, R_1 and R_2 , and the two

Fig. 1.—Elementary Interferometer. Two beams of light from a source, S , pass through the rectangular openings R_1 , R_2 and falling on the screen at right produce a system of interference fringes which by the introduction of material at C are shifted by a certain amount depending on the thickness and refractive index of the material.

beams overlap as they fall on the screen at the right. At a point, O , equidistant from R_1 and R_2 the light waves arrive in the same phase, and a light spot or band results; but at all other points on the screen the paths of the two beams are of different lengths. Thus at X_1 or X_2 , this path difference is exactly one-half wave-length, the two beams

"interfere" and a dark band results; at Y_1 or Y_2 the retardation is a whole wave-length, the two sets of waves arrive at the screen again in the same phase, and a bright band is observed. In this way there is formed on the screen a series of alternate bright and dark bands, or so-called interference fringes.

With monochromatic light as the source (*e. g.*, the light from a sodium flame) the bands are alternately black and the color of the light source (*e. g.*, yellow); with white light, on the other hand, only the central band is pure white, the next bright band beyond the adjacent dark spaces being edged with blue toward the center of the system and with red on the outside, while the bands still further away from the center appear successively more and more diffusely colored, finally fading into a uniform white.

Now if any material is placed in the path of one beam, as at C , the light waves of this beam will be retarded by an amount depending on both the thickness and refractive index of the material. The optical path is therefore lengthened, the expression for the path difference p being

$$p = l(n - n_0) \quad (I)$$

where l is the thickness and n the refractive index of the material and n_0 that of the surrounding medium. Since the optical path R_2O has now been lengthened, the two trains of light waves arrive in the same

phase no longer at O but at another point O' ; the central bright band originally at O is therefore displaced to the point (O') which is optically equidistant from R_1 and R_2 . Furthermore, it can readily be shown that for light of wave-length λ the number of fringes between O and O' —that is, the displacement of O measured in fringes (each made up of one bright and one dark band)—follows the simple relation,

$$N = p/\lambda,$$

whence by (I)

$$N = l(n - n_0)/\lambda \quad (\text{II})$$

Therefore, by counting the number of fringes, we may determine the product $l(n - n_0)$ and hence either the thickness or the difference in refractive index if the other is known.

Again, it is evident that by inserting a plate in the path of each beam, we can in this way determine the difference in refractive index of the two plates, if the thickness of each is known. Likewise, if we have a pair of similar vessels of appropriate construction, place one in the path of each beam, and observe the displacement of O (in terms of fringes) consequent upon the filling of each vessel with a transparent substance (or mixture), we can by this means determine the difference in refractive index of the two substances. Such an arrangement constitutes a differential refractometer, which is capable of giving with a very high degree of accuracy the difference of refractive index of any two mixtures (or pure substances, liquid or gaseous); and this difference can be utilized as a convenient and accurate measure of the concentration of a single varying component in a solution (or gaseous mixture). A convenient instrument designed for this purpose is the Zeiss Water Interferometer,¹ the essential features of which we proceed to outline.

Description of the Zeiss Interferometer and of Its Mode of Operation.

—The simplified interferometer shown in Fig. 1 would be inconvenient in practice; a more useful arrangement is that of Fig. 2, which illustrates the set-up first used by Rayleigh, and later embodied with slight modifications in the apparatus made by Zeiss. White light from a slit is made parallel by a collimating lens, L (Fig. 2a), passes through the two rectangular openings R_1 R_2 as two beams which unite at O , forming a system of interference fringes which are viewed with a suitable eye-piece (not shown in this figure). Two similar chambers, C_1 C_2 , of appropriate construction are placed, one in each light path; the displacement of the fringes caused by a difference in refractive index of their contents is com-

¹ Made by Carl Zeiss, Jena. Full details of the construction of this instrument may be found in papers by Löwe (*Z. Instrumentenkunde*, 1910, 321), by Haber and Löwe (*Z. angew. Chem.*, 23, 1393 (1910)) and in the descriptive literature published by the Zeiss firm.

pensated—i. e., the central bright fringe is brought back to the zero position—by tilting the inclined glass plate P_1 , P_2 being fixed.

This tilting changes the effective thickness of the compensating plate P_1 ; when the central bright fringe is restored to the zero position, the change in effective thickness of the compensator just neutralizes the difference in the optical path through C_1 and C_2 . This arrangement is

Fig. 2.—Diagram of arrangements of interferometer; the two interfering beams are separated and reunited in (a) by two lenses, in (b) by a single lens.

essentially that used in the Zeiss Laboratory Interferometer (for gases); for the sake of compactness and portability it is modified slightly in the Water Interferometer and Portable Gas Interferometer. In this modification, illustrated in Fig. 2b, the same lens serves the double purpose of separating and reuniting the two interfering beams.

The actual arrangement of the Water Interferometer is shown in some detail in Fig. 3, which is a diagram in plan and elevation of the instrument in use here.

White light is furnished by the small 4 volt tungsten lamp F . By means of the lens A , a mirror and the totally reflecting prism K , the image of the filament F is focused on the narrow slit S (see Fig. 3, lower half); this slit acts as a (very narrow) secondary source, the light from which is rendered parallel (just as in Fig. 2b) by the lens L . The light then passes through the two compartments C_1 C_2 of the water chamber and the rectangular apertures R_1 R_2 , thence to a mirror, M , where the two beams of light are reflected back upon themselves, pass through the water chamber again and finally, by means of the lens L , are reunited at O ,

forming a series of interference fringes. These fringes are viewed by the cylindrical ocular *E*, which gives a magnification of 50 diameters, but in the horizontal direction only; the reasons for the use of a cylindrical ocular will be referred to later.

Besides the two interfering beams of light already considered, another pair proceed from the slit *S* in a precisely similar way, except that they pass *below* and not through the chamber *C*, likewise forming at *O* a second system of interference fringes. This latter fringe system is (practically) fixed in position; its sole purpose is to furnish a set of fiduciary lines

Fig. 3.—Drawing in plan (below) and elevation (above) of the Zeiss Water Interferometer.

which take the place of the cross-hairs ordinarily used as reference marks in optical instruments. Accordingly, if the eye is placed at *E*, one sees two sets of alternate bright and dark bands, the two sets being separated by a narrow horizontal dark line.¹ In each set of fringes only one of the bright bands is pure white, and the bands adjacent to it are bordered with blue towards the center and with red on the outside; it is this central

¹ The width of this line is made very small by means of the auxiliary plate *H*. Furthermore, the cylindrical eye-piece by magnifying only in horizontal direction does not increase the apparent thickness of the horizontal line. This feature of the cylindrical ocular is quite apart from its further advantage of giving, for a 50 diameter magnification, 50 times more light than an ordinary magnifier of the same power.

achromatic band (or the black bands immediately adjacent to it) which constitute the reference point of each system.

The upper set of bands can be displaced relatively to the lower set by tilting the movable inclined plate P_1 (P_2 is fixed); this is effected by turning the micrometer screw with attached drum D , by means of which, therefore, the two achromatic bands can be brought to coincidence, and the corresponding reading on the drum observed. Now, by placing one liquid (*e. g.*, pure water) in compartment C_2 and a second (*e. g.*, a dilute salt solution) in C_1 , the upper set of bands is displaced to the left; but they can be restored to their original position by turning the drum D in the proper direction. When an exact match is again obtained—*i. e.*, when the achromatic fringe is brought to a position directly above that of the corresponding fringe of the fixed lower system—the drum reading is again observed; a series of such settings can be made which will differ by no more than 1 division on the drum (which corresponds to about one-twentieth of a band or to 2 parts solute per million of water). The reading is a measure of the difference in refractive index of solution and water, and hence a measure of the concentration of the solution in C_1 . The interpretation of the readings in terms of actual concentration will now be treated.

Analysis of Solutions.—Since with the interferometer we determine a single variable, namely a difference in refractive index—or rather, an arbitrary reading related to it—it is evident that its utility for the analysis of solutions is limited to (1) the determination of the concentrations of a single substance in (*a*) a given liquid or (*b*) a mixture of liquids, or of liquids and solids, of constant composition; (2) the determination of the concentration of a solution containing several solids in fixed proportion (*e. g.*, sea water); and (3) the analysis of a mixture of two soluble solids (by making up a solution of known total solid content).

Let us now consider the application of the instrument to the analysis of a simple solution—of a single salt dissolved in water; the procedure of course is substantially identical in all cases. The interferometer may be used for the analyses of solutions in two ways: (1) as a direct reading instrument, (2) as a zero instrument. In either method the zero reading of the instrument is first obtained by bringing the fringes to coincidence when water (or the same solution) is placed in each compartment of the chamber; these “zero” readings, which, however, vary only very slightly from one day to another, are in all cases subtracted from the final readings.

In the first method, which is the one generally used heretofore, a series of solutions of the salt, of known concentration, are made up, and compared on the interferometer with samples of the water used in making up the comparison solutions. The readings¹ r are plotted against the

¹ Or preferably the values of the closely related quantity r' (*cf. postea*).

values of the concentration (c); the most convenient way of doing this is to plot r against c/r and to connect the series of points by a smooth curve. The concentration of any solution of this salt can then be determined by observing the reading when it is compared with water (preferably the water from which this solution was made up) and interpolating by means of the curve.

The sensitiveness and range depend on the length of the water chamber, which is supplied in 4 sizes, 5, 10, 20 and 40 mm. in length; in all cases settings can be made to one division on the drum and there are altogether the equivalent of 3,000 divisions. With the 40 mm. chamber one division corresponds to 1.5–3.0 parts substance per million of water for most aqueous solutions; the greatest differences of concentration which can be directly compared are therefore from 0.45–0.9%. An increase of range can be obtained either by using a shorter chamber (with corresponding loss in sensitiveness) or by using throughout as the comparison substance a standard solution of the salt in place of water.

The relative sensitiveness of the usual form of Water Interferometer for various substances in aqueous solution may be seen by referring to Table I. The column headed $\Delta c/\Delta r$ gives the amount of each salt (in parts per million parts of water) corresponding to one scale division when the 40 mm. chamber is used.

TABLE I.

Sensitiveness in parts per million per scale division ($\Delta c/\Delta r$) of the Zeiss Interferometer (with 40 mm. chamber) for various substances in aqueous solution.

Substance.	$\Delta c/\Delta r$.	Substance.	$\Delta c/\Delta r$.	Substance.	$\Delta c/\Delta r$.

In the second method the solution of unknown concentration is compared directly with two known solutions, one preferably of slightly higher, the other of slightly lower concentration, which should differ from one another by not more than 200 scale-divisions; from these two readings its concentration is then easily interpolated. This method requires the use of but a small portion of the scale of the interferometer, and presupposes an approximate knowledge of the concentration of the solution. Of the two methods the latter, while in general somewhat more laborious, is applicable to solutions of any concentration and is not subject to the

source of error noted below. The former method (1), on the other hand, while inherently more convenient and more rapid, is subject to a disadvantage connected with a phenomenon already noted by Marc¹ (in the case of colloidal solutions only)—the alteration and apparent shift of the white central band. This phenomenon, which is of general occurrence with compensation interferometers used with white light,² is an insidious source of error, which must be guarded against; its cause and the means of predicting in advance the exact amount of this shift will now be taken up.

Alteration in Character of the Comparison Band; its Apparent Shift.—

In the central or zero position the interference pattern, as seen in the field of the eye-piece, consists of three bright bands, a central white band separated on either side by a narrow black band from the parti-colored adjacent band, each of which is blue on the side towards the center of the field. Now if, by movement of the compensator, the left-hand bright band is brought to the center, it is seen to be not pure white but edged with blue on the right and red on the left, while the neighboring band to the left will be strongly colored on both edges; thus in this case there is no uncertainty as to which is the proper band on which to make the setting. Moreover, if the water in compartment C_1 be replaced by a very dilute solution, the original central achromatic band can (by turning the drum) be brought back into the field of view and distinguished without ambiguity. But in general the situation is somewhat different.

We may best understand what happens by supposing that in some way the concentration of a solution in C_1 is increased slowly and continuously from zero onwards, and that at the same time the original achromatic band is kept central by appropriate movement of the compensator. We would then, in most cases, observe that the original achromatic band gradually becomes colored at the edges, while the adjacent bands to right and left become, respectively, more and less strongly colored; with further increase of concentration the central band becomes identical in appearance with the band on the left, and, at length, the latter is achromatic while the central band is now parti-colored just as the right-hand band was originally. The comparison band has thus *apparently* shifted one band to the left; with further increase of concentration the same sequence of events occurs, and the apparently correct comparison band is shifted one additional band to the left for a certain concentration difference, this difference for KCl being (on our instrument) about 0.07% (280 divi-

Now, since in making readings on a series of solutions of a substance, *Proc. Roy. Soc. London, Ser. A*, **Chem. Zig.**, 36, 539 (1912).

Use of monochromatic light would obviate this difficulty, but on the other hand it necessitates special means to enable one to identify the original central band. The magnitude of this interval varies from one salt to another, being for instance much smaller for KNO_3 than for KCl; cf. *postea*.

stance we ought obviously to make the final setting always upon the same band, we shall err if the setting is made each time upon the most nearly achromatic band; and there will be one discontinuity for each such "concentration interval."

The explanation of this wandering of the original achromatic band is found in the relative optical dispersion of solution and water, on the one hand, and of glass (of the compensator plates $P_1 P_2$) and air, on the other hand. To obtain a quantitative expression for the magnitude of this effect it is first to be noted that in the type of instrument under consideration the lengthening of the optical path due to replacement of water by solution is compensated by the shortening of the *same* path by decreasing the effective thickness of an interposed glass plate. For the refractive indices of solution, water and glass we write n_1 , n_2 , and n , respectively, and put

$$\nu = n_1 - n_2$$

with appropriate subscripts attached to ν to denote the wave length to which it refers. The dispersive power (β') of the solution with respect to water¹ is defined by the relation

$$\beta' = (\nu_F - \nu_C)/\nu_D$$

and similarly,

$$\beta'' = \frac{n_F - n_C}{n_D - 1}$$

Now it can readily be shown² that with an interferometer of the type under discussion the position of the most nearly achromatic band will, as the concentration of the solution increases, shift one fringe to the left for a certain number r_1 of divisions on the drum, where

$$r_1 = 0.320 r_f / (\beta' - q\beta'') \quad (\text{III})$$

r_f being the number of divisions corresponding to one fringe in white light³ and q a constant depending on the refractive index of the compensator plate, and its initial inclination.⁴

Accordingly, the exact amount of the wandering of the achromatic band for any solution may be predicted in advance, and this source of

¹ It is to be noted that this quantity β' is not the same as the difference in relative dispersion of solution and water, *i. e.*,

$$\frac{n_{1F} - n_{1C}}{n_{1D} - 1} - \frac{n_{2F} - n_{2C}}{n_{2D} - 1} \text{ is not equal to } \frac{\nu_F - \nu_C}{\nu_D}$$

β'' on the other hand is the ordinary relative dispersion of the glass.

² See L. H. Adams, *J. Wash. Acad.*, 5, 276 (1915).

³ Or more specifically the light of the tungsten lamp which is ordinarily used as the light-source.

⁴ For the ordinary case of an initial inclination of about 45° and refractive index n ,

$$q = \frac{2n(n-1)}{(2n^2-1)^{1/2} - (2n^2-1)}$$

error thus guarded against, if the appropriate values of β' and β'' are known. The value of β'' for various kinds of glass may be found in tables of constants;¹ thus for the (crown) glass, of which the compensator plates in our instrument are made, $\beta'' = 0.015$, $n = 1.514$, and therefore $q = 0.48$.

β' has been measured for various salts in aqueous solution;² for KCl it is about 0.032. Consequently for a series of solutions of KCl (taking $r_f = 22$)³ $r_1 = 0.320 \times 22/0.025 = 280$ divisions; therefore, at a concentration corresponding to 140 scale divisions the originally white central band will have become identical in appearance with the left-hand band and at 280 divisions the original left-hand band will have become the achromatic one. This difficulty could be entirely obviated by using compensator plates of such glass that $q\beta' = \beta''$ for the solutions (or mixtures) under investigation. But, unfortunately, this can be done only to a limited extent, for high dispersion in glasses is accompanied by high refractive index, so that even in the extreme case of heaviest flint glass, $\beta'' = 0.051$, $n = 1.963$, $q = 0.35$, and therefore $q\beta''$ is only 0.018, while the corresponding quantity β' may be as high as 0.045 for solutions such as the nitrates and even higher for other salts such as the bromides and iodides. But, at any rate, it would be an improvement to substitute compensator plates of heavier optical glass for the usual crown glass ones. Thus compensator plates of the glass mentioned above (Jena optical glass No. S 57) would match all sulfate solutions (β' about 0.016) very well and for use with all other solutions would be at least as suitable as crown glass plates. But in general this difficulty of the wandering of the achromatic band can only be circumvented by recourse to one of two methods of procedure: (1) the employment of the "zero method" described above, which is in general the more satisfactory mode of operation, for in that case dispersion differences are of little consequence and in most cases will not lead to error, especially if the maximum reading in the scale is never greater than 100 or 200 divisions; or (2) a careful preliminary determination of the "concentration intervals," using as a guide Equation III above and the following Table II which summarizes the available mean values of β' for salts and other substances in aqueous solution. But it may be worth while to make this series of preliminary observations and so be enabled to use the direct method in the not infrequent case when a large number of similar solutions have to be analyzed; it is for this reason that this question of the shifting of the achromatic band has been discussed here at some length.

¹ Thus Landolt-Börnstein-Roth (p. 980) gives "reciprocal relative dispersion" $1/\beta'$.

² W. Hallwachs, *Ann. Physik*, 47, 381 (1891); A. H. Borgesius, *Ann. Physik*, 54, 221 (1895); D. Dijken, *Z. Physik. Chem.*, 24, 81 (1897).

³ On our instrument r_f for white light varies from 22 at the lower end of the scale to about 28 at the upper end.

TABLE II.

Mean Values of β' ($= (\nu_F - \nu_D)/\nu_D$) for Various Substances in Aqueous Solution.

Substance.	β' .	Substance.	β' .	Substance.	β' .
LiCl.....	0.037	NaBr.....	0.047	Na ₂ SO ₄	0.016
NaCl.....	0.036	KBr.....	0.045	K ₂ SO ₄	0.015
KCl.....	0.032	LiNO ₃	0.048	MgSO ₄	0.014
MgCl ₂	0.032	NaNO ₃	0.043	ZnSO ₄	0.015
ZnCl ₂	0.031	KNO ₃	0.042	(NH ₄) ₂ SO ₄	0.016
BaCl ₂	0.028	Mg(NO ₃) ₂	0.038	H ₂ SO ₄	0.022
HCl.....	0.045	Zn(NO ₃) ₂	0.035	CH ₃ COOH.....	0.021
NH ₄ Cl.....	0.035	NH ₄ NO ₃	0.043	Cane sugar.....	0.012
LiBr.....	0.049	Li ₂ SO ₄	0.017		

Inspection of this table shows that there is a wide range in the values of β' for different substances in aqueous solution; however, the substances may be divided into several groups, in each of which β' is nearly constant. Thus for all of the sulfates β' is not far from 0.016; for the chlorides β' is not far from 0.035, for the bromides 0.047 and for the nitrates about 0.040. The nonelectrolyte, cane sugar (and probably also mannite) is exceptionally low.

Interpretation of the Interferometer Readings in Terms of Refractive Index.—Although the interferometer reading is a measure of a difference in refractive index, a knowledge of refractive indices *per se* is not essential for the analysis of solutions or mixtures, since the readings on an arbitrary scale are converted directly into concentrations by means of a previously determined calibration curve or table. Nevertheless, it is of interest to note the exact connection between the reading r of the instrument and the refractive index differences ν of the mixtures in question. Owing to the manner in which the micrometer screw moves the inclined compensator plate, the readings r on the drum are not quite directly proportional to ν , but by means of a small and easily applied correction they may be made so. It can readily be shown¹ that the change in optical path p caused by the rotation through an angle θ , (reckoned from the initial position at 45° to the light rays), of a plane-parallel plate of thickness h and refractive index n is found by the relation

$$p = \sqrt{2}h(\sqrt{H} - 1 - \sqrt{H} + \sin 2\theta + \cos \theta + \sin \theta)$$

where $H = 2n^2 - 1$. Furthermore, if R is the distance (in mm.) through which the micrometer screw moves and a the constant perpendicular distance from the center of rotation to the line of motion of the screw, then

$$\sin \theta = R/\sqrt{R^2 + a^2}$$

and

$$\cos \theta = a/\sqrt{R^2 + a^2}.$$

Substituting these values in the above expression we have, with sufficient approximation,

¹ See L. H. Adams, *J. Wash. Acad. Sci.*, 5, 267-9 (1915).

$$\frac{p}{\sqrt{2}h} = \frac{R}{a} \left(1 - \frac{1}{\sqrt{H}}\right) - \frac{R^2}{2a^2} \left(1 - \frac{1}{H^{1.5}}\right). \quad (\text{IVa})$$

Let R' be a quantity such that

$$\frac{p}{\sqrt{2}h} = \frac{R'}{a} \left(1 - \frac{1}{\sqrt{H}}\right)$$

then

$$R' = R - \frac{R^2}{2a} \left(\frac{1 - 1/H^{1.5}}{1 - 1/\sqrt{H}} \right). \quad (\text{IVb})$$

Now in our instrument $r \doteq 200 R$, $a = 110$ mm., $n = 1.51$. Making these substitutions we obtain finally the relation (for our instrument)

$$r' = r - 0.000041 r^2. \quad (\text{IV})$$

R' (and hence also r') is a number proportional to the decrease in optical path of the compensator plate, and therefore is strictly proportional to the quantity ν .

Although not essential, it is advantageous to use r' rather than r in all work with the interferometer; because, as the concentration c varies, the variation of the quotient c/r' is more regular than that of c/r . In the case of practically all substances in aqueous solution, c/ν , and hence c/r' , *increases* slowly with increasing concentration; c/r on the other hand usually *decreases* rather rapidly, while in using the zero method one may obtain values of c/r (the concentration gradient) which increase and decrease in a very irregular way, depending on the magnitude of c and of r . The data of Table III on mannite solutions (for which I

TABLE III.

Conc. parts per million.	\bar{c} . (Av.)	Δc .	r .	$\Delta c/r$.	r' .	c/r' .
504 0	252	504	217	2.32	215	2.34
1024 0	512	1024	447	2.29	438	2.34

am indebted to Mr. R. E. Hall) illustrate this point. Inspection of this table, which is self-explanatory, shows the much greater regularity of the concentration gradient obtained by converting the readings r into the "corrected" readings r' according to Equation IV. This procedure not only makes for greater convenience in plotting calibration curves and interpolating from them, but, in addition, it renders the detection of errors from various sources much more easy and certain.

As an example of the numerical relation between r' and ν we may take the following case:

A KCl solution containing 357 parts per million of water gives in the 40 mm. chamber of our instrument a reading $r = 150$, which by Equation IV corresponds to $r' = 149$. The retardation N in wave-lengths, is then $N = r'/r_f = 149/22.0 = 6.78$, and by Equation II, $\nu = N\lambda/l$. Here l is twice the length of the chamber or 80 mm. Hence, taking $\lambda = 0.00058$ mm. we have the difference in refractive index between solution and water, $\nu = 0.0000497$ at 22° . This result may be compared with the results of Dijken² and Borgesius³ for KCl solutions. By interpolation from their results ν_D at 22° for the same KCl concentration is 0.0000505 (Dijken), 0.000478 (Borgesius).

Concluding Remarks.—A few hints with regard to methods which have proved useful in actual working with the instrument may be worth mentioning. Changing of solutions is effected by means of a pipet (preferably provided with a rubber syringe bulb), over the tip of which is slid a small piece of rubber tubing in order to obviate damage to the water chamber. It is advisable to rinse two or three times; filter paper can be used to absorb the few drops remaining in the chamber each time, except in the final rinsing. One must wait until the temperature of the solutions is uniform, since otherwise the bands are distorted. Several independent settings of the drum should be made on each sample of solution, and it is advisable for the highest accuracy to take readings on more than one sample of each solution.

It has already been mentioned that one advantage of the interferometer is its insensitiveness to temperature changes as compared with ordinary refractometers. The temperature coefficient is not absolutely *nil*, however; for example, in the case of KCl solutions it is about -0.2% per degree (at 20 – 25°) and for KNO_3 solutions about -0.5% per degree; that is, if in reading one KCl solution against another we find $r = 200$ at 25° , the corresponding reading at 20° would be 202. It is evident that for small temperature fluctuations and with small readings such as are obtained when using the "zero" method, the temperature effect may be neglected; but if greater accuracy is desired the temperature coefficients may easily be determined and the necessary small corrections applied.

A number of possible applications of the interferometer to chemical work has already been suggested at various times. The instrument was originally designed for the analysis of sea-water and has been successfully used for that purpose, while Marc has employed it for the analysis of colloidal solutions. Another purpose for which the interferometer would be especially suitable is the standardization of solutions for volumetric analysis; other uses will readily suggest themselves. One such use only

¹ N , and hence ν , may be calculated without reference to r' by using formula IVa and knowing h and n for the compensator plate.

² D. Dijken, *Z. physik. Chem.*, **24**, 96 (1897).

³ A. H. Borgesius, *Ann. Physik*, **54**, 233 (1895).

will be mentioned; namely, that mixtures of sodium and potassium salts may be rapidly analyzed with an accuracy equaling or even exceeding that of the most careful gravimetric analyses. For instance, suppose we wish to determine the amounts of soda and potash in a mixture of their sulfates, which need not weigh more than 50 mg. altogether. We dissolve this mixture in exactly 200 times its weight of water and compare it on the interferometer with a standard solution containing pure, dry K_2SO_4 dissolved in 200 times its weight of water; the reading will range from 430 to 0 as the composition of the mixture ranges from pure $NaSO_4$ to pure K_2SO_4 . In this way any mixture can, with the aid of a calibration curve previously determined once for all, be analyzed in a few minutes with an accuracy of 0.1 mg. of either constituent (on a 50 mg. sample).

Summary.

The foregoing pages present a brief description of the principle and mode of operation of the interferometer, a form of instrument which enables one to determine the single varying constituent in a mixture or solution, with ease, rapidity, and very great accuracy. The only important source of error arises from differences in optical dispersion; it can readily be obviated by use of the methods discussed in the text.

THE VISCOSITIES OF BINARY MIXTURES OF THE ASSOCIATED LIQUIDS, WATER, FORMIC ACID AND ACETIC ACID.¹

By P. B. DAVIS AND HARRY C. JONES.

Received March 16, 1915.

Jones and Murray² showed in 1903 that when two associated liquids are mixed, each diminishes the association of the other. They determined the molecular weight of water in formic acid on the one hand, and in acetic acid on the other. Also the molecular weight of formic acid in water, and in acetic acid, and finally the molecular weight of acetic acid in water and in formic acid.

They found that the molecular weight of water in formic acid varied from 19.7 at dilution 0.93 *N* to 21.9 at 6.18 *N*, showing that the formic acid diminished slightly the association of the water.

The molecular weight of water in acetic acid varied from 21.7 at 0.64 *N* to 38.8 at 12.65 *N*. This showed that the acetic acid diminished greatly the association of the water.

¹ This work was done in connection with an investigation which is being carried out with the aid of a Grant from the Carnegie Institution of Washington, to H. C. Jones.

² *Am. Chem. J.*, 30, 193 (1903).

The molecular weight of acetic acid in water varied from 55.4 at 0.17 *N* to 72.1 at 7.06 *N*, showing that water diminished very appreciably the association of acetic acid.

The molecular weight of acetic acid in formic acid varied from 61.9 at 0.18 *N* to 83.8 at 9.17 *N*. The association of the acetic acid was thus diminished considerably by the formic acid.

The molecular weight of formic acid in water varied from 45.2 at 0.38 *N* to 51.0 at 6.16 *N*, showing that water had very little effect on the association of the formic acid; and, finally, the molecular weight of formic acid in acetic acid varied from 50.4 at 0.82 *N* to 65.7 at 8.26 *N*.

If we take into account the dissociating action of the water on the formic and acetic acids, we are justified in concluding that water and formic acid affect each other's association very little; acetic acid and formic acid affect each other's association considerably, while both water and acetic acid have a marked effect each on the association of the other.

These facts were used by Jones and Veazey¹ to explain the increase in viscosity which takes place when water and alcohol are mixed. These are both strongly associated solvents, and each, therefore, very probably diminishes appreciably the association of the other. From a smaller number of larger molecules of each solvent, we have a larger number of smaller molecules of each solvent produced. The surfaces of the molecules present are therefore increased, and, consequently, the friction of these molecules as they move over one another. Viscosity is a function of the surface friction of the molecules.

In the same manner Jones and Veazey² were able to explain why it is that salts of potassium, rubidium and caesium lower the viscosity of water and other solvents³ in which they are dissolved. The large atomic volumes of these cations when mixed with the molecules of water, diminish the frictional surfaces which come in contact, and, consequently diminish the viscosity.

Having found the above action of water, formic acid and acetic acid, each on the association of the other, the question arose, what would be the effect of each on the viscosity of the other? If the above explanations offered by Jones and Veazey were correct, then two liquids, like water and acetic acid, which diminished each others association, ought to increase the viscosity of one another—the viscosity of the mixture should be greater than that of either pure liquid separately.

The viscosities of binary mixtures of the above-named three liquids were measured at 15° and 25°. Water was regarded as the solvent for

formic acid and acetic acid, and solutions of these acids in water were prepared containing by volume 10, 20, 30, 40, 50, 60, 70, 80, 90%. The acids themselves contained somewhat less than 1% of water. The viscosity and the fluidity (reciprocal of viscosity) data are given in the following tables:

¹ Values for water taken from Thorpe & Roger, *Phil. Trans.*, 185A, 449 (1894).

The viscosity data at 15° are plotted in curves, Fig. 1; and the viscosity data at 25° in curves, Fig. 2. The viscosities of acetic acid in water pass through a well-defined maximum, which, before we carried out a single measurement of the viscosities of mixtures of these two solvents,¹ we predicted, would be the case from the molecular-weight determinations of this acid in water made by Jones and Murray.

The viscosities of formic acid in acetic acid pass through a slight maximum, as would be expected from the effect of each of these solvents on the molecular weight of the other.

Fig. 1.

Fig. 2.

The viscosities of mixtures of water and formic acid, on the other hand, fall almost on a straight line. This again is just what would be expected, from the fact that neither solvent alters appreciably the molecular weight of the other.

These results are, then, all in keeping with

¹ Since completing our work, we find that a few measurements of the viscosities of mixtures of acetic acid in water had been made by Dunstan and Thole, *J. Chem. Soc.*, 85, 825 (1904); 95, 1560 (1909).

the suggestion made by Jones and Veazey, that the increase in viscosity which results when associated liquids which diminish each other's association are mixed, is due to the *larger number of smaller parts* that are present.

These results are also in perfect accord with their suggestion as to the cause of the diminution in the viscosity of water, produced by salts whose cations have very large ionic volumes, such as salts of potassium, rubidium and caesium.

JOHNS HOPKINS UNIVERSITY.

NOTES.

Some New Forms of Apparatus: I. A Substitute for the Twin-bulb Trap in Toluene-Mercury Thermoregulators.—Toluene, on account of its high coefficient of expansion, is to be preferred to all other liquids for use in thermoregulators. Since, however, it is practically a nonconductor and quite volatile, it is ordinarily used with mercury for the contact in all electrically operated thermostats.

In order to use these two liquids together, the common form of apparatus hitherto employed has been the twin-bulb device, which, however, has the following disadvantages:

1. It is very fragile and can only be made by an expert glass-blower.
2. When the mercury level in the capillary has been once adjusted for any given temperature and the toluene reservoir sealed, the regulator is practically useless for any higher temperatures without opening the reservoir and removing the excess of toluene in order to preserve the equilibrium in the two bulbs.
3. It is difficult to prevent the toluene from finally creeping around between the mercury and the glass walls into the capillary and fouling the contact surface of the mercury, since the same continuous tube contains both the toluene and mercury.

To overcome these difficulties as far as possible the apparatus illustrated in Fig. 1 has been devised. This consists of a bulb (a) attached at the bottom by the tube (b) to the toluene reservoir which may be of any desired form. Exactly opposite to (b) is a corresponding tube (c), which carries the capillary and sealed-in platinum contact.

The interior construction of (a) is as shown in the figure. The small tubes (e) and (f) are prolongations of (c) and (b), respectively, having a length nearly equal to

Fig. 1.

the diameter of the bulb. These tubes are inclined at an angle of about 30° from the perpendicular. The short side tube (*d*) is used in filling the regulator and is in exact alignment with (*f*).

To prepare the regulator for use, mercury is poured in through the capillary until the bulb (*a*) is from one-half to three-fourths filled. A tube drawn out to a small diameter is then inserted through (*d*) and (*f*) into (*b*), and toluene allowed to run in until the reservoir is filled and also the space in (*a*) above the mercury. The tube (*d*) is then sealed, and by adding or withdrawing mercury from the capillary the contact level may be adjusted for any desired temperature.

By this method a toluene-mercury regulator is constructed with a range of 50° or more, all adjustments being made through the capillary which should be of from 1.5 to 2 mm. bore, according to the capacity of the toluene reservoir.

All danger of the toluene creeping into the capillary is removed since the tubes (*e*) and (*f*) terminate in the same liquid which is contained in them.

This trap is compact, not easily broken and is comparatively simple to construct. In addition to this it lies within the plane of the reservoir and contact tubes.

P. B. DAVIS.

II. A New Form of Pycnometer for Liquids.—The authors have recently had occasion to carry out a large number of density determinations with various liquids. For this purpose a modified form of the Sprengel pycnometer, as described by Jones and Bingham¹ and Jones and Veazey,² was first adopted, but was found to have the following disadvantages:

1. In instruments of large capacity (10 to 20 cc.) the long capillary side-arm adds greatly to the weight and hence impairs the accuracy of the pycnometer.

2. The fragility of the older form makes rapid handling practically impossible.

3. The instrument is difficult to dry and polish before weighing.

To remove these defects the form shown in Fig. 2 was devised, and has been found to be more convenient and accurate than the old form.

In the figure the symbols have the following significance:

(*a*) A reservoir of thin-walled glass tubing which may be of any desired capacity; those in use in this laboratory holding, respectively, about 6, 10 and 20 cc.

(*b*) Tapering tube of thin glass reaching almost to the bottom of (*a*), and having a bore at the open end equal to or slightly greater than that of

¹ *Amer. Chem. J.*, 34, 48 (1905).

² *Z. phys. Chem.*, 61, 641 (1908).

the capillary (0.5–0.75 mm.). This tube is of use in drying and filling the instrument.

(c) Outlet tube sealed on to the end of (b). This is drawn out slightly at the end and is bent at an angle of 60° close to the reservoir.

Fig. 2.

(d) Slight enlargement in (c) which holds in position the wire used to suspend the pycnometer on the balance.

(e) Expansion bulb of sufficient size to accommodate the increased volume of any liquid when warmed 10° . If the instruments are used only at 25° this bulb need be only very small.

(f) Fine line etched around the capillary at the lower limit of the taper in the bulb (e).

In adjusting the instrument when filled, a rubber tube is attached to the horizontal capillary above (e), and the liquid blown out gently until the level in (e) just reaches the mark (f). The excess of liquid is then removed from the end of (c) with filter paper. On removing the pressure, the level of the liquid in (c) falls until it comes to rest near

the bend in the capillary, thereby lessening the danger from evaporation or accidental spilling after adjustment.

The advantages of this form of pycnometer can readily be seen, e. g., the projecting arms are both short and hence not easily broken. Also the net weight has been materially lessened, since the amount of necessary capillary has been reduced to a minimum. The instrument is also much easier to clean and dry before weighing than the older form.

This pycnometer may be provided with ground-on caps when used with alcohol or other volatile liquids, to prevent possible evaporation.

CHEMICAL LABORATORY, JOHNS HOPKINS UNIVERSITY. P. B. DAVIS AND L. S. PRATT.

CORRECTIONS.

Professor James M. Bell has kindly called my attention to an article by Bell and Taber,¹ which was overlooked by me in my article on the

¹ *J. Phys. Chem.*, 12, 171 (1908).

determination of hydrates.¹ In this work, the authors determined, as we did, the solubility of copper sulfate in sulfuric acid solutions at 25° and Professor Bell has now recalculated the solubility results to a common basis and finds our results confirm his earlier ones. The composition of the hydrates in equilibrium with the solutions was determined by Bell and Taber by the method of residues and graphical extrapolation. We obtained the residues free from mother liquor by treatment with alcohol, depending on the composition of the solutions in a series of determinations for information as to whether the residues thus obtained were pure hydrates or mixtures of two. Both investigations show the presence of the same hydrates. Bell and Taber also calculated the approximate vapor pressures of the hydrates from the vapor pressures of the solutions, a point which we briefly considered without knowing of their work.

H. W. FOOTE.

The Stannic-Stannous Potential.—Mr. H. W. Richter, at present collaborating with one of us, has kindly called our attention to an error in our paper entitled "The Measurement of Oxidation Potentials at Mercury Electrodes. I. The Stannic-Stannous Potential," *THIS JOURNAL*, 36, 2035 (1914). Owing to neglect of the temperature coefficient of the normal calomel electrode, its electromotive force at 25° was assumed as 0.560 instead of 0.564 volt. Therefore, 0.004 volt must be added to each of the single potentials recorded, and the value of the stannic-stannous potential at 25° becomes

$$\pi = 0.430 + 0.030 \log \frac{\text{Sn}^{\text{IV}}}{\text{Sn}^{\text{II}}} - 0.011 \times \text{conc. HCl}.$$

GEORGE SHANNON FORBES AND EDWARD PAYSON BARTLETT.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF CORNELL UNIVERSITY.]

THE ORCINOLPHTHALEINS, THE ORCINOLTETRACHLOROPHTHALEINS, AND SOME OF THEIR DERIVATIVES.

BY W. R. ORNDORFF AND E. R. ALLEN.

Received March 9, 1915.

Historical.

Orcinolphtalein was first made and studied by Emil Fischer,² working under the direction of A. von Baeyer at Strassburg, and the results published as his inaugural dissertation in 1874. He obtained small amounts of this phthalein by heating orcinol and phthalic anhydride to 210–220°. Much better results were obtained by heating freshly fused anhydride, distilled orcinol and concentrated sulfuric acid for two hours to 135°.

¹ *THIS JOURNAL*, 37, 288 (1915).

² *Ann. (Liebig)*, 183, 63 (1876).

Final purification was effected by crystallization from acetone or from glacial acetic acid. The analyses of the product dried at 180° agreed with the formula $C_{22}H_{16}O_6$, and a structure analogous to that held for fluorescein at that time was proposed for it.

Dilute alkalis and ammonia dissolve it readily with an intensely dark red color. The solutions of the pure substance show no fluorescence, those of the crude product only a faint greenish fluorescence.

The phthalein showed no melting point, decomposing at about 230° . By boiling the phthalein with acetic anhydride he obtained a colorless product, insoluble in alkalis, which gave results on analysis for the diacetyl derivative. It is completely analogous to diacetyl fluorescein, and melts at $219-220^{\circ}$.

According to Fischer the behavior of orcinolphthalein toward glacial acetic acid is peculiar; for, while with care it can be crystallized in short, perfectly colorless prisms, if the solution be heated for some time the crystals suddenly turn yellowish red, and even by repeated crystallization they cannot again be obtained colorless. This colored compound dissolves in alkalis with the same color as the pure phthalein, but is precipitated unchanged by acetic acid. Before the reason for this phenomenon was understood the purification of the phthalein was rendered unusually difficult, since at one time colorless crystals were obtained from acetic acid, while at another they were red. Further investigation led Fischer to conclude that this conversion was caused by the acetic acid itself. By heating the phthalein with acetic acid in a sealed tube to 150° he obtained a compound, which, on analysis gave results approximating those required for a monoacetyl derivative, *i. e.*, $C_{22}H_{16}O_6(C_2H_3O)$.

Calculated: C, 71.64; H, 4.47; found: C, 72.13; H, 4.46.

The high carbon content found he attributes to a slight admixture with the phthalein (see p. 1205).

As an example of the dark red compounds which orcinolphthalein forms with mineral acids Fischer isolated and analyzed the hydrochloride. Even in the cold hydrochloric acid colors the white phthalein red, but for complete conversion an excess of hydrochloric acid is added to an alcoholic solution of the phthalein, which becomes colored dark red. On evaporating the alcohol, the compound separates in dark red flocks. These were dried in a vacuum over sulfuric acid. They then analyzed in close agreement with the formula $C_{22}H_{16}O_6.HCl$.

On the addition of bromine in excess to the boiling glacial acetic acid solution of the pure phthalein, the tetrabrom substitution product was obtained. Its solution in alkalis has an almost black color, which on dilution becomes dark brown, and shows a peculiar blackish green fluorescence (see p. 1207). In regard to the positions occupied by the bromine atoms Fischer points out that they are probably equally distributed

between the two orcinol residues, since each of these contains but two hydrogens in the benzene nucleus.

Baeyer and Fischer point out, in conclusion, that a comparison of fluorescein with orcinolphthalein shows that, in spite of their analogous constitution, they show surprising differences in physical and chemical properties.

Later¹ Richard and Heinrich Meyer took up the study of orcinolphthalein to see if an explanation for this great lack of analogy between orcinolphthalein and fluorescein could be found. The differences were mainly that orcinolphthalein is only formed with condensing agents, and that it dissolves in alkalis with a carmine red color without fluorescence. Orcinolphthalein then resembles more closely in its formation and properties phenolphthalein than fluorescein.

As in the investigation of hydroquinonephthalein² they determined whether the orcinolphthalein contained an anhydride oxygen as firmly bound in a ring as in the case of fluorescein, by benzoylating in alkaline solution, assuming that if the phthalein contained a pyrone ring a dibenzoate would be formed, but, if a less stable anhydride ring were present, during the benzoylating it would be ruptured and a tetrabenzoate would result in consequence of the formation of two new hydroxyl groups. Experiment decided the question in favor of the first assumption. Orcinolphthalein prepared according to the method of Fischer gave a well characterized dibenzoate by the Schotten-Baumann reaction, a direct benzoyl determination proving beyond a doubt that the formula was $C_{22}H_{14}O_6$ ($C_7H_5O_2$)₂. In purifying this dibenzoate, however, R. and H. Meyer obtained two other benzoates, which could be only incompletely separated by means of solvents, one of which, on saponification, gave a cherry-red, the other a green fluorescent solution. This led to the conclusion that in the crude orcinolphthalein a mixture of the three possible structural isomers existed.

This assumption was proved correct by their subsequent work. The third formula belongs undoubtedly to the fluorescent substance, which is a true fluorescein, giving on bromination an eosin, but which formula to

¹ *Ber.*, 29, 2627 (1896).

² *Ibid.*, 28, 2959 (1896).

assign to each of the other two isomers they were unable to decide. To distinguish between the three isomers they designate the product of Emil Fischer,¹ soluble in alkalis with a carmine red color as α , the one soluble in alkalis with a cherry-red color as β , and the one soluble with fluorescence as γ .

They state that as a result of experiments with different condensing agents they found that sulfuric acid, zinc chloride, tin tetrachloride, phosphorus pentoxide, or ferric chloride gave a product consisting chiefly of approximately equal parts of the α - and β -compounds, with only subordinate amounts of the γ -, while if glacial phosphoric acid be used the γ -product was obtained in relatively better yields (see p. 1215).

For separating the isomers they depended on their different behavior towards alkalis. α -Orcinolpthalein is soluble only in caustic alkalis, but not in ammonia or the alkali carbonates; the β -compound dissolves easily in the latter also, but not in a solution of ammonium sesquicarbonate; γ -orcinolphthalein unites even with ammonia gas to form an ammonium salt easily soluble in water.

In the experimental part of their paper the authors state that the best way to obtain the crude product is to follow the directions of Emil Fischer, and add, that if, instead of concentrated sulfuric acid as a condensing agent, phosphorus pentoxide be used a better yield of the γ -isomer is obtained.

The crude fused mass was poured into cold water, and the orange colored precipitate dissolved in sodium hydroxide. The mixture of the three phthaleins was precipitated by dilute sulfuric acid, and washed free from inorganic impurities by means of hot water. The residue was then dried at 120°, finely ground and treated under a bell jar with gaseous ammonia for some hours. By means of water the ammonium salt of the γ -phthalein was dissolved with a brown color and greenish fluorescence. From the residue, dilute ammonium sesquicarbonate (1 : 15) dissolves the remainder of the γ -compound, leaving only the α - and β -phthaleins, and from this mixture cold soda solution removes all the β -compound, leaving almost pure α -phthalein.

They observe that this separation is not absolutely sharp, especially when working with large amounts of material, but it sufficed for the preliminary work, since each compound was further purified as described below.

α -Orcinolpthalein.—Besides the above described method, this isomer was obtained by washing the crude product with aqueous ammonia till the latter was no longer colored cherry-red but bluish red. The residue is almost pure α -phthalein and gives at once colorless crystals from glacial acetic acid. These they considered to be pure if their solution in soda was

¹ Fischer's product was probably a mixture of α - and β -orcinolphthaleins (see pp. 1205, 1206 and 1207).

completely decolorized by shaking with ether or remained only faintly bluish red, not cherry-red. Potassium and sodium hydroxides dissolve the α -phthalein readily with a bluish red color. It dissolves in cold ammonia only slightly, and in soda solution only on warming, and even then with difficulty, with the same color. The solutions in ammonia and soda are decolorized on shaking with ether, whereupon the phthalein goes into the ether. Contrary to expectation, a very dilute potassium hydroxide solution acted in the same way (see p. 1225). In all cases a colorless ether solution resulted which, on evaporation, left the free colorless phthalein, and which gave up the phthalein again when treated with concentrated caustic alkali with the production of a red color. This behavior shows the extremely weak acid nature of the α -phthalein. By mixing an alcoholic solution of the phthalein with alcoholic potassium hydroxide a blue potassium salt separated in clusters of small needles having a bronzy luster (see p. 1208).

The red hydrochloric acid addition product described by E. Fischer was also obtained by R. and H. Meyer, from the *pure* α -phthalein but was not isolated or analyzed by them.

The brown "*monoacetate*," mentioned by Fischer (see p. 1202) as formed by heating his phthalein with glacial acetic acid, was never observed by R. and H. Meyer. Heating the α -phthalein with glacial acetic acid in a sealed tube to $150-180^{\circ}$ gave them only colorless crystals of the phthalein. They state that the analyses of E. Fischer, as well as his description of the conduct of his *so called monoacetate*, agree so well with those of the β -phthalein described below that it is very probable the two compounds are identical (see p. 1206).

Tetrabromo- α -orcinolphthalein was prepared by dissolving pure α -phthalein in hot glacial acetic acid, and treating with the calculated amount of bromine. The yellow needles which separated were obtained from hot nitrobenzene as flat, yellow prisms which analyzed in agreement with the formula $C_{22}H_{12}Br_4O_6$. These dissolve in alkalis with a violet color, which on heating becomes stronger and pure blue. On cooling the reddish blue color returns (see p. 1220).

β -Orcinolphthalein.—The β -phthalein is found in the cherry-red solution obtained by extracting the crude material, from which most of the γ -compound had been removed, with soda. From this solution acids precipitate a bright yellow compound, which was purified by dissolving in ammonia, precipitating with sulfuric acid, and washing with water. The residue was dissolved in alcohol and hot water added until the liquid becomes turbid. On further heating this disappears, and the formation of crystals begins. As soon as these separated the solution was filtered while still warm, in order that any γ -compound remaining might be held in solution. This crystallization was repeated, until the dried crystals

when treated with gaseous ammonia neither changed their color nor gave a fluorescent solution on the addition of water. The crystals thus obtained were mostly a mixture of more or less brownish needles and orange-colored leaflets, which, however, in both cases were pure β -orcinolphthalein (see p. 1227). In order to obtain them all as needles a dilute (1 : 20) alcoholic solution of the phthalein is run while hot into ten times the amount of cold water, and digested on the water bath till the milky white turbidity has been converted into clusters of microscopic needles. If, on the other hand, the phthalein be dissolved in ten times the amount of hot alcohol, one-half the volume of water added to this, and the solution boiled, fairly large, orange-colored, six-sided plates separate. These lose no water *even at* 205°, and decompose at higher temperatures. Although this residue gave data on combustion in agreement with the formula for the anhydrous phthalein, the authors state: "dieselbe kann aber unter den obwaltenden Umständen kaum als entscheidend angesehen werden." Four other combustion analyses are given, 1 and 2 are on the leaflets obtained by the addition of water to the alcoholic solution, 3 is on the amorphous material precipitated from the alkaline solution by sulfuric acid, and finally 4 is on the phthalein recovered from the β -phthaleindibenzoate, and which had been dissolved in alcohol and crystallized by heating with water. In 1 and 2 the substance was dried in a xylol bath, and in 3 and 4 in an aniline bath. The analyses agree with the formula $C_{22}H_{16}O_6 \cdot \frac{1}{2}H_2O$ (see p. 1428).

Calculated: C, 72.13; H, 4.55; found: C (1) 72.01, (2) 72.10, (3) 71.98, (4) 72.13; H, (1) 4.50, (2) 4.49, (3) 4.23, (4) 4.37.

These analyses are in agreement with those given by E. Fischer for his "*monoacetate*" (see p. 1202), and the following observations according to R. and H. Meyer also prove the identity of the two: If the needle-shaped crystals of the β -phthalein be dissolved in glacial acetic acid by gently warming, then on cooling almost colorless needles separate; if, on the other hand, the solution be boiled strongly, yellowish red leaflets crystallize out on cooling. From dilute alkaline solutions this phthalein is thrown down as a white precipitate by acetic acid (see p. 1209).

The β -phthalein does not show a definite melting point. It is easily soluble with a brown color in methyl and ethyl alcohols, and in ethyl acetate, difficultly soluble in hot water, benzene or glacial acetic acid. Ether dissolves the amorphous substance easily. It dissolves in caustic alkalies and their carbonates, as well as in ammonia, with an intense cherry-red color, which even in extreme dilution does not disappear on shaking with ether. Mineral acids precipitate the free phthalein out of this solution in yellow flocks. Solutions of sodium phosphate or sodium acetate also dissolve it, on warming, with a cherry-red color, but this color disappears on shaking with ether, which takes up the phthalein.

With fuming hydrochloric acid the β -phthalein forms a deep red addition product insoluble in hydrochloric acid similar to that of the α -isomer (see p. 1205).

Tetrabromo- β -orcinolphthalein was obtained by boiling the β -phthalein with glacial acetic acid and the calculated amount of bromine. Brown crystals separated. These were washed with alcohol, dissolved in sodium hydroxide, precipitated with sulfuric acid, the precipitate washed with water, and extracted with alcohol. The white crystalline residue gave, on recrystallization from hot nitrobenzene, irregular colorless plates. These gave results on analysis agreeing with the formula $C_{22}H_{12}Br_4O_5$. It dissolves with difficulty in all solvents except hot nitrobenzene. Caustic alkalies and the alkali carbonates dissolve it with a greenish black color; when very dilute this solution shows by transmitted light a smudgy red color. R. and H. Meyer point out that this description agrees so well with that given by Emil Fischer (see p. 1202) for his tetrabromoorcinolphthalein that there can be no doubt that it was actually the tetrabromo- β -orcinolphthalein with which he was working. The substance is not a dye. Gaseous ammonia does not act on it, and hence it may be easily isolated from a mixture of tetrabromo- β - and - γ -orcinolphthaleins (see p. 1232).

γ -Orcinolphthalein.—To isolate this body the crude product was treated with gaseous ammonia, extracted with water, and the resulting solution allowed to stand in the air for some time, when some β -phthalein precipitated. This was filtered off and from the filtrate the γ -phthalein was precipitated by sulfuric acid. This was washed with hot water, dissolved in ammonia, alcohol added, the solution acidified with sulfuric acid and steam passed into the milky solution to remove the alcohol. On cooling, tolerably large, pale yellow prisms separated. From hot, concentrated, glacial acetic acid solution dark orange-colored crystals separated on cooling. The analyses of the two products dried at 180° were in accord with the formula $C_{22}H_{16}O_5$ (see p. 1235).

The γ -orcinolphthalein is easily soluble with a brown color in alcohol, methyl alcohol, and hot glacial acetic acid. From dilute alcohol it separates on slow evaporation in bright yellow clusters of broad, truncated needles. It exhibits the greatest analogy to fluorescein. When precipitated in the amorphous form it is deep yellow colored, and dissolves in alkalies, ammonia, and their carbonates with a brown color and greenish fluorescence. This is not so intense as in the case of fluorescein, but is considerably increased by the addition of alcohol. The substance dyes silk yellow. It dissolves on heating in sodium phosphate and sodium acetate solutions, presumably due to the formation of the sodium salt (as in the case of fluorescein). These solutions fluoresce, and are not decolorized on shaking with ether (distinction from β -orcinolphthalein). On boiling with calcium carbonate, carbon dioxide is expelled and the

substance goes into solution as the calcium salt. When boiled with hydrochloric acid or dilute sulfuric acid small amounts of it dissolve with a yellow color. The amorphous substance is easily soluble in ether with a yellow color and without fluorescence. The ammonium salt forms readily under the action of gaseous ammonia, as mentioned above. The ammonia passes off completely from this compound, however, on long exposure to the air.

In his paper on "Untersuchungen über die Abkömmlinge des Triphenylcarbinols,"¹ Baeyer gave some attention to the α -orcinolphthalein of R. Meyer. As will be shown below he concludes that in this isomer the hydroxyl groups occupy the positions ortho to the methane carbon atom. He proposes to replace the designation α - with the term vicinal, since it is customary to designate the volatile nitroresorcinol of Kauffman in which the nitro group occupies an analogous position as vicinal nitroresorcin. The mother substance, which has, however, not yet been made, would then be designated as *vic*-resorcinolphthalein, and likewise the triphenylcarbinol derivative as *vic*-resorcinolbenzein. For the β -orcinolphthalein of R. Meyer which is an intermediate product between the vicinal and the ordinary form, he proposes the term semi-vicinal, to be shortened to "semi-vic," while the γ -substance is to be designated simply as orcinolphthalein.

According to Baeyer the *vic*-orcinolphthalein corresponds so exactly in its conduct to the *vic*-nitroresorcinol, that it must possess the structure given below:

He calls attention to the fact that Meyer's statement (see p. 1205) "Beim Vermischen einer alkoholischen Lösung des Phtaleins mit alkoholischen Kali, bildet sich ein in alkohol unlösliches blaues Kaliumsalz, das in kleinen bronzeglänzenden Nadelbüscheln ausfällt" is incomplete. According to Baeyer, if a little alcoholic potash be added to an alcoholic solution of the vicinal orcinolphthalein, the solution is at first colored violet, but this soon disappears, and a potassium salt separates in colorless, elongated, right-angled plates. This salt, Baeyer states, may be used advantageously for the complete separation of the vicinal orcinolphthalein from its isomers. For if it be heated with a large amount of water the salt is decomposed by hydrolysis into the free orcinolphthalein and into alkali, which holds a small part of the vicinal orcinolphthalein and all of

¹ Ann. (Liebig), 372, 120 (1910).

its isomers in solution. The *vic*-orcinolphthalein when filtered off is pure white, and is completely extracted from its red solution in soda on shaking with ether.

If more alcoholic potash be added to the solution of the phthalein (from which the white crystals of the potassium salt have separated), and the solution be boiled it becomes a deep reddish violet, and crystals separate which appear black under the microscope, but which possess the same forms as the white, *i. e.*, are apparently pseudomorphs. If, however, the alcoholic solution of the phthalein be added to an excess of alcoholic potash heated to boiling, black needles, obliquely truncated, separate. Besides these, blue, transparent leaflets are also formed.

When the white crystals are boiled with soda solution, there separates on cooling, hair-like needles of a violet color, but, if they are warmed with concentrated potassium hydroxide, the liquid becomes pure blue. On dilution the solution turns violet.

From this Baeyer concludes that there are at least three kinds of salts, a white, a red, and a blue, the formation and composition of which he accounts for in the following manner:

From the formula for the vicinal orcinolphthalein (see p. 1208), it would be simplest to assume that, in the first place, the hydrogen atoms of the two hydroxyl groups are replaced by metal. Such a salt must, however, be colorless. Since now a violet color first appears, it is to be assumed that in the first place the rupture of the lactone ring takes place with the formation of a violet salt, corresponding to fluorescein, which, however, contains instead of a para- an ortho-quinoid group.

Fluorescein.

First violet salt.

This first violet salt changes into the colorless, monopotassium salt of the phthalein through reformation of the lactone ring, which, as the decolorization of an alkaline solution by means of ether shows, takes place very readily in the case of the vicinal orcinolphthalein.

Colorless salt.

On the addition of more alkali the lactone group is broken again, and there is formed in consequence of this a tertiary alcohol, to the active nature of which is to be attributed the rupture of the xanthone ring. That this rupture actually takes place even at ordinary temperature is shown by the analysis of the colored potassium salt, according to which it contains between 3 and 4 atoms of potassium. This is possible, however, only on the assumption of the hydrolytic cleavage of the oxygen bridge. The colored salt containing four atoms of the metal can only have the following constitution because of the symmetrical structure of the orcinol:

since it is immaterial, whether the hydroxyl already present or that formed from the bridge oxygen becomes quinoid. Analyses of the potassium salts (see pp. 1222 to 1227):

1. Colorless potassium salt:¹ calc. for $C_{22}H_{14}O_6K_3$: K, 17.89; for $C_{22}H_{14}O_6K$: K, 9.37; found: K, 13.64.

2. Blue potassium salt: calc. for $C_{22}H_{14}O_6K_4$: K, 29.43; found: K, 27.05.

In regard to the analogy between phenyl-2,2'-dioxyxanthanol (*vic*-resorcinolbenzein)

and α -orcinolphthalein Baeyer says:²

"Aus der Identität der Färbung, welche das Chlorid in Alkalischer Lösung zeigt, mit der des α -orcinphthaleins von R. Meyer, geht hervor, dass letzteres wirklich, wie angenommen, *vic*-orcinphthalein ist."

Recently Kehrman³ has prepared ethers and esters of the phthaleins and benzeins of orcinol with a view to studying their oxonium salts.

In order to completely free the β -phthalein from the tenaciously adhering γ -isomer, Kehrman dissolves the crude β -compound (isolated according to the method of R. and H. Meyer) in boiling alcohol, adds a few drops of ammonia, and then boiling water until the solution becomes

¹ The formula for the monopotassium salt is $C_{22}H_{14}O_6K$, and according to 1915 atomic weights contains 9.82% potassium; that of the dipotassium salt $C_{22}H_{14}O_6K_2$, and 17.92% potassium; that of the tetrapotassium salt $C_{22}H_{14}O_6K_4$, and 29.48% potassium. The tripotassium salt of the *carbinol carboxylic acid*, $C_{22}H_{14}O_6K_3$, contains 23.82% potassium (see p. 1227).

² *Ann.* (Liebig), 372, 133 (1910).

³ *Ber.*, 45, 3505 (1912).

turbid. During the cooling the β -isomer crystallizes out, while the mother liquor shows the presence of the γ -compound by its fluorescence. Repeated three times this method gave a product which no longer yielded a fluorescent mother liquor when treated in this manner, and was, therefore, certainly free from the γ -isomer.

Kehrmann states that β -orcinolphthalein exists in *two modifications*, a *yellow quinoid*, and a *colorless lactoid form*, and he adds in a footnote that R. and H. Meyer had already observed both modifications, but that it was not quite certain whether their product was perfectly free from the γ -isomer (see p. 1228). Acidification in the cold of the dark brownish red alkaline solution gives, according to him, an orange yellow precipitate, which when heated to boiling becomes perfectly white. The lactoid form is here the stable one, while the salts, those with alkalis as well as those with acids, are derived from the quinoid modification, which is unstable in the free condition (see p. 1229). The latter form becomes the stable one, however, by esterifying the carboxyl or by replacing it with hydrogen, as the study of γ -orcinolbenzein has shown.

In order to completely free the γ -isomer from traces of the tenaciously adhering β -derivative, Kehrmann states that treatment of the crude product with methyl alcohol and hydrochloric acid was found to be very advantageous. The hydrochloride, which separated quite completely in bright orange-yellow leaflets having a bluish reflection, was chemically pure. In a footnote he states that the base exists in a yellow and in a colorless form (see p. 1234).

Experimental.

The investigation of the orcinolphthaleins and of the orcinoltetrachlorophthaleins was undertaken (1) to study the effect of introducing negative groups into the phthalein molecules; (2) to observe to what extent these compounds and their derivatives exist in colored and colorless modifications, and to see whether these forms are in agreement with the theory of color held by chemists at the present time; and (3) to study the conditions affecting the formation of the different isomers, and the methods of separating these, thus throwing possible light on the problem of the isomeric fluoresceins.¹

At the outset some difficulty was encountered in preparing the orcinoltetrachlorophthaleins (see p. 1239). This difficulty, together with the fact that R. and H. Meyer had not carefully studied the colored and colorless forms of the orcinolphthaleins, and had omitted certain important derivatives prompted the repeating and enlarging of the major part of the work previously done on these phthaleins.

The phthalic anhydride used in this work was pure sublimed material. The orcinol obtained from Merck was pure and had a melting point of

¹ THIS JOURNAL, 36, 680 (1914).

58°. It was freshly fused before using. The fused material¹ melted sharply at 107°.

In the preparation of the orcinolphthaleins the directions of E. Fischer were first employed. Fifty grams of phthalic anhydride, 85 g. of orcinol, and 45 cc. of concentrated sulfuric acid were placed in a flask and heated to 135° for two hours. The mass became semi-liquid, and red colored, but did not solidify toward the end of the reaction. It was poured into water, the yellowish incoherent mass filtered, washed, and the filtrate preserved for the recovery of unchanged orcinol. The material was then dissolved in alkali, the solution filtered, the phthaleins precipitated as a yellowish flocculent mass with acetic acid, and the mixture heated to boiling by blowing in steam. The material darkened slightly and showed a tendency to collect in pasty masses. The anhydrous material weighed 104.5 g., corresponding to 85.9% of the theory, calculated from the amount of phthalic anhydride used.

Fifty grams of this material were purified (see pp. 1216 and 1217) and the following amounts of isomers obtained:

Isomer.	Grams.	Percentage.
α	10.0	23.0
β	27.0	62.2
γ	5.4	12.5
Tar.....	1.0	2.3
Total.....	43.4	100.0

The use of phosphorus pentoxide at 135° as a condensing agent was next tried. One hundred grams phthalic anhydride, 170 g. orcinol, and 170 g. phosphorus pentoxide were placed in a flask and heated to 135° for two hours. The dark red mass was ground, dissolved in alkali, and the solution filtered. The phthaleins were then precipitated by adding dilute sulfuric acid, and the mixture heated to boiling with steam, filtered and washed in the usual manner. This product differed markedly from that of the previous fusion in that it became dark, almost black, on heating to boiling with steam, and collected in a sticky mass which on drying became hard and brittle. The crude anhydrous material weighed 140 g., corresponding to 57.5% of the theory.

Fifty grams of this material were purified, and resolved into its isomers:

Isomer.	Grams.	Percentage.
α	5.0	11.9
β	21.0	50.0
γ	14.0	33.3
Tar.....	2.0	4.8
Total.....	42.0	100.0

The synthesis was repeated, keeping the temperature between 180° and 190°. The material from this fusion was purified as usual. It was precipitated from the alkaline solution as yellow flocks by the addition of mineral acids. On heating this mixture to boiling with steam the material became dark colored and collected in a pasty mass.

¹ The statement of Hesse, *J. prakt. Chem.*, [2] 57, 270, that the melting point of anhydrous orcinol is 100–101°, is certainly incorrect. We have determined this melting point many times and on large quantities of material, and have invariably found it to be 107°.

Fifty grams phthalic anhydride, 87 g. of fused orcinol and 90 g. of P_2O_5 gave 87 g. of anhydrous material corresponding to a yield of 71.5%.

Fifty grams of this material gave on purification:

Isomer.	Grams.	Percentage.
α	5.7	13.2
β	22.0	50.9
γ	14.0	32.4
Tar.....	1.5	3.5
Total.....	43.2	100.0

Sulfuric acid at a high temperature was then used as a condensing agent. The bath was heated to 180–190°, and the flask containing 25 g. phthalic anhydride, 43 g. orcinol, and 23 cc. of concentrated sulfuric acid was immersed in it for two hours. The reaction was vigorous, and was accompanied by boiling. The temperature of the mixture showed a tendency to rise above 180° as a result of the heat of the violent reaction. A too high rise was avoided by removing the flask occasionally from the bath. The melted mass was poured into water, and purified in the usual manner. The phthalins were precipitated from the alkaline solution with sulfuric acid as yellow flocks, which when heated to boiling by blowing in steam darkened but slightly, and showed but little tendency to form pasty masses. The yield of anhydrous material was 92.5%. The entire product (55.5 g.), gave the following amounts of the different isomers:

Isomer.	Grams.	Percentage.
α	14.7	28.2
β	29.4	56.4
γ	7.6	14.6
Tar.....	0.4	0.8
Total.....	52.1	100.0

Meyer states that (see p. 1204) glacial phosphoric acid gives a larger yield of the γ -isomer. This substance was therefore used as a condensing agent. Twenty grams phthalic anhydride, 39 g. orcinol, and 60 g. glacial phosphoric acid were ground together and heated. The reaction took place very slowly even at 195–200°. At the end of two hours the heating was discontinued and the fused mixture freed from unchanged orcinol, phthalic anhydride, and inorganic materials in the usual manner. On heating to boiling with steam the product was obtained as a black, tarry mass, which on drying became hard and brittle. The anhydrous material (27.6 g.) corresponded to a yield of 56.7% of the theory (see p. 1215).

A smaller amount of phosphorus pentoxide was next tried to see if the production of tar could be avoided. Twenty grams phthalic anhydride, and 34 g. orcinol were fused at 180°, and the condensing agent, 13 g. P_2O_5 , then added. The temperature was maintained at 180° for two hours, and the product of the fusion was purified in the usual manner. Upon the addition of an acid to an alkaline solution of the crude material a yellowish brown flocculent precipitate was obtained which blackened and formed a pasty mass on heating to boiling. A yield of only 52.8% was obtained by this method. The experiment failed, therefore, to accomplish the desired end.

The experiment was repeated at a temperature of 120°. While the crude product was free from tar, *i. e.*, precipitated as yellow flocks, which remained unchanged on heating to boiling, only 9 g. corresponding to a yield of 18.5%, was obtained. On separation this product yielded the following amounts of isomers:

Isomer.	Grams.	Percentage.
α	1.2	13.8
β	5.0	57.5
γ	2.5	28.7
Total.....	8.7	100.0

The experiment was again repeated but the temperature maintained at 135°. The crude anhydrous phthaleins which contained some tar, weighed 15 g., corresponding to a yield of 30.8%.

Fuming sulfuric acid was next tried as a condensing agent. Twenty grams phthalic anhydride, 34 g. orcinol, and 18 cc. fuming sulfuric acid (15% SO₃) were used. The first two were fused at 120°. The fuming sulfuric acid was then added, and a vigorous reaction took place at once, accompanied by change of color, boiling, and evolution of steam. The flask was quickly removed from the bath, but the temperature continued to rise, finally reaching 200°, but on being left to stand at room temperature returned to 120° in 20 minutes. The flask was then replaced in the bath and the temperature of the contents held at 120° for two hours. The melted mass, which showed no tendency to solidify, was poured into water. The lumps which formed at once were easily broken up, and the whole mass soon became yellow and pulverulent. When dissolved in alkali and subsequently precipitated with mineral acids it separated as bright yellow flocks, which on heating to boiling with steam did not change in the least, *i. e.*, it was perfectly free from tar. The material was filtered off, washed, and dried to constant weight in the water oven. After this treatment it weighed 47.5 g., 97.9% of the theory.

The product was next resolved into its isomers by the usual method. It was found to be so nearly free from tar that on filtering the ether solution (see p. 1217) only enough was present to color the filter paper slightly. The entire 47.5 g. gave:

Isomer.	Grams.	Percentage.
α	11.7	27.4
β	25.0	58.5
γ	6.0	14.1
Total.....	42.7	100.0

This synthesis was repeated using the same amounts of materials. The reaction took place slowly even at room temperature, the contents of the flask turning red, and the temperature in a few minutes rising to 75°. The flask was then immersed in boiling water for four hours. The content was stirred by an occasional shaking. The purification was carried out exactly as in the preceding experiment, and the product was exactly similar in all respects. The anhydrous material weighed 47.5 g., 97.9% of the theory. Separated into its isomers the following results were obtained:

Isomer.	Grams.	Percentage.
α	11.0	25.9
β	25.0	58.8
γ	6.5	15.3
Total.....	42.5	100.0

Zinc chloride was finally used as a condensing agent. Twenty grams phthalic anhydride, 34 g. orcinol, and 34 g. freshly fused zinc chloride were intimately ground in a mortar, transferred to a flask, and heated to a temperature of 120° for two hours. The mass became red in color and semi-liquid, and at the end of two hours had partially solidified. Purified as in previous cases the material (24.7 g.) was found to be practically free from tar. The yield was, however, only 50.8% of the theory.

SUMMARY OF IMPORTANT SYNTHESSES.

Condensing agent.	Temperature.	Crude yield. %	Percentage Isomers.		
			α .	β .	γ .
P ₂ O ₅	135°	57.5	11.9	50.0	33.3
P ₂ O ₅	180°	71.5	13.2	50.9	32.4
P ₂ O ₅	120°	18.5	13.8	57.5	28.7
H ₂ SO ₄	135°	85.9	23.0	62.2	12.5
H ₂ SO ₄	180°	92.5	28.2	56.4	14.6
H ₂ S ₂ O ₇	120°	97.9	27.4	58.5	14.1
H ₂ S ₂ O ₇	95°	97.9	25.9	58.8	15.3

These results show that from the standpoint of crude yield and purity of product, fuming sulfuric acid is the best condensing agent, concentrated sulfuric acid, and phosphorus pentoxide following in the order named. The last gives a relatively higher percentage of the γ -phthalein, and if it could be used in such a manner as to give a good yield without the production of tar, it would be the most desirable condensing agent to use for the preparation of the γ -compound. Glacial phosphoric acid is very nearly worthless; evidently the statement of R. and H. Meyer in regard to the use of this substance is a typographical error. Zinc chloride, if used, must be employed for a longer period than two hours or at a higher temperature than 120°.

A critical study of the methods of isolating the isomers was also made. After a large number of experiments, testing the methods described in the literature for the separation of such isomers, and also such methods and modifications as seemed most promising, a fairly satisfactory method was developed. At the outset it was found that some of the methods used by Meyer in separating the phthaleins were slow, or gave incomplete separation, or both, and had to be modified or abandoned. For instance, the method he used for extracting the γ -phthalein (see p. 1207) was found to be unsatisfactory because (1) not all of the γ -phthalein was removed from the crude product, and (2) some β -phthalein was always carried through into the ammoniacal filtrate, which upon standing for some time was precipitated as a colloidal mass that could not be removed by filtration. This difficulty had been previously noted by Acker¹ and the method was abandoned by him. Meyer's separation of the γ - and β -isomers was therefore incomplete.

Even less complete was Meyer's separation of the α - and β -compounds. He extracted the residue obtained after removal of the γ -phthalein by means of cold soda solution or with dilute ammonia until the washings were blue-red instead of the cherry-red color first obtained. A critical examination of this method showed that it was unsatisfactory for two reasons; first, the β -phthalein was very slowly removed, and so large a number of extractions were necessary that the method was laborious, the more so as

¹ Diplom-Arbeit, Chemie-Schule in Mülhausen i/E, 1910.

with each extraction with soda the solutions became more and more difficult to filter, due to the fact that the tarry material gradually became gelatinous under the influence of the alkali; and secondly, not inconsiderable amounts of α -phthalein were carried into the soda solution.

The method of Kehrmann for separating the γ - from traces of the β -isomer gave better results than that employed by Meyer. As mentioned above (see p. 1211) Kehrmann dissolved the crude material in methyl alcohol and passed in hydrochloric acid gas, keeping the solution at 0° , whereupon the γ -hydrochloride separated in the pure state. The last traces of the γ -compound were removed from the β -phthalein by dissolving the latter in alcohol, adding a few drops of ammonia, heating to boiling, and adding hot water until the solution became turbid. On cooling the pure β -compound crystallized out (see p. 1210). It remained then to develop a method for separating the α - from the β -compound. To accomplish this, advantage was taken of the difference in behavior of an ethereal solution of these isomers toward dilute soda solution. Meyer states that the soda solution of the α -isomer is decolorized on shaking with ether, or remains only pale bluish red. Baeyer states, however, that the soda solution of the α -compound is completely decolorized by shaking with ether. The latter statement was found to be more nearly correct, although if an ethereal solution of the α -phthalein be shaken with soda solution some color is imparted to the latter, unless the ethereal solution be quite dilute. Meyer states that the soda solution of the β -phthalein is not decolorized by ether. While this is true, a large part of the phthalein does go into the ethereal layer. On the other hand an ethereal solution of the β -isomer gives up part of its phthalein to sodium carbonate solutions, and by successively removing the latter all the β -compound can be removed from the ether.

To separate the α - from the β -isomer, the mixture of the freshly precipitated phthaleins is dissolved in ether. This ethereal solution is *filtered* and then shaken with normal sodium carbonate solution when some of the β - and a much smaller amount of the α -phthalein goes into the soda solution. This latter solution is now removed and shaken with a small portion of *fresh* ether which removes *all* the α - and a little of the β -phthalein, leaving only the β -isomer in the soda solution. After removing the sodium carbonate solution from the original ether solution, it is again extracted with fresh soda solution, the latter drawn off and shaken with the *same smaller portion of ether* that was used to extract the first soda solution. This process of extraction is repeated until a fresh portion of the soda solution when shaken with the original ether solution is only faintly colored, and this color is at once removed when the soda solution is shaken with the smaller portion of ether. The α -phthalein is now found in the ether solutions while the several soda solutions will contain only the β -compound.

For a 50 g. portion of the crude orcinolphthaleins two liters of ether in a four liter separatory funnel are used for the main ethereal solution. The smaller portion of ether is usually about 500 cc. while the portions of normal soda solution used for extraction are usually about 300 to 500 cc.

Another very important step in the purification was the removal of tarry material from the crude product. To do this advantage was taken of the very great solubility of the freshly precipitated phthaleins in ether, and of the relative insolubility of the tar in this solvent.

The method used in separating and purifying the three isomers was as follows: The cold filtered alkaline solution of the crude product is precipitated by pouring slowly into a large volume of dilute *mineral* acid (acetic acid is not suitable here because on subsequent shaking with ether it is taken up by the latter to some extent, and reduces the solubility of the phthaleins in this solvent). The mixture of the freshly precipitated phthaleins and water is shaken up in a large separatory funnel with a large amount of ether, allowed to stand until the two layers have sharply separated, when the tarry by-products collect in a flocculent dark-colored mass between the two layers. The aqueous layer is then removed, and the ether filtered (first through muslin and then through filter paper). The clear ether solution is now shaken with about one-third of its volume of normal soda solution, the two layers allowed to separate, and the aqueous one removed. This contains all the γ - except traces, considerable β -, and some of the α -phthalein. The last and most of the β -compound are removed by shaking the soda solution with fresh portions of ether, and the α - and β -phthaleins are separated as outlined above. The γ -phthalein and a little of the β -product remaining in the soda solution are recovered by acidification and the γ -isomer purified by the hydrogen chloride method of Kehrman. For final purification of the β -phthalein, the alcoholic ammonia method of Kehrman is used.

α -Orcinolphthalein.

Compound with Methyl Alcohol.—The crude α -orcinolphthalein obtained by the method of separation outlined above is quite pure, and when precipitated from its alkaline solution by acetic or a mineral acid, it separates in the form of *pure white* flocks. It can be crystallized quite readily from methyl or ethyl alcohol, or from glacial acetic acid. As a rule the material for experimental work was crystallized from methyl alcohol, then from glacial acetic acid, and finally from dilute warm solutions in methyl and in ethyl alcohols by the addition of water. In the latter cases, that is, when water was added to the dilute solution in either of the alcohols, perfectly white, nearly rectangular plates were obtained. The pure white material from the methyl alcohol solution was analyzed:

Subst. (I) 0.1186, (II) 0.2430; loss, (I) 0.0098, (II) 0.0195. Calc. for $C_{22}H_{18}O_4$. CH_3OH : 8.17; found: (I) 8.26, (II) 8.02.

Sample I had been dried in the air for about 20 hours. It lost all its alcohol in one-half hour at 110° , and nothing condensed on the cool part of the tube,¹ *i. e.*, it contained no water. It lost no further weight on heating to 180° . Sample II was dried in the air for about 10 days and then heated in the electric drying apparatus² for one-half hour at 185° . Hence α -orcinolphthalein crystallizes from methyl alcohol with a molecule of methyl alcohol.

The residue obtained in determination II was analyzed.

Subst., 0.1003; CO_2 , 0.2691; H_2O , 0.0409. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_6$: C, 73.31; H, 4.48; found: C, 73.17; H, 4.57.

α -Orcinolphthalein is insoluble in water, but easily soluble in dilute caustic alkalis with a beautiful purplish red color, the alkaline salts possessing a high tinctorial power. It dissolves with difficulty in aqueous ammonia, and in solutions of the alkaline carbonates it dissolves only on warming. The solutions in these weak alkalis are *wine-red*, not *purplish red*. Dry ammonia gas and dry hydrochloric acid gas do not act on the α -phthalein. In the more concentrated (50%) solutions of the caustic alkalis it dissolves with a pure *blue* color. From all alkaline solutions the free phthalein is thrown down on the addition of acids as white flocks. It is quite soluble in methyl and ethyl alcohols and in glacial acetic acid, and is very soluble in acetone. It is insoluble in benzene. When perfectly pure it dissolves in an alcoholic solution of ammonia *without color*. When this solution is diluted with water it becomes *reddish violet* and after a time the α -phthalein crystallizes out and the solution becomes *colorless*. The slightest trace of β - or γ -phthalein can thus be detected in the α -phthalein (see pp. 1228 and 1234).

Compound of α -Orcinolphthalein with Ethyl Alcohol.— α -Phthalein, shown to be pure by the above analysis, was dissolved in hot absolute alcohol, and the solution then allowed to cool. The fine crystals which separated during the cooling were filtered off, and the mother liquor allowed to stand two days longer. Large, well formed, colorless prisms slowly formed. These were filtered off, and water added to the mother liquor. Minute colorless crystals separated, which under the microscope were seen to possess the same form as the large ones. A sample of each crop when heated at 170° came to constant weight in one-half hour, and during the heating no moisture condensed on the cool part of the tube. The following results were obtained:

Subst., (I) 0.4793, (II) 0.4871; loss (I) 0.0545, (II) 0.0526. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_6 \cdot \text{C}_2\text{H}_5\text{OH}$: 11.34; found: (I) 11.37, (II) 10.80.

Determination I was on the phthalein crystallized from absolute alcohol on long standing, while II was on the material obtained by addition of

¹ *Am. Chem. J.*, 41, 404 (1909).

² *THIS JOURNAL*, 32, 635 (1910); *Am. Chem. J.*, 48, 477 (1912).

water to the mother liquor. The phthalein therefore crystallizes with one molecule of ethyl alcohol.

Compound of α -Orcinolphtalein with Acetic Acid.—Some of the pure α -phthalein was dissolved in boiling glacial acetic acid, and the hot solution quickly filtered. On cooling a large crop of white, well formed, stout needles separated. These were filtered off and allowed to stand in the air for two days, when all odor of acetic acid had disappeared. A portion was then finely ground and analyzed.

Subst., 0.4069; loss, 0.0653. Calc. for $C_{22}H_{16}O_6 \cdot CH_3COOH$: 14.29; found: loss 16.05.

The sample came to constant weight when heated for one hour at 175° . In order to determine the acetic acid actually present, a weighed amount of the sample was boiled with distilled water and after filtration the free acid in the solution was titrated with standard alkali using phenoltetrachlorophthalein as the indicator.

Subst., (I) 0.7844, (II) 1.1930, (III) 0.6985; 0.1 *N* NaOH, (I) 20.57, (II) 30.00, (III) 14.67 cc. Calc. for $C_{22}H_{16}O_6 \cdot CH_3COOH$: 14.29; found: (I) 15.74, (II) 15.10, (III) 12.61.

Sample I was analyzed immediately after grinding, II, 5 hours, and III, 72 hours after grinding. The phthalein therefore crystallizes with a molecule of acetic acid.

α -Orcinolphtalein Diacetate.—Fifteen grams of pure α -phthalein were boiled for one hour with an equal weight of anhydrous sodium acetate and seven times its weight of acetic anhydride. When the material was poured into cold water it separated as a colorless oil. After this had solidified, the supernatant liquid was decanted and the solid material triturated with cold normal sodium hydroxide solution, filtered off, washed and dried. It was first crystallized from absolute alcohol, from which solvent it separated in perfectly white, well-formed, stout prisms. In the melting point tube the material shrinks markedly above 230° , and finally melts sharply at $246-247^\circ$, incipient decomposition being indicated at slightly higher temperatures by the production of a greenish color. Recrystallized from ethyl acetate it formed the same type of crystals, which behaved in the same manner in a melting point tube, and melted sharply at $246-247^\circ$. It was finally crystallized from benzene and gave a melting point of $246-247^\circ$. A sample of this material heated for one-half hour at 180° , lost 2.78% (benzene of crystallization). The material left was then analyzed.

Subst., 0.1404; CO_2 , 0.3627; H_2O , 0.0594. Calc. for $C_{22}H_{14}O_6(COCH_3)_2$: C, 70.25; H, 4.54; found: C, 70.45; H, 4.73.

α -Orcinolphtalein diacetate is insoluble in water, and in the alkalies, soluble in benzene and rather sparingly soluble in alcohol, and in ethyl acetate. It is readily saponified by alcoholic potash.

α -Orcinolphtalein Dibenzoate.—Five grams of pure α -phthalein

were dissolved in dilute alkali in a bottle, 10 g. benzoyl chloride added, the bottle stoppered and the contents shaken vigorously for some time. Benzoyl chloride and strong alkali were added from time to time as necessary, and the shaking continued till the mixture was only slightly violet colored. The slightly yellowish, somewhat oily product was stirred up with soda solution, filtered and allowed to dry in the air. It crystallized from hot benzene in fine, white needles which melted at 276° . Recrystallized from absolute alcohol it melted at 277° . The melting point is not changed by recrystallizing from benzene. Meyer gives the melting point of this derivative as 284° . For analysis a sample was heated to constant weight at 180° for one-half hour.

Subst., 0.1060; CO_2 , 0.2958; H_2O , 0.0435. Calc. for $\text{C}_{22}\text{H}_{14}\text{O}_4(\text{COC}_6\text{H}_5)_2$: C, 76.03; H, 4.26; found: C, 76.11; H, 4.39.

The dibenzoate is insoluble in water and in alkalis. Aqueous alkalis do not saponify it perceptibly in the cold, and only with difficulty on warming; alcoholic potash acts more rapidly, but still more slowly than it does on the diacetate. The dibenzoate is soluble in hot benzene, and in hot acetone, and rather difficultly soluble in hot absolute alcohol.

Tetrabromo- α -orcinolphthalein.—To 10 g. of pure α -phthalein in 125 cc. of glacial acetic acid 22 g. of bromine in 50 cc. glacial acetic acid were added dropwise with constant shaking. After standing over night the pale yellow powder was filtered off and extracted with boiling absolute alcohol. The air dried material weighed 17 g., corresponding to a yield of 90%. Five grams of this material were used in preparing the acetyl derivative (see p. 1221), and the rest dissolved in alkali by heating to boiling, filtered and precipitated by pouring into dilute hydrochloric acid. The tetrabromo compound separated as slightly colored gelatinous flocks, which on heating became very nearly white. Filtered, dried, and extracted with boiling alcohol the material was obtained as a colorless powder. The compound thus prepared agrees with the description of tetrabromo- α -orcinolphthalein prepared by Meyer (see p. 1207). It dissolves only partly in cold alkali, and on cooling the hot alkaline solution a dark-colored product slowly separates. A portion of the amorphous material was heated to constant weight at 180° and analyzed.

Subst., (I) 0.4048, (II) 0.5122; 0.1 N AgNO_3 , (I) 21.41, (II) 27.08 cc. Calc. for $\text{C}_{22}\text{H}_{12}\text{O}_4\text{Br}_4$: Br, 47.31; for $\text{C}_{22}\text{H}_{12}\text{O}_4\text{Br}_3$: Br, 39.12; for $\text{C}_{22}\text{H}_{12}\text{O}_4\text{Br}_2$: Br, 40.17; found: Br, (I) 42.27, (II) 42.25.

The compound therefore loses bromine, in the alkaline solution, since the diacetate (see p. 1221) prepared from the same tetrabromo- α -orcinolphthalein analyzed in agreement with the theory. It evidently loses bromine quite easily, since the alkali used was only a little stronger than normal. The preparation was repeated.

The pale yellow powder was seen under the microscope to consist of well

formed rectangular prisms. These were extracted with 200 cc. of boiling benzene which removed nearly all the color, and then with acetone, whereupon a *perfectly white product* was obtained. A sample was heated to constant weight at 180° and analyzed.

Subst., 0.3765; 0.1 *N* AgNO₃, 22.17 cc. Calc. for C₂₂H₁₂O₄Br₄: Br, 47.31; found: Br, 47.06.

This compound differs from the one previously described, and also from the one described by Meyer, in that it dissolves with difficulty in cold aqueous alkalis with a *pure blue* color, no violet being perceptible. On warming, more of the material goes into solution and the color becomes an intense pure blue; on cooling the color gradually fades, but does not become violet, and a white crystalline substance separates, presumably a salt of the tetrabromo- α -orcinolphthaleincarbinolcarboxylic acid (see pp. 1222 and 1227).

The tetrabromo compound is acted on by dry ammonia gas forming a very pale blue *di-ammonium* salt.¹

Subst. (dried at 140°), 0.6160; gain in weight: 0.0318. Calc. for C₂₂H₁₂O₄Br₄·2NH₃: 4.80; found: NH₃, 4.90.

The salt is unstable, however, and loses its ammonia very quickly in the air, more quickly indeed than is the case with the corresponding β -compound (see p. 1232).

Tetrabromo- α -orcinolphthalein Diacetate.—Five grams of tetrabromo- α -orcinolphthalein were boiled with 5 g. of sodium acetate and 50 cc. of acetic anhydride for one hour, and the mixture poured into a large volume of water. The slightly colored oil was allowed to solidify, filtered off, washed, dried, and dissolved in hot benzene. The solution was concentrated by distillation, and on cooling microscopic, irregular prisms separated. The colorless compound thus prepared melted at 297° with slight decomposition. Upon recrystallization from acetone the melting point was unchanged. A sample heated to constant weight at 180° was analyzed.

Subst., 0.5111; 0.1 *N* AgNO₃, 27.00 cc. Calc. for C₂₂H₁₀O₄Br₄(CH₃CO)₂: Br, 42.07; found: Br, 42.22.

Tetrabromo- α -orcinolphthalein diacetate is insoluble in water and in alkalis. It is soluble in hot benzene, difficultly soluble in hot acetone, and almost insoluble in methyl and in ethyl alcohol.

α -Orcinolphthalein Hydrochloride.—Five grams of pure α -phthalein were dissolved in 100 cc. of absolute alcohol, the solution cooled to 0° , and treated with dry hydrochloric acid gas for two hours. A small crop of dark reddish crystals separated, which increased considerably on allowing the solution to stand over night at 0° . The dark red product was filtered off and allowed to stand in the air till the odor of hydrochloric

¹ This work was done by Mr. J. J. Kennedy.

acid had disappeared. Examined under the microscope the material was seen to consist of well formed needles. A portion was finely ground and the loss on heating determined. The material lost weight slowly at 95° , more rapidly at 140° , finally coming to constant weight in three-quarters of an hour at 178° . It slowly became *colorless* as it lost weight.

Subst., 0.3055; loss, 0.0343. Calc. for $C_{22}H_{10}O_4 \cdot HCl$: HCl, 9.20; found: loss, 11.23.

The hydrochloric acid actually combined was determined by weighing a portion of the air-dried material into an Erlenmeyer flask, adding water and warming till the solution was decolorized, *i. e.*, the hydrochloride was completely decomposed. The insoluble phthalein was filtered off, washed and the free acid in the filtrate determined by titration with standard alkali using phenoltetrachlorophthalein as the indicator. From the above loss in weight the weight of the phthalein actually taken was calculated.

Hydrochloride, 0.6346; phthalein, 0.5633; HCl, 0.05762. Calc. for $C_{22}H_{10}O_4 \cdot HCl$: HCl, 9.20; found: HCl, 9.28.

Therefore, one molecule of α -orcinolphthalein combines with one molecule of hydrogen chloride. Probably a small amount of alcohol was present in this compound as indicated by the figure for the loss on heating. The hydrochloride is quite stable as shown by the fact that a fairly high temperature is required to drive off the hydrochloric acid.

Dry hydrochloric acid gas is without action on the α -phthalein, but when treated with fuming hydrochloric acid the *white* phthalein forms the dark red hydrochloride without dissolving in the acid.

Colorless Monopotassium Salt of α -Orcinolphthalein Carbinol Carboxylic Acid.

This salt was first prepared by A. von Baeyer (see p. 1208). According to him, it forms so readily that it may be employed as a means of separating the α - and β -isomers. The lactoid formula, which he gives to this salt to explain its lack of color, is very unusual and the compound was therefore again prepared and carefully studied.

Several preparations were made, of which the following may be taken as typical: Very pure α -phthalein, was dissolved in absolute ethyl alcohol. To this colorless solution half normal alcoholic potassium hydroxide was added slowly from a buret with constant shaking. A purplish red coloration appeared, which very quickly disappeared at first, but more slowly as the end point was approached, and meanwhile a white crystalline powder separated. The addition of alkali was discontinued before a permanent color was imparted to the solution. The potassium salt was then filtered off. It was pure white but on drying in the air for some time assumed a faint lavender tint. Dried for one-half hour at 120° in a current of hydrogen the material reached constant weight and became *markedly colored dark bluish wine-red* (it became brownish as a result of oxidation if not heated in an inert gas). The

hydrogen and escaping vapors were bubbled through cold water contained in a U-tube. The contents of this tube gave a faint but distinct test for alcohol. The loss in weight (I) is due to water and some alcohol. On standing in the air all the alcohol is lost and the loss in weight from the lavender compound corresponds to one molecule of water. On heating moisture collected on the cool part of the tube of the drying apparatus, and the water through which the escaping vapors were passed gave no test for alcohol (II).

Subst., (I) 0.2804, (II) 0.3731; loss, H_2O , (I) 0.0224, (II) 0.0166.

Calc. for $C_{22}H_{17}O_4K.H_2O$: 4.33; found: H_2O , (I) 7.99, (II) 4.45.

Material dried for this short time is hygroscopic, and on *absorption of moisture becomes again nearly colorless*. If the dried red salt be heated for an hour and a half at 120° in a current of hydrogen it increases in weight a trifle over the weight obtained on heating for one-half hour at 120° , becomes slightly brownish, but is no longer hygroscopic, and does not lose its color on standing in the air for several days.

Potassium determinations were made in the following manner: a weighed amount of the dried sample was warmed in aqueous solution with an excess of 0.1 *N* hydrochloric acid until the salt was entirely decomposed. After filtering and washing the precipitated phthalein, the excess of acid remaining was determined by titration with standard alkali using phenol-tetrachlorophthalein as the indicator.

Subst., (I) 0.3532, (II) 0.3218; 0.1 *N* HCl, (I) 8.86, (II) 7.95 cc.

Calc. for $C_{22}H_{17}O_4K$: K, 9.82; found: K, (I) 9.81, (II) 9.66.

Another sample of the *freshly prepared* salt was analyzed by Mr. F. W. Sherwood.

Subst., (I) 0.3639, (II) 0.4805; loss at 160° , (I) 0.1005, (II) 0.1300. Calc. for loss of 3 C_2H_5OH and 1 H_2O :¹ 28.16; found: (I) 27.62; (II) 27.06.

Both water and alcohol were given off, and the salt became *colored red*. The residues were fumed down with sulfuric acid to determine the amount of potassium present.

Subst., (I) 0.2642, (II) 0.3481; K_2SO_4 , (I) 0.0556, (II) 0.0755.

Calc. for $C_{22}H_{17}O_4K$: K, 9.82; found: K, (I) 9.45, (II) 9.74.

This colorless monopotassium salt of α -orcinolphthaleincarbinolcarboxylic acid dissolves with difficulty in water, imparting a wine-red color to the solution. On boiling or on long standing this dilute solution becomes colorless, and a white precipitate separates, the lactoid form of the α -orcinolphthalein.

¹ Kober and Marshall, *THIS JOURNAL*, 34, 1424 (1912), have made colorless monopotassium and monosodium salts of phenolphthalein carbinolcarboxylic acid, and have found that, when made in alcoholic solutions, these salts contain both water and alcohol. In aqueous solutions these salts undergo hydrolysis and phenolphthalein precipitates exactly as this colorless salt of α -orcinolphthalein carbinolcarboxylic acid gives α -orcinolphthalein on hydrolysis.

Colored Monopotassium Salt of α -Orcinolpthalein.

Baeyer states that, if α -orcinolphthalein be boiled with soda solution, fine, hair-like needles of the violet disodium salt separate out on cooling. This product was not analyzed and it was therefore deemed necessary to repeat this work, and isolate and analyze the compound. Boiling α -phtalein with normal soda solution did give on cooling a crop of hair-like needles. Under the microscope these were seen to be quite well formed and appeared wine-red by transmitted light. They formed felt-like masses on the filter and packed together so tightly that they could not be sucked dry, and as they were unstable in the presence of water or of alcohol there seemed to be no method of completely removing the mother liquor. The potassium salt prepared in an analogous manner presented similar difficulties. It was finally obtained pure as follows: Five grams of potassium carbonate dissolved in 250 cc. of 50% alcohol, were heated to boiling, and an alcoholic solution of pure α -orcinolphthalein (5 g. in 50 cc.) was added through the reflux condenser. The solution became at once purplish red colored. It was allowed to stand forty eight hours, by which time crystals had formed which were filtered off. They appeared dark red in mass and under the microscope were seen to be long, purplish red needles, almost perfectly formed. They dissolved only partly in water, and imparted a wine red color to the solution. On drying in hydrogen a sample came to constant weight in one case, I, in one hour at 110° , and in another, II, in one-half hour at 120° .

Subst., (I) 0.1379, (II) 0.1551; loss, (I) 0.0080, (II) 0.0081.

Calc. for $C_{22}H_{10}O_4K.H_2O$: 4.33; found: H_2O , (I) 5.80, (II) 5.22.

Sample I had been allowed to dry in the air for a few hours before heating, while II had stood for four days. The dried anhydrous material showed no tendency to absorb moisture and become colorless as was the case with the colorless monopotassium salt (see p. 1223). A potassium determination was made in the same manner as in the case of the colorless monopotassium salt. A portion of the dried sample, I, was used.

Subst., 0.1294; 0.1 N HCl, 3.34 cc. Calc. for $C_{22}H_{10}O_4K$: K, 9.82; found K, 10.09.

The following analyses were made by Mr. F. W. Sherwood on a fresh preparation of this salt:

Subst., (I) 0.1738, (II) 0.2013; loss, (I) 0.0139, (II) 0.0160.

Calc. for $C_{22}H_{10}O_4K.2H_2O$: 8.30; found: H_2O (I) 8.00, (II) 7.95.

Subst., (I) 0.1600, (II) 0.1856; K_2SO_4 , (I) 0.0366, (II) 0.0422.

Calc. for $C_{22}H_{10}O_4K$: K, 9.82; found: K, (I) 10.27, (II) 10.20.

The substance is therefore a *mono*- and not a *di*-potassium salt as stated by Baeyer.

Professor Gill of the Department of Mineralogy and Crystallography of Cornell University has examined the crystals of this *red* monopotassium salt and reports as follows: "Elongated crystals or needles, which show

parallel extinction and are so frequently flattened as to indicate that they are probably not tetragonal or hexagonal. Long direction less elasticity, greater absorption. Pleochroism strong, from colorless or yellowish red to purple in very thin crystals; from red with brown-orange tinge to black in the stout needles. Stout crystals with six-sided cross section. Double refraction not strong, interference color obscured by absorption in thick crystals. Optical figure symmetrical, hence not monoclinic. Without much doubt orthorhombic, possibly hexagonal, as the plane of the optical axis seems parallel to the elongation. Good cross cleavage at right angles to the length."

If this monopotassium salt of α -orcinolphthalein be boiled with a large amount of water, the wine red solution becomes decolorized, and well formed *colorless* needles of the α -phthalein separate. The solution does not become colored on cooling. If a few drops of an alcoholic solution of phenoltetrachlorophthalein be added to this colorless supernatant liquid, a marked reddish coloration results, *i. e.*, free alkali is present. The phenomenon of decoloration is, therefore, one of hydrolysis, and is in accord with the statement of Baeyer (see p. 1208) in regard to the decomposition of the colorless salt in aqueous solution and also agrees with Meyer's statement (see p. 1205) in regard to the very weak acid nature of the α -phthalein.

The ease with which this potassium salt undergoes hydrolysis in aqueous solution also explains the fact, noted by Meyer, that the solution of the α -phthalein in *dilute* potassium hydroxide is decolorized by shaking with ether. The free phthalein is very soluble in ether, but insoluble in water, and, as fast as it is formed by the hydrolysis of the salt, it is removed by the ether until finally none is present in the alkaline solution, *i. e.*, the solution is decolorized.

Dipotassium Salt of α -Orcinolphthalein.

Baeyer states that if α -orcinolphthalein be boiled with concentrated potassium hydroxide the solution becomes pure blue, and crystals of the *tetrapotassium* salt separate. He believed that the formation of this salt was due to the rupture of the pyrone ring. Since the rupture of this ring is unusual, and takes place only in the case of the very acid phthaleins and since α -orcinolphthalein is a very weak acid, it was deemed necessary to repeat this work. Concentrated aqueous potassium hydroxide (1 : 1) gave a large crop of poorly crystallized material that could not be even approximately freed from its mother liquor. Analysis of this product gave over 30% potassium, the large amounts of potassium hydroxide and potassium carbonate present being indicated by slight white incrustations on the air-dried material. Anticipating this difficulty, a portion of the freshly prepared material was filtered separately, and washed several

times with absolute alcohol. The filtrate was strongly purplish red colored and the material on the filter analyzed as follows:

Subst., 0.2735, dried, 0.2654; 0.1 *N* HCl, 10.83 cc. Calc. for $C_{22}H_{14}O_6K_4$: K, 29.48. Calc. for $C_{22}H_{14}O_6K_3$: K, 17.92; found: K, 15.96.

The salt evidently breaks up in alcoholic solution, and the potassium hydroxide or potassium ethylate formed is washed out at a greater rate than is the free phthalein. A fairly pure salt was finally obtained as follows: seventy-five cc. of 1 : 1 potassium hydroxide were diluted to 150 cc. with water, heated to 85° and 5 g. of pure α -phthalein, dissolved in 100 cc. alcohol, added. The solution became violet, not blue colored, and on cooling two liquid layers formed. About 85 cc. of the alcohol and water were then distilled off, when the solution became pure blue and homogenous, and blue crystals having a bronzy luster began to separate from the hot solution. The whole was allowed to cool, whereupon the separation of the salt was nearly complete, and the mother liquor was no longer highly colored, due to the formation of the *tripotassium* salt of the carbinol acid (see p. 1227). The crystals were filtered off and dried in the air. In mass they appeared blue with a decided bronzy luster. Under the microscope they appeared pure blue. They dissolved in water almost completely at once and imparted a purplish red color to the solution. On heating in hydrogen the crystalline material came to constant weight in one-half hour at 110°.

Subst., (I) 0.4895, (II) 0.4141; loss, (I) 0.0233, (II) 0.0163.

Calc. for $C_{22}H_{14}O_6K_3 \cdot H_2O$: 3.97; found: H_2O , (I) 4.76, (II) 3.94.

Sample I had been allowed to dry over night in the air, while Sample II had stood in the air for ten days.

Potassium was determined in the same manner as in the case of the monopotassium salts.

Subst., (I) 0.4653, (II) 0.3969; 0.1 *N* HCl, (I) 21.91, (II) 19.00 cc. Calc. for $C_{22}H_{14}O_6K_4$: K, 29.48; calc. for $C_{22}H_{14}O_6K_3$: K, 17.92, found: K, (I) 18.41, (II) 18.72.

The salt is therefore a *di*- and not a *tetrapotassium* salt as stated by Baeyer (see p. 1210).

This blue dipotassium salt was obtained beautifully crystallized by dissolving 2.5 g. of the *pure* α -phthalein diacetate in 900 cc. of hot alcohol and pouring this solution into a boiling solution of 7.5 g. of potassium hydroxide in 100 cc. of alcohol. After boiling for a short time one-half of the alcohol was distilled off and the solution allowed to stand over night. The crystals were then filtered off, dried in the air, and analyzed.¹

Subst., (I) 0.3436, (II) 0.3352; loss at 110°, (I) 0.0114, (II) 0.0111. Calc. for $C_{22}H_{14}O_6K_2 \cdot H_2O$: 3.97; found: H_2O , (I) 3.32, (II) 3.31.

This salt contained no alcohol, the loss being due entirely to water.

Subst., (dried) (I) 0.2925, (II) 0.2877, (III) 0.1408; cc. 0.1 *N* HCl, (I) 13.96, (II) 13.47, (III) 6.55. Calc. for $C_{22}H_{14}O_6K_2$: K, 17.92; found: K, (I) 18.66, (II) 18.31, (III) 18.19.

¹ This salt was made and analyzed by Mr. F. W. Sherwood.

Professor Gill has examined the crystals of this *blue* dipotassium salt and reports as follows: "The substance is thoroughly crystalline, though not in good single crystals but in rosette-like groups of somewhat thick plates. These groups reach about $\frac{1}{8}$ mm. in diameter, and are composed of many sub-parallel individuals. There seem to be no impurities present in any appreciable quantity. The fact that extinction is in some positions parallel and in others as high as 15° or even 20° would suggest monoclinic crystallization. The surface color is a brilliant yellowish or greenish bronze. In very thin crystals the marked pleochroism is from dark purplish blue to a lighter clear blue, while thicker individuals change from black to dark blue when rotated above a nicol prism. Not enough light is transmitted to enable observation of the figure in converging polarized light." This dipotassium salt of the α -phthalein behaves, on boiling, in dilute aqueous solutions just as do the two monopotassium salts, although, of course, a proportionately larger amount of water is required to produce complete decoloration.

Tripotassium Salt of α -Orcinolphtalein Carbinol Carboxylic Acid.

This salt was obtained from the mother liquor from which the dipotassium salt had crystallized out (see p. 1226). In mass the salt appeared *pale blue* to the naked eye, but under the microscope it could be seen to consist of almost *colorless needles* mixed with some crystals of the *blue* dipotassium salt. After being dried at 155° in hydrogen the material gave results on analysis agreeing with those required for the tripotassium salt of the carbinol carboxylic acid.¹

Subst., (I) 0.3216, (II) 0.4053; loss, (I) 0.0284, (II) 0.0347. Calc. for $C_{22}H_{11}O_6K_3 \cdot 2.5H_2O$: 3.38; found: (I) 8.83, (II) 8.56. Subst., (dried) (I) 0.3584, (II) 0.2968; K_2SO_4 , (I) 0.1880, (II) 0.1537. Calc. for $C_{22}H_{11}O_6K_3$: K, 23.82; found: K, (I) 23.54, (II) 23.24.

This salt undergoes hydrolysis when boiled with water, exactly as the other potassium salts of the α -phthalein do. Kober and Marshall² have made a *tripotassium* salt of phenolphthalein carbinolcarboxylic acid which hydrolyzes with water in the same manner that this salt does.

It is highly probable that this is the salt analyzed by Baeyer and which he called a *tetrapotassium* salt (see p. 1210).

β -Orcinolphtalein.

β -Orcinolphtalein was obtained free from its isomers as outlined above (see p. 1217). The last traces of the γ -compound were removed by the ammonia method of Kehrmann. In order to insure the complete removal of the α -isomer from the soda solution it is necessary to use *two* portions of ether, and also to take care that the concentration of the α -phthalein

¹ These analyses were made by Mr. F. W. Sherwood.

² THIS JOURNAL, 33, 1780 (1911).

in the smaller portions of ether does not become sufficiently great to permit this compound to pass into the soda solution.

The crude β -orcinolphthalein was crystallized first from methyl alcohol, then from methyl alcohol by the addition of water, and finally from ethyl alcohol by the addition of water. From the last two solutions a mixture of colorless and colored needles were obtained when the water was added to the *hot* solutions. Perfectly white needles were obtained by the addition of cold water to the solution in methyl alcohol surrounded by ice. This product was filtered off, allowed to dry in the air, and the loss on heating determined. The material came to constant weight in one hour at 120° *without becoming colored*, but on further heating for one-half hour at 185° it was converted into the stable *yellow quinoid form without change of weight*. The following determinations show that the product crystallized from methyl alcohol by the addition of water contains a molecule of methyl alcohol (I), or is a mixture of this compound with the hydrate (II), (III).

Subst., (I) 0.3640, (II) 0.5611, (III) 0.1655; loss, (I) 0.0336, (II) 0.0369, (III) 0.0117. Calc. for $C_{22}H_{16}O_5 \cdot CH_3OH$: 8.17; for $C_{22}H_{16}O_5 \cdot H_2O$: 4.76; found: (I) 9.23, (II) 6.58, (III) 7.07.

The yellow material obtained in determination (I) was shown to be the anhydrous β -orcinolphthalein (see p. 1206) by the following analysis:

Subst., 0.0920; CO_2 , 0.2482; H_2O , 0.0358. Calc. for $C_{22}H_{16}O_5$: C, 73.31; H, 4.48; found: C, 73.58; H, 4.36.

The colored quinoid form of the β -orcinolphthalein was obtained crystalline in the following manner: a few grams of the material, shown to be pure by the above analysis, were dissolved in boiling alcohol, an equal volume of hot water added and the boiling continued. Yellow crystals separated, which consisted of minute, well formed, six-sided plates. The air-dried material lost only 0.1% of its weight on heating for one-half hour at 185° . From the filtrate there separated on cooling a mixture of the colored and colorless forms consisting of plates and needles, respectively. The yellow quinoid form of the β -orcinolphthalein may also be obtained crystalline from glacial acetic acid (see p. 1230).

β -Orcinolphthalein dissolves in ammonia, caustic alkalies, and in alkali carbonates with an intense cherry-red color. It does not, however, dissolve appreciably in cold ammonium carbonate, or in cold sodium bicarbonate solutions. It dissolves in alcoholic ammonia with a *red* color. When this solution is treated with water it turns *blood red*. When perfectly pure, and when none of the γ -phthalein is present, the solution in alcoholic ammonia shows no trace of the *greenish fluorescence* so characteristic of the γ -phthalein (see p. 1234). Dry ammonia gas does not act upon the *quinoid* form of the phthalein provided it be *perfectly pure*. Curiously enough, however, the *dry lactoid* modification absorbs nearly a molecule of dry ammonia gas (found 4.07 and 3.92% NH_3 , calculated

for one molecule of ammonia, 4.51%) without becoming colored. This colorless compound with ammonia loses all the ammonia when heated to 130°. When allowed to stand in the air for several weeks it loses all its ammonia and takes up moisture to form the colorless hydrate (see below).

β -Orcinolpthalein is precipitated from alkaline solutions by acetic acid as white flocks and by mineral acids as yellow flocks. The latter slowly become white on standing or at once if the mixture be heated. Kehrman (see p. 1211) regarded this color change as one from the quinoid form of the free β -phthalein to the stable lactoid form. This is, however, incorrect, the *yellow quinoid* form being, as shown above, the *stable* one, while the *white* product is a mixture of the *unstable lactoid* and *lactoid hydrate* forms (see p. 1230). The yellow compound obtained on precipitation with mineral acids contains a small amount of the *colored* quinoid sulfate or hydrochloride, which slowly hydrolyzes in the cold, or rapidly on heating, to the colorless phthalein and its hydrate. Acetic acid does not form a salt with the phthalein, therefore it precipitates the phthalein as the *white* hydrate, which goes over to the *colored* anhydrous form on boiling (see p. 1230).

β -Orcinolpthalein Hydrate.— β -Phthalein was dissolved in dilute alkali and poured into dilute acetic acid. A white, flocculent precipitate separated, a portion of which was filtered off, washed, dried in the air, and the loss on heating determined. The material came to constant weight in one-half hour at 150°, and did not change color, but on heating for one-half hour at 185° it became *colored yellow without change of weight*.

Subst., (I) 0.2653, (II) 0.1941, (III) 0.4659; loss, (I) 0.0140, (II) 0.0100, (III) 0.0244. Calc. for $C_{23}H_{18}O_6 \cdot H_2O$: 4.76; found: H_2O , (I) 5.28, (II) 5.15, (III) 5.24.

This material had been dried in the air for two weeks. It probably contains a small amount of acetic acid (see p. 1231). Another portion of the above suspension of freshly precipitated hydrate was boiled for one hour, which caused it to change slowly from the *colorless* hydrate to the yellow phthalein. This product lost only 1.16% on heating for one-half hour at 150°. It is therefore the anhydrous quinoid form, containing a very small amount of the hydrate. This transformation was no doubt due to the solvent action which the small excess of acetic acid had on the hydrate, thus lowering decidedly the temperature of transition into the stable quinoid form. Such a transformation by partial solution is also illustrated by the following experiment. Some of the colorless air-dried hydrate was boiled in benzene for thirty minutes. It was converted into the yellow phthalein, which lost only 0.63% on heating.

That the product obtained on heating was really the anhydrous β -orcinolphthalein is shown by the following analysis:

Subst., 0.1349; CO_2 , 0.3611; H_2O , 0.0558. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_5$: C, 73.31; H, 4.48; found: C, 73.00; H, 4.63.

If the β -orcinolphthalein be precipitated from alkaline solution by mineral acids it separates as a mixture of the lactoid phthalein and its colorless hydrate:

Subst., (I) 0.4246, (II) 0.2863, (III) 0.1898; loss, H_2O , (I) 0.0112, (II) 0.0070, (III) 0.0040. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_5 \cdot \frac{1}{2}\text{H}_2\text{O}$: 2.44; found: H_2O , (I) 2.64, (II) 2.45, (III) 2.11.

The yellow product which at first separates is completely hydrolyzed during the subsequent filtering and washing, so that the final product is perfectly white. It becomes white at once on heating the mixture, but is not further transformed into the stable quinoid form.

Behavior of β -Orcinolphthalein toward Glacial Acetic Acid.—Inasmuch as E. Fischer believed that orcinolphthalein formed a monoacetyl derivative (see p. 1202) on heating with glacial acetic acid, and further since Meyer considered this monoacetyl derivative of E. Fischer to be identical with his β -orcinolphthalein (see p. 1206), because the combustion analyses and certain properties of E. Fischer's product agreed with those of his β -orcinolphthalein, the behavior of the pure β -phthalein toward glacial acetic acid was carefully studied.

Some of the white β -orcinolphthalein hydrate was boiled with glacial acetic acid for some time. Only partial solution took place and the insoluble material assumed a yellow color. This material was filtered off. From the hot filtrate there separated on cooling a small crop of yellow plates exactly similar to those obtained from hot alcohol (see p. 1228). The yellow substance, which did not dissolve in the acetic acid, was examined under the microscope and seen to consist of needles. This material was finely ground, allowed to stand in the air until all odor of acetic acid had disappeared, and the loss in weight on heating to 125° determined.

Subst., 0.3164; loss, 0.0009 g.; loss, 0.28%.

That this dried material is the anhydrous phthalein is shown by the following analysis:

Subst., 0.1122; CO_2 , 0.3015; H_2O , 0.0457. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_5$: C, 73.31; H, 4.48; found: C, 73.29; H, 4.56.

The material which separated from the hot filtrate in yellow plates was filtered off, dried, and analyzed. It came to constant weight in one-half hour at 190° .

Subst., 0.2351; loss, 0.0024 g.; loss, 1.02%.

The material thus dried was shown to be the anhydrous phthalein by the following analysis:

Subst., 0.0969; CO_2 , 0.2599; H_2O , 0.0393. Calc. for $\text{C}_{22}\text{H}_{18}\text{O}_5$: C, 73.31; H, 4.48; found: C, 73.15; H, 4.54.

The results show that Emil Fischer's monoacetyl orcinolphthalein was

probably β -orcinolphthalein containing a small amount of acetic acid (see pp. 1202 and below).

Compound of β -Orcinolpthalein with Acetic Acid.—From the cold mother liquor obtained in the preceding preparation there separated on *long standing* a small amount of perfectly white microcrystalline powder. This was filtered off, dried in the air, finely ground, and allowed to stand till the odor of acetic acid had entirely disappeared. Heated in the drying apparatus it lost considerable weight at 115° , but at the end of an hour and a half it had not come to constant weight, so the temperature was increased to 180° . In one hour it had reached constant weight, but was only slightly yellow. It assumed the *yellow* color of the quinoid β -phthalein on heating for one-half hour longer.

Subst., 0.3793; loss, 0.0569. Calc. for $C_{22}H_{16}O_5 \cdot CH_3COOH$: 14.29; found: loss, 15.00

A sample was weighed into an Erlenmeyer flask, heated with water and the filtrate from this titrated, using phenoltetrachlorophthalein as the indicator.

Subst., 0.6238; 0.1 *N* NaOH, 15.14 cc. Calc. for $C_{22}H_{16}O_5 \cdot CH_3COOH$: 14.29; found: 14.57.

The yellow material which remained after heating at 180° was pure β -phthalein.

Subst., 0.1182; CO_2 , 0.3173; H_2O , 0.0466. Calc. for $C_{22}H_{16}O_5$: C, 73.31; H, 4.48; found: C, 73.21; H, 4.41.

β -Orcinolpthalein Diacetate.— β -Orcinolpthalein, free from its isomers and from tar, was converted into the acetate (see p. 1219), and this dissolved in hot benzene. On cooling clusters of *pure white* needles separated having a melting point of $226-227^{\circ}$. The melting point remained the same when the substance was recrystallized from absolute alcohol or from ethyl acetate. For the analysis it was heated to constant weight for one-half hour at 180° .

Subst., (I) 0.1754, (II) 0.1020; CO_2 , (I) 0.4527, (II) 0.2625; H_2O , (I) 0.0732, (II) 0.0440. Calc. for $C_{22}H_{14}O_5(CH_3CO)_2$: C, 70.25; H, 4.54; found: C, (I) 70.39, (II) 70.19; H, (I) 4.67, (II) 4.83.

β -Orcinolpthalein diacetate is insoluble in water, and in the alkalies, but is easily saponified by heating in the latter. It is quite readily soluble in hot benzene, slightly less so in hot absolute alcohol. It is rather easily soluble in acetone. It corresponds closely in its properties to the compound prepared by Meyer except that he reports it as being slightly colored.

β -Orcinolpthalein Dibenzoate.—Attempts to prepare this compound by boiling the β -phthalein with benzoyl chloride gave a product insoluble in alkalies, but which contained tar that was not easily removed by crystallization. It was then prepared by the Schotten-Baumann reaction (see p. 1219), boiled with alcohol, and the white residue crystallized from benzene.

Fine, white needles were obtained which melted at 234–235°. When recrystallized from benzene by the addition of absolute alcohol, or from alcohol they melted at 235–236°. The melting point given by Meyer for this compound, 244–245°, is certainly incorrect. For analysis the compound was dried at 195°.

Subst., 0.1342; CO₂, 0.3741; H₂O, 0.0535. Calc. for C₂₂H₁₄O₆ (C₆H₅CO)₂: C, 76.03; H, 4.26; found: C, 76.03; H, 4.46.

β-Orcinolphtalein dibenzoate is insoluble in water, and in alkalies, and saponifies somewhat slowly with alkali. It is easily soluble in hot benzene, rather difficultly soluble in hot alcohol, difficultly in ethyl acetate.

Tetrabromo-β-orcinolphtalein was made from 20 g. of pure β-orcinolphtalein by the method given for the corresponding α-compound (see p. 1220). It weighed 35 g. which corresponds to 94.8% of the theory. Ten grams of this material were used for conversion into the diacetate, while the remainder was dissolved in cold alkali, filtered, and precipitated by pouring into dilute acid. It separated in white, gelatinous flocks, which after filtering and washing were extracted with three portions of alcohol, whereby a white amorphous powder was left. This gave the following result on analysis:

Subst., 0.5355; 0.1 N AgNO₃, 31.68 cc. Calc. for C₂₂H₁₂O₆Br₄: Br, 47.31; found: Br, 47.28.

This tetrabromo-β-orcinolphtalein corresponds, in the main, to the compound prepared by Meyer. It is practically insoluble in all ordinary solvents; it dissolves in alkalies with a peculiar dirty dark reddish brown color, which in large volumes appears almost black by reflected light, but appears a dirty red by transmitted light.

Action of Dry Ammonia on Tetrabromo-β-orcinolphtalein.—Gaseous ammonia dried by passing through soda-lime, and then through a tube containing sodium wire was allowed to act on a weighed amount of tetrabromo-β-orcinolphtalein dried at 185°. The ammonia acted at once on the phtalein as indicated by the marked color, although eight hours were required to reach constant weight. The salt is almost black and is unstable. For this reason it must be placed in a tightly stoppered weighing tube when removed from the apparatus and weighed at once. On standing in the open air approximately half the ammonia was lost in three-quarters of an hour, and practically all of it had disappeared at the end of two days.

Subst., 0.3847; gain, 0.0360. Calc. for C₂₂H₁₂O₆Br₄·3NH₃: 7.03; for C₂₂H₁₂O₆Br₄·4NH₃: 9.16; found: NH₃, 8.56.

The statement of Meyer¹ that "Ammoniakdämpfe wirken nicht auf ihn ein, sodass er sich leicht aus einer Gemenge von Tetrabrom-β- und γ-orcinolphtalein isoliren lässt," is therefore incorrect.

¹ Ber., 29, 2637 (1896).

Tetrabromo- β -orcinolphthalein Diacetate.—Ten grams of the tetrabromo- β -phthalein were converted into the acetate (see p. 1221). The crude product dissolved in hot benzene and crystallized by the addition of alcohol gave white needles which melted at 265–266°. Recrystallized from ethyl acetate they melted at 266–267°. A sample was dried at 180° for one-half hour and analyzed.

Subst., 0.3897; 0.1 *N* AgNO₃, 20.50 cc. Calc. for C₂₂H₁₀O₆Br₄(CH₃CO)₂: Br, 42.07; found: Br, 42.04.

Tetrabromo- β -orcinolphthalein diacetate is insoluble in alkalis; it is less readily saponified by aqueous alkali than the β -orcinolphthalein diacetate. It is quite soluble in hot benzene, rather difficultly soluble in hot ethyl acetate, and almost insoluble in hot absolute alcohol.

β -Orcinolphthalein Hydrochloride was made by the method given for the α -compound (p. 1221). The product was bright red, and under the microscope appeared as almost perfectly formed diamond-shaped plates. A small portion was finely ground and the loss on heating determined. It lost weight very slowly at 140°, but came to constant weight in one and one-half hours at 175°, gradually changing from *red* to *yellow*.

Subst., 0.3408; loss, 0.0415. Calc. for C₂₂H₁₀O₆.HCl: HCl, 9.20; found: loss, 12.18.

The amount of hydrochloric acid combined was determined by titration as in the case of the α -compound.

Subst., 0.5564; phthalein, 0.4887; HCl, 0.0499. Calc. for C₂₂H₁₀O₆.HCl: HCl, 9.20; found: HCl, 9.26.

Hence, one molecule of the phthalein combines with one molecule of hydrochloric acid. The difference between the figures obtained for the loss on heating and the hydrochloric acid actually present is probably due to a small amount of alcohol. Dry hydrochloric acid gas is without action on the β -phthalein, but the scarlet red hydrochloride is formed at once when it is treated with fuming hydrochloric acid.

γ -Orcinolphthalein.

γ -Orcinolphthalein was separated from the crude material by the method outlined above (see p. 1217). It may also be extracted from the crude product with a 10% solution of sodium bicarbonate. This dissolved the γ -isomer very slowly, however. Ammonium carbonate is a little more rapid, but has the disadvantage that traces of the β -compound are removed by it. The hydrochloric acid method of purifying the crude γ -compound proposed by Kehrmann (see p. 1211) was used in order to insure an absolutely pure product for this work. The solution in methyl alcohol was cooled to 0°, and treated with hydrochloric acid gas. The yellow-brown hydrochloride, which separated in rather poorly formed needles, was dissolved in alkali, the phthaleins precipitated with dilute acetic acid, washed and dried. This *bright yellow* material was then crystallized from

methyl alcohol and again converted into the hydrochloride, which now separated as clear yellow, almost perfectly formed needles. When this salt was dissolved in alkali, and the solution poured into dilute acetic acid the hydrate of the pure phthalein separated as *white* flocks (see p. 1235). In this manner a product is obtained which is absolutely free from tar (which apparently adheres more tenaciously to this isomer than to the others) and is also free from the isomeric phthaleins.

The γ -orcinolphthalein thus purified dissolves in alkalies with a clear yellow color, showing only a faint fluorescence, whereas the crude material exhibited a marked fluorescence. In both cases the fluorescence is very much increased by the addition of alcohol. Thicker layers of the more concentrated alkaline solutions show a slightly reddish brown color. When an alkaline solution of this *carefully purified* phthalein is poured into dilute acetic acid a *white* flocculent precipitate of the hydrate is formed (see p. 1235), whereas if not pure it gives a *yellow* precipitate. The hydrate made from *pure* material becomes beautifully crystallized on boiling for a short time with water (see p. 1236), being converted into the *yellow* anhydrous phthalein.

Pure γ -orcinolphthalein has remarkably little color in alkaline solutions as compared with the α - and β -isomers. For this reason, and because of the slight fluorescence in dilute alkaline solutions, the compound was not recognized as a phthalein until an analysis had been made. It is quite probable that the γ -phthalein in alkaline solutions exists largely in the form of salts of the carbinol acid. Towards *concentrated* alkalies it conducts itself exactly as fluorescein¹ does. If a small stick of solid caustic potash be added to an alkaline solution of the phthalein and the solution be boiled, the color changes from red to bluish green. On dilution this color changes back to red and, on standing or warming, to yellow with a greenish fluorescence which shows more distinctly on the addition of alcohol.

γ -Orcinolphthalein dissolves in ammonium and alkali carbonates and bicarbonates with the evolution of carbon dioxide. It dissolves quite slowly in ammonium carbonate, and in sodium and ammonium bicarbonate solutions. In alcoholic ammonia it dissolves with a *red* color and strong *greenish fluorescence*. When diluted with water this solution turns yellow and the greenish fluorescence becomes less marked. It crystallizes well out of methyl or ethyl alcohol, and acetic acid, or by the addition of water to any of these solutions.

Compound of γ -Orcinolphthalein with Ethyl Alcohol.—Some of the pure material was dissolved in ethyl alcohol, the solution cooled, and crystallization caused to take place by the addition of water. The material separated as colorless plates, which on heating at 110° for two hours

¹ See *Ann.*, 372, 108 (1910).

came to constant weight and became *bright golden yellow*. When heated to 185° it became *grayish white without further loss of weight*.

Subst., 0.3074; loss, 0.0352. Calc. for $C_{22}H_{18}O_6 \cdot C_2H_5OH$: C_2H_5OH , 11.34; found: C_2H_5OH , 11.45.

This loss was due entirely to alcohol; no moisture condensed on the tube.

γ -Orcinolphtalein therefore crystallizes with a molecule of ethyl alcohol. That the above material is the pure phtalein is shown by the following analysis:

Subst., 0.1139; CO_2 , 0.3078; H_2O , 0.0497. Calc. for $C_{22}H_{18}O_6$: C, 73.31; H, 4.48; found: C, 73.70; H, 4.88.

The *dark orange* colored product observed by R. and H. Meyer (see p. 1207) was obtained in this work only in the case of *impure material*. Crude γ -phtalein which had been obtained from the unpurified mixture was crystallized from glacial acetic acid, whereby *dark orange* colored, rather poorly formed crystals separated. This product after drying in the air, when heated to 175° in the drying apparatus lost weight and fused to a dark, plastic mass which on cooling became hard and brittle, *i. e.*, contained tar. The carefully purified γ -phtalein when crystallized from glacial acetic acid is *yellow*; the *dark orange* colored product observed by Meyer and also in this work is therefore impure.

Compound of γ -Orcinolphtalein with Methyl Alcohol.—If a saturated solution of pure γ -phtalein in methyl alcohol be allowed to stand, colorless cubical crystals separate. These lose weight very slowly at 110° , rapidly at 160° , coming to constant weight in one-half hour. They change to a bright yellow color as they lose weight and on heating to 185° or 190° for one-half hour longer they change to a grayish white.

Subst., (I) 0.9046, (II) 0.5225, (IIa) 0.3824, (IIb) 0.3481; loss, (I) 0.0762, (II) 0.0434, (IIa) 0.0316, (IIb) 0.0288.

Calc. for $C_{22}H_{18}O_6 \cdot CH_3OH$: CH_3OH , 8.17; found: CH_3OH , (I) 8.42, (II) 8.31, (IIa) 8.26, (IIb) 8.27.

Determinations I and II were made on material crystallized from pure methyl alcohol, (IIa) and (IIb) on the white needles obtained by the addition of water to the mother liquor from which the material used in determination II had separated. The loss was entirely due to alcohol as no moisture condensed on the tube.

γ -Orcinolphtalein Hydrate.—A few grams of *pure* γ -phtalein were dissolved in sodium carbonate solution, and poured into dilute acetic acid. The *white* flocculent precipitate was filtered off, washed, dried in the air, and the loss on heating determined. All the water was given off in two hours at 70° , and moisture condensed on the cool part of the drying tube. The material gradually changed to a *bright yellow* as it lost water. It lost no further weight on being heated for one-half hour at 180° .

Subst., (I) 0.2472, (II) 0.2448, (III) 0.1907, (IV) 0.2304; loss, (I) 0.0123, (II) 0.0116, (III) 0.0093, (IV) 0.113.

Calc. for $C_{22}H_{14}O_8 \cdot H_2O$: H_2O , 4.76; found: H_2O , (I) 4.98, (II) 4.74, (III) 4.88, (IV) 4.90.

These determinations were made on three different preparations: (I), (II) and (III) were on material that had dried in the air from five to seven days, while (IV) was on material that had stood in the air for *five weeks*.

When the hydrate is boiled with water it is converted into anhydrous γ -phthalein. A portion of the above prepared hydrate was boiled with water for two hours, at the end of which time it had become *yellow* and beautifully crystallized in rhomboidal plates. This material lost only 0.01% of its weight on heating to 180° for half an hour, *i. e.*, it is the anhydrous phthalein. Another preparation of the hydrate lost 4.53% water and became *bright yellow* when kept in a Hempel vacuum desiccator for 24 hrs. with sulfuric acid.

γ -Orcinolphthalein Diacetate.— γ -Phthalein was converted into its diacetyl derivative in the same manner as in the case of the α -isomer (see p. 1219). The colorless crude product was crystallized from benzene. Perfectly white needles were obtained which melted sharply at $206-207^\circ$. When recrystallized from absolute alcohol, and then from ethyl acetate, the melting point of the substance remained the same. For analysis a sample was dried for three-quarters of an hour at 195° .

Subst., 0.1470; CO_2 , 0.3782; H_2O , 0.0613. Calc. for $C_{22}H_{14}O_8(CH_3CO)_2$: C, 70.25; H, 4.54; found: C, 70.17; H, 4.67.

The diacetate corresponds exactly to the compound prepared by Meyer. It is insoluble in water and in alkalis and is easily saponified by the latter, especially if alcohol be added. It is soluble in benzene, hot absolute alcohol, and hot ethyl acetate, and crystallizes from any of these solutions.

γ -Orcinolphthalein dibenzoate was made by the method used in making the α -isomer (see p. 1219). After filtering off the slightly orange-colored product, it was triturated with alkali, washed with water, boiled with alcohol and crystallized from benzene by the addition of absolute alcohol. Pure white needles were obtained which melted at $284-285^\circ$, with slight carbonization. When recrystallized from acetone its melting point was unchanged. For analysis the material was dried for one-half hour at 190° .

Subst., 0.0825; CO_2 , 0.2300; H_2O , 0.0334. Calc. for $C_{22}H_{14}O_8(C_6H_5CO)_2$: C, 76.03; H, 4.26; found: C, 76.04; H, 4.53.

The dibenzoate is insoluble in alkalis, and is saponified rather slowly by these solutions. It is easily soluble in benzene, and rather difficultly soluble in hot acetone. It is almost insoluble in methyl and ethyl alcohols and in ethyl acetate.

Tetrabromo- γ -orcinolphthalein was made in the same manner as the

α -isomer (see p. 1220), dissolved in alkali, and precipitated by pouring into dilute acid. The orange-colored flocks were filtered off, washed, and then boiled with alcohol, this treatment changing the product to a colorless form. For analysis it was heated for half an hour to 175° .

Subst., 0.4616; 0.1 *N* AgNO₃, 27.27 cc. Calc. for C₂₂H₁₂O₆Br₄: Br, 47.31; found: Br, 47.22.

Tetrabromo- γ -orcinolphthalein corresponds closely with the compound prepared by Meyer. It shows the greatest analogy to eosin of any of the tetrabromoorcinolphthaleins, dissolving in alkalis with a rose-red color. It is a good dye and is almost insoluble in all the ordinary solvents.

Tetrabromo- γ -orcinolphthalein diacetate was made by the method used in preparing the α -isomer (see p. 1221). The crude product was crystallized from ethyl acetate. In the melting point tube it became pink above 240° ; this color disappeared above 270° , and the slightly darkened material melted quite sharply at 282 – 283° , and carbonized at a slightly higher temperature. When recrystallized from absolute alcohol it was obtained as perfectly white, well formed rhomboidal plates. These behaved in a melting point tube exactly as did the above material, and also melted at 282 – 283° . Bromine determinations were made on the material dried at 180° for one-half hour.

Subst., (I) 0.3358; (II) 0.5090; 0.1 *N* AgNO₃, (I) 17.35, (II) 26.25 cc. Calc. for C₂₂H₁₀O₈Br₄(CH₃CO)₂: Br, 42.07; found: Br, (I) 41.30; (II) 41.23.

The only explanation of the low percentage of bromine that suggests itself is that during the acetylation a small amount of bromine was eliminated by the action of the sodium acetate, since the tetrabromo compound from which the diacetate was made gave results on analysis for bromine agreeing with the theory (see above).

The diacetate is soluble in hot benzene, moderately in hot ethyl acetate, and quite difficultly soluble in hot absolute alcohol. It is insoluble in water and in alkalis, and is saponified rather difficultly by aqueous solution of the alkalis.

Action of Dry Ammonia Gas on γ -Orcinolphthalein.

Diammonium Salt of γ -Orcinolphthalein.—That γ -orcinolphthalein is more acid than its isomers is shown by the fact that it is acted upon so readily by dry ammonia gas. When the pure dry γ -phthalein was placed in a current of dry ammonia gas it gained weight rapidly, changed color (yellow to orange) and came to constant weight in 17 minutes. The boat containing the material was placed at once in a tightly stoppered tube and weighed. The gain in weight corresponds to two molecules of ammonia. The salt formed is unstable, however, and loses its ammonia rapidly on standing in the air.

Subst., 0.3871; gain, (NH₃), 0.0377. Calc. for C₂₂H₁₄O₆(NH₄)₂: NH₃, 8.64; found: NH₃, 8.87.

Fluorescein and tetrachlorofluorescein¹ conduct themselves towards dry ammonia gas in the same manner as the γ -phthalein, thus showing the close resemblance of the γ -phthalein to fluorescein. The γ -phthalein is the only one of the isomers which forms a *salt* with ammonia gas.

Action of Dry Ammonia Gas on the Anhydrous Tetrabromo- γ -orcinolphthalein.—Dry ammonia gas was allowed to act on the anhydrous tetrabromo- γ -orcinolphthalein. It became pink at once, changed in a short time to a bright red, and at the end of three hours had become dark red. Approximately four molecules of ammonia are absorbed. The compound thus formed is unstable, giving up its ammonia slowly on standing in the air.

Subst., 0.5677; gain, (NH_3) , 0.0551. Calc. for $\text{C}_{22}\text{H}_{12}\text{O}_5\text{Br}_4 \cdot 3\text{NH}_3$: NH_3 , 7.03. Calc. for $\text{C}_{22}\text{H}_{12}\text{O}_5\text{Br}_4 \cdot 4\text{NH}_3$: NH_3 , 9.16; found: NH_3 , 8.85.

Tetrachloroeosin combines with *five* molecules of ammonia.²

γ -Orcinolphthalein Hydrochloride.—A portion of the γ -phthalein hydrochloride, purified as described above (see p. 1233), was dried in the air, ground, and the loss on heating determined. The compound is quite stable, losing weight slowly at 140° , and coming to constant weight only after four and one-half hours heating at 175° .

Subst., 0.4373; loss, 0.0502. Calc. for $\text{C}_{22}\text{H}_{16}\text{O}_6 \cdot \text{HCl}$: HCl, 9.20; found: loss, 11.48.

The amount of hydrochloric acid actually present was determined by titration in the same manner as in the case of the isomeric compounds (see pp. 1221 and 1233).

Hydrochloride, 0.3287; phthalein, 0.2910; HCl, 0.02891. Calc. for $\text{C}_{22}\text{H}_{16}\text{O}_6 \cdot \text{HCl}$: HCl, 9.20; found: HCl, 9.04.

The difference between the loss on heating and the amount of hydrochloric acid actually present is due to the presence of a small amount of alcohol.

Dry hydrochloric acid gas acts on the anhydrous γ -phthalein, one molecule of the acid being taken up with but little change in color. When heated to 180° the hydrochloride loses all its hydrochloric acid and gives the original weight of the γ -phthalein. The material thus obtained, when placed in a current of dry hydrochloric acid gas, again absorbs an equivalent of one molecule of hydrochloric acid, coming to constant weight in an hour and a half. The original weight of the γ -phthalein was obtained a second time by heating the hydrochloride to 180° .

Subst., (I) 0.4472, (II) 0.4472; gain in wt., (I) 0.0494, (II) 0.0452. Calc. for $\text{C}_{22}\text{H}_{16}\text{O}_6 \cdot \text{HCl}$: HCl, 9.20; found: HCl, (I) 9.95, (II) 9.18.

In (I) the boat containing the material was quickly transferred to a tightly stoppered tube, and weighed at once. In (II) the material was

¹ THIS JOURNAL, 36, 690 (1914).

² *Ibid.*, 36, 706 (1914).

allowed to stand in the air a few minutes before being placed in the weighing bottle.

γ -Orcinolphtalein therefore combines with one molecule of hydrochloric acid gas. It is the only one of the three orcinolphtaleins that does this. It thus shows its great analogy to fluorescein which also combines with a molecule of hydrochloric acid gas.¹ When treated with fuming hydrochloric acid the γ -phtalein also forms the yellow hydrochloride.

Orcinoltetrachlorophthaleins.

The orcinoltetrachlorophthaleins were prepared by fusing tetrachlorophthalic acid with pure orcinol in the presence of zinc chloride, phosphorus pentoxide, concentrated sulfuric acid, or fuming sulfuric acid (containing 15% of free SO_3). The tetrachlorophthalic acid was the commercial product of Heller and Merz purified by the method of Delbridge.² The purity of the product used was checked by molecular weight determinations made by titrating a weighed sample with standard alkali.³

Subst., (I) 0.5781, (II) 0.3398; 0.1 N NaOH, (I) 37.03, (II) 21.72 cc. Calc. for $\text{C}_6\text{Cl}_4(\text{COOH})_2 \cdot 0.5\text{H}_2\text{O}$: mol. wt., 312.90; found: mol. wt., (I) 312.20, (II) 312.87.

Twenty grams tetrachlorophthalic acid, 19 g. orcinol, and 19 g. freshly fused zinc chloride were ground intimately, transferred to a 250 cc. round bottom flask and heated in a sulfuric acid bath to 160–170°. The reaction began at once, as indicated by the appearance of a red color, and the mixture soon formed a pasty mass which partly solidified at the end of two hours. The hard red mass was ground, dissolved in normal alkali by heating, the solution filtered, and acidified with hydrochloric acid. *Dark red flocks* separated. The mixture was then boiled with steam, and the crude orcinoltetrachlorophthaleins filtered off. The *dark red* product dried at 110° (28 g.) corresponded to a yield of 85%.

Phosphorus pentoxide was next used as the condensing agent. One hundred and fifty-six grams of tetrachlorophthalic acid, 145 g. of orcinol, and 140 g. of phosphorus pentoxide were ground together and fused as above. The contents of the flask melted to a red viscous mass which did not solidify in two hours. The mixture treated as before gave 162 g. of a *dark red* product, a yield of 65%.

The crude product obtained in these two syntheses could be separated into its isomers only with the greatest difficulty. Ether could not be satisfactorily used, as it had been in the case of the orcinolphtaleins (see p. 1216), owing to the fact that a dark red material caused the ether to form emulsions with the alkali, which were so stable that the process was slow and laborious. Sufficient amounts of the isomers were finally obtained, however, to show that this dark red material was an impurity and not a quinoid form of one of the isomers. Indeed it was found (see p. 1242) that this red material was formed by the decomposition of the β -orcinoltetrachlorophthalein itself in *hot* dilute alkaline solutions. Consequently, in the subsequent preparations the crude material was dissolved only in *cold* alkali.

Sulfuric acid was then used as the condensing agent. Fifty grams of tetrachlorophthalic acid, 48 g. of orcinol and 45 cc. concentrated sulfuric acid were heated to 135° for two hours. During the fusion the temperature rose to 150° for a short time. A

¹ THIS JOURNAL, 36, 701 (1914).

² *Am. Chem. J.*, 41, 414 (1909).

³ *Ibid.*, 41, 401 (1909).

secondary reaction set in as evidenced by the frothing of the mass, the formation of brownish tarry material, and the vigorous evolution of sulfur dioxide. This reaction almost entirely ceased, however, on lowering the temperature to 135° . At the end of two hours the melted mass was poured into water, the product filtered off and dissolved in *cold, dilute* alkali. On acidification the phthaleins separated as *light yellow* flocks. The mixture was heated to boiling with steam, the crude product filtered off and dried at 110° . Yield, 63%.

All of this product (46 g.) was separated into the isomers by the method given below and gave

Isomer.	Grams.
α	11.0
β	17.0
γ	8.0

and in addition a large amount of tar.

Fuming sulfuric acid was next used as the condensing agent. Forty-one grams of tetrachlorophthalic acid and 20 cc. of fuming sulfuric acid were placed in a flask and heated to 150° for some time. The temperature was then lowered to 135° and 38 g. orcinol added. The reaction proceeded so slowly that 20 cc. more of fuming sulfuric acid were added. The reaction then proceeded, as indicated by the red color of the mixture. At the end of the two hours the product was treated exactly as in the preceding case. A *light yellow* product was obtained, which after drying at 110° weighed 57 g. corresponding to a yield of 88%. This material yielded the following amounts of the different isomers:

Isomer.	Grams.
α	12.5
β	32.0
γ	7.5

On attempting to repeat this synthesis the temperature rose to 140° for a few moments. Instantly a vigorous secondary reaction began, accompanied by the evolution of sulfur dioxide. This reaction decreased somewhat when the temperature was lowered to 100° , but began again as soon as heat was applied. The product formed was largely tarry material, which contained only a small percentage of the phthaleins.

It seems from the results presented here that zinc chloride is the best condensing agent to use in the preparation of the orcinoltetrachlorophthaleins. The dark red decomposition products obtained from the material made with this condensing agent (see p. 1239) would probably not have been formed if it had not been dissolved in *hot* alkali.

The method used in isolating the isomeric orcinoltetrachlorophthaleins was very similar to that used in the case of the orcinolphthaleins (see p. 1217). γ -Orcinoltetrachlorophthalein is soluble in dilute solutions of the alkali carbonates and bicarbonates; β -orcinoltetrachlorophthalein is soluble in sodium carbonate solution, and is removed from its ethereal solution by aqueous solutions of this salt; α -orcinoltetrachlorophthalein is readily soluble only in solutions of potassium and sodium hydroxide and differs from α -orcinolphthalein in that it is not even *partially* removed from its ether solution by sodium carbonate solutions. The separation of the α - and β -isomers by ether and sodium carbonate is therefore complete.

The method used was as follows: The crude material was dissolved in cold normal alkali, and precipitated by pouring into dilute mineral acid. This mixture was then shaken with a large volume of ether, the aqueous layer drawn off, and the ether solution of the phthaleins filtered to remove tar. The ether solution was then shaken with one-fourth its volume of normal soda solution. This removed all the γ -compound, and a small amount of the β -isomer. The latter was extracted by shaking the soda solution with several portions of *fresh* ether. The crude γ -product obtained by acidifying this soda solution is only approximately pure, and is further purified as indicated below (see p. 1243). The ether solutions now contain the α - and β -compounds. The latter is removed by shaking with several portions of soda solution and then the former by means of sodium hydroxide solution.

α -Orcinoltetrachlorophthalein.

The major part of the α -tetrachlorophthalein obtained as outlined above was dark colored, *i. e.*, contained tarry by-products, although some portions were perfectly white. The dark colored material after being recrystallized from ethyl acetate, methyl alcohol, and ethyl alcohol, was still straw colored. It was, however, nearly pure as shown by the following analysis made on material dried at 180°:

Subst., 0.3382; 0.1 N AgNO₃, 26.95 cc. Calc. for C₂₂H₁₂O₆Cl₄: Cl, 28.49; found: Cl, 28.26.

This material was purified by dissolving in ethyl alcohol and precipitating with water. The air dried substance lost 7.45% of its weight on heating to 180° and some moisture condensed on the cold part of the tube. The loss calculated for one molecule of alcohol would be 8.45%. It is quite likely therefore that this compound, like the α -orcinolphthalein crystallizes with one molecule of alcohol.

An attempt was made to obtain a colorless product by saponification of the pure diacetate (see p. 1242). Fifteen grams of the diacetate were suspended in 150 cc. of absolute alcohol, an equal volume of normal sodium hydroxide solution added, and the mixture boiled for 50 minutes. The solution was then filtered, diluted and acidified with sulfuric acid. Chocolate colored flocks separated, which when filtered off, and crystallized several times from different solvents were still colored pale yellow. The filtrate obtained after saponification gave no reaction for chlorides.

Pure α -orcinoltetrachlorophthalein dissolves in alkalis with an almost *pure blue* color, having but a faint trace of red, thus differing markedly from α -orcinolphthalein. It is only slightly soluble in aqueous ammonia, and in sodium carbonate solutions. The fact that it is *not* removed from its ether solution by sodium carbonate solution while the α -orcinolphthalein is slowly extracted is unexpected, since this would seem to indicate that it unites with weak alkalis less readily than the mother substance. α -Or-

cinoltetrachlorophthalein is soluble in glacial acetic acid, methyl and ethyl alcohols, ethyl acetate and acetone. It is perceptibly less soluble in solvents than is the α -orcinolphthalein. When *absolutely pure* it is *colorless* and dissolves in alcoholic ammonia *without color*. The slightest trace of its isomers can thus be detected (see pp. 1243 and 1244). When water is added to this colorless solution it turns *blue* and after a few days' standing the *colorless* α -tetrachlorophthalein crystallizes out.

α -Orcinoltetrachlorophthalein Diacetate. — α -Orcinoltetrachlorophthalein was converted into the diacetate in the usual manner (see p. 1219). It was crystallized alternately from benzene and ethyl acetate until a perfectly white product was obtained which showed a constant melting point of 292° . A chlorine determination on a sample of this material dried at 180° gave the following result:

Subst., 0.3000; 0.1 *N* AgNO₃, 20.50 cc. Calc. for C₂₂H₁₀O₆Cl₄(CH₃CO)₂: Cl, 24.37; found: Cl, 24.23.

The diacetate is soluble in benzene, ethyl acetate, and acetone, and rather difficultly soluble in absolute alcohol. It crystallizes in minute, perfectly colorless rhombs. It is insoluble in water and in solutions of the alkalis, but is saponified readily on being heated in the latter. Some decomposition takes place even in the cold if alcoholic alkali be used (see p. 1241).

β -Orcinoltetrachlorophthalein.

The β -orcinoltetrachlorophthalein obtained by the method of separation described above contained a small amount of red material that imparted a faint pink tint to the product. Crystallization from methyl alcohol, ethyl alcohol, ethyl acetate and glacial acetic acid gave a product that was colorless, but on heating to 150° a faint pink tint appeared. It was shown to be pure by the following determinations made on material dried at 180° :

Subst., (I) 0.3153, (II) 0.2825, (III) 0.2830; 0.1 *N* AgNO₃, (I) 25.20, (II) 22.46, (III) 22.56 cc.

Calc. for C₂₂H₁₀O₆Cl₄: Cl, 28.49; found: Cl, (I) 28.34, (II) 28.19, (III) 28.27.

In order to determine whether this pink color was due to an impurity or to a quinoid form of β -tetrachlorophthalein, an attempt was made to obtain pure white material by the saponification of the pure β -orcinoltetrachlorophthalein diacetate (see p. 1243) with alcoholic caustic potash. The reaction began in the cold, as indicated by the production of a red color. The mixture was boiled on the water bath for one hour and filtered. A small amount of dark red, well crystallized material separated, presumably a potassium salt. The filtrate on dilution and acidification with sulfuric acid gave a precipitate of *dark red flocks, identical in properties with the dark red material* described above (see p. 1239). The filtrate from this product gave a strong reaction for chlorides. β -Orcinoltetrachlorophthalein there-

fore decomposes in hot alkaline solutions with the elimination of chlorine to give a substance which in the free state is dark red. The faint pink color noted in the β -orcinoltetrachlorophthalein is no doubt due to a trace of this material. The red crystalline material, presumably a potassium salt, was soluble in water, and this solution when acidified gave a red flocculent precipitate.

Pure β -orcinoltetrachlorophthalein is soluble in methyl and ethyl alcohols, acetone, glacial acetic acid, and ethyl acetate. It is soluble in alkalis with a smudgy red color intermediate between that of β -orcinolphthalein and tetrabromo- β -orcinolphthalein. From these solutions it is precipitated as a *white hydrate* by acids. A colored form of the free β -orcinoltetrachlorophthalein analogous to that obtained in the case of β -orcinolphthalein was never observed. In alcoholic ammonia it dissolves with a deep red color, but *without fluorescence*. It is thus possible to detect the presence of the slightest trace of the γ -compound (see p. 1244).

β -Orcinoltetrachlorophthalein Diacetate.— β -Orcinoltetrachlorophthalein was acetylated in the usual manner (see p. 1219). The brownish diacetate was crystallized from benzene, ethyl acetate, and ethyl alcohol until a perfectly white product was obtained, which showed the constant melting point of 239° . A chlorine determination was made on a sample dried for one-half hour at 180° .

Subst., 0.3330; 0.1 *N* AgNO₃, 22.73 cc.

Calc. for C₂₂H₁₀O₅Cl₄(CH₃CO)₂: Cl, 24.37; found: Cl, 24.20.

The diacetate is soluble in benzene, ethyl acetate, acetone, and rather difficultly soluble in absolute alcohol. It is insoluble in water, and in alkalis. Like the isomeric α -compound it undergoes decomposition when boiled with alcoholic potash (see p. 1242).

γ -Orcinoltetrachlorophthalein.

The crude γ -orcinoltetrachlorophthalein obtained from the ether solution of the mixture of the isomers (see p. 1241) by the first extraction with soda solution was quite impure, containing sufficient of the dark red material to prevent crystallization. It was converted into its diacetate, which was more readily purified, and the pure diacetate (see p. 1244) saponified with half normal alcoholic potassium hydroxide. The solution was filtered, diluted and acidified. Perfectly white flocks separated which crystallized from methyl alcohol by the addition of water in fine, white needle clusters. After drying in the air, a sample heated to 180° for one-half hour came to constant weight without change of color and moisture condensed on the cool part of the tube.

Subst., (I) 0.4672, (II) 0.2484; loss, (I) 0.0310, (II) 0.0165.

Calc. for C₂₂H₁₀O₅Cl₄·2H₂O: H₂O, 6.88.

Calc. for C₂₂H₁₀O₅Cl₄·CH₃OH: CH₃OH, 6.04; found: (I) 6.63, (II) 6.64.

A chlorine determination on the anhydrous material gave the following result:

Subst., 0.3234; 0.1 *N* AgNO₃, 25.93 cc. Calc. for C₂₂H₁₂O₆Cl₄: Cl, 28.49; found: Cl, 28.43.

γ -Orcinoltetrachlorophthalein possesses practically the same solubilities in the ordinary organic solvents as the α - and β -isomers. It is, however, more readily soluble in aqueous ammonia and in alkali bicarbonates than its isomers. Its dilute alkaline solutions are yellow and show a green fluorescence which is apparently greater than that of γ -orcinolphthalein. Evidence on this point was obtained by dissolving molecular equivalent quantities of the two compounds in equal amounts of tenth normal alkali and comparing the two. When dissolved in alcoholic ammonia the solution has a reddish yellow color and a marked *greenish* fluorescence.

γ -Orcinoltetrachlorophthalein Diacetate.—The crude reddish brown phthalein was acetylated in the usual manner (see p. 1219). The brownish diacetate was crystallized alternately from benzene and ethyl acetate till a perfectly white compound was obtained which showed the constant melting point of 252–253°. This material dried for one-half hour at 180° was analyzed.

Subst., 0.2778; 0.1 *N* AgNO₃, 19.03 cc. Calc. for C₂₂H₁₀O₆Cl₄(CH₃CO)₂: Cl, 24.37; found: Cl, 24.29.

The diacetate is soluble in benzene, ethyl acetate, and acetone; rather difficultly soluble in absolute alcohol. From benzene it crystallizes in long, flat needles. It is insoluble in water and in alkalis, but is saponified by the latter on heating or slowly in the cold in the presence of alcohol.

Absorption Spectra of the Orcinolphthaleins, the Tetrabromo- and the Orcinoltetrachlorophthaleins.

For absorption spectra studies weighed amounts of the pure phthaleins were dissolved in potassium hydroxide solutions of such strength that four molecules of alkali were present to each molecule of phthalein. In the case of the β - and γ -derivatives alcoholic potassium hydroxide was used, but in the case of the α -compounds aqueous alkali was used because of the tendency of these phthaleins to assume the carbinol form in the presence of alcohol. The absorption bands were studied by means of transmission curves. This work was carried out by Professor Gibbs and Mr. K. S. Gibson of the Physics Department. The following description and figures, taken from their report explain the methods used and the results obtained: "The observations were made by means of a Lummer-Brodhun spectrophotometer (see p. 1245). Light from the acetylene flame *L*, was reflected into the collimators *C*₁ and *C*₂ by mirrors, *M*₁ and *M*₂. Ground glass plates, *G*₁ and *G*₂, were placed in front of the slits in order to produce a uniform field. After passing through the collimators light passes through the Lummer-Brodhun prism, and is then dispersed and

observed by the telescope. The liquid to be observed is placed in the cell opposite the slit S_1 . The slit in the telescope and the slit S_1 were set at equal widths and kept constant, while the observations were made by varying the width of slit S_2 until the two fields were of equal intensities.

LUMMER-BRODHUN SPECTROPHOTOMETER.

Fig. 1.

On account of the large variation in the absorption of liquids, cells of various widths were used, and in some cases it was necessary to use capillary films, which was done by putting a small amount of liquid in a cell and drawing the liquid up on one side by means of a piece of glass placed at one edge. In this way, a wedge-shape film of various widths was secured. In all cases, a cover was kept on the cells in order to prevent evaporation of the alcohol, and in all cases observations made towards the end of the run checked with those made at the beginning, indicating that very little evaporation had occurred. This precaution was found very necessary either because of the evaporation of the alcohol or because

of the absorption by the liquid of something from the atmosphere, possibly carbon dioxide. In the accompanying curves the percentage of transmission is computed by dividing the observation made with the cell removed, by the observation made with the cell and liquid in place, due correction having been made for reflection at the boundary of the glass and air and at the boundary of the glass and liquid, which, in the case of the capillary film, required a correction for four boundaries of glass and air and two of glass and liquid. The wave lengths of the points of minimum transmission, *i. e.*, of maximum absorption are shown in the following table:"

	Wave lengths.		
	α .	β .	γ .
Orcinolpthaleins.....	0.528	0.536	0.498
Orcinoltetrachlorophthaleins.....	0.562	0.554	0.521
Tetrabromoorcinolpthaleins.....	0.572	0.576	0.529
Tetrabromoorcinoltetrachlorophthalein (very dilute solution)			0.555

In the study of these absorption curves it will be noticed that in every case the absorption bands are gradually shifted towards the red end of the spectrum as we pass from the orcinolphthaleins to their bromine and chlo-

Fig. 2.

rine derivatives, just as was found to be the case in the study of the absorption spectra of fluorescein, eosin, tetrachlorofluorescein and tetrachloroeosin.¹

¹ THIS JOURNAL, 36, 680 (1914).

Again, the shifting caused by the entrance of *four* chlorine atoms into the *phthalic acid* residue of γ -orcinolphthalein is almost the same as that

Fig. 3.

caused by introducing *two* bromine atoms into *each* of the two residues of orcinol, i. e., the shifting is proportional to the *number* of halogens

Fig. 4.

introduced, rather than to the increase in molecular weight. For example, the absorption bands of γ -orcinoltetrachlorophthalein and of tetrabromo- γ -orcinolphthalein are very nearly identical, while the molecular weights of these substances are 498 and 676.

It is interesting to note that only one absorption band is to be seen here in the case of the γ -orcinolphthalein and its halogen derivatives, while *two* were observed in the case of fluorescein and its chlorine and bromine substitution products. For this reason it seemed of importance to make the tetrabromo- γ -orcinoltetrachlorophthalein and examine its spectrum. This substance was prepared and analyzed by Mr. J. J. Kennedy. An examination of its absorption curve (see p. 1247) shows one band at 0.555 and there is evidence of another at approximately 0.520. The shape of the curves of β -orcinolphthalein and its chlorine and bromine derivatives (see p. 1247) also shows evidence of *two bands*, the second one, however, in this case being on the boundary between the visible and the ultraviolet part of the spectra.

The curves for the γ -phthaleins are the typical curves found for fluorescent substances, and these phthaleins are unquestionably derivatives of fluorescein, and have, therefore a similar chemical structure.

Theoretical.

As pointed out above R. Meyer (see p. 1203) suggested Formula III for γ -orcinolphthalein, and Baeyer (see p. 1208) concluded that α -orcinolphthalein possesses the vicinal or symmetrical structure represented by Formula I. This leaves the unsymmetrical Formula II (see p. 1203) as the only one possible for the β -compound.

While there seems to be but little doubt regarding the correctness of Formula III assigned to γ -orcinolphthalein by R. Meyer, because of the marked analogy of this compound and its tetrabromo derivative to fluorescein and eosin, the evidence furnished by Baeyer (see pp. 1208 and 1210) in regard to the structure of α -orcinolphthalein is perhaps less conclusive. However, Formulas I for the α -compound and II for the β -isomer are in accord with all the known facts. According to this arrangement β -orcinolphthalein would be expected to possess properties intermediate between those of the α - and γ -isomers. In general this is the case. For example, the γ - is the strongest acid and the α -compound the weakest, while the β - is intermediate between these two. The free γ -compound exists only in the quinoid form, the β - in the lactoid and quinoid forms while the α -compound is known only in the lactoid modification. The γ -compound is the one most disposed to the formation of colored salts with acids. It evidently forms a salt even with acetic acid, as the pure material precipitated from alkaline solution by this acid is at first *colored* but on standing becomes *colorless*, just as does the compound of the β -isomer when precipitated with a *mineral acid*. In both cases this color change is

probably due to hydrolysis of the colored salts of the acids. This is in accord with the fact that dry hydrochloric acid gas unites with the γ -compound while it is without action on the α - and the β -phthaleins. As pointed out by Kehrmann the β -compound is, in turn, clearly more disposed to the formation of salts with acids than is the α -compound. The nature of the absorption spectra also is in agreement with the supposition that the β -phthalein occupies a position intermediate between that of the α - and γ -isomers. It is also interesting to note that the melting point of the γ -diacetate is 207° ; that of the β -compound 227° , and of the corresponding α -isomer 247° . However, as this relation does not hold in the case of the diacetates of the orcinoltetrachlorophthaleins, it perhaps should not be considered as having too much weight.

α -Orcinolphtalein, its diacetate and dibenzoate, its compound with ethyl alcohol and with acetic acid, are all colorless and hence have lactoid formulas:

α -Orcinolphtalein diacetate and dibenzoate.

Compound of α -orcinolphtalein with ethyl alcohol.

Compound of α -orcinolphtalein with acetic acid.

The colorless monopotassium salt formed from α -orcinolphtalein is represented as a derivative of the carbinolcarboxylic acid, Formula I (see p. 1250). As it is formed in alcoholic solution, and, when freshly prepared, loses approximately three molecules of alcohol and one of water when heated and becomes colored, it is represented by Formula II. On standing in the air all the alcohol is given off but not the water of constitution. Formula II without the alcohol represents this compound. Both these forms of the monopotassium salt must be considered as derivatives of the α -carbinolcarboxylic acid (I), since they are colorless and on heating lose water and alcohol or water alone and go over to the colored ortho-quinoid form (III) (see below). The lactoid formula (see p.

1209) proposed by Baeyer for this colorless monopotassium salt is not in accord with this behavior.

The steps involved in the changes of color which α -orcinolphthalein undergoes when treated with alkalis as proposed by Baeyer are given on p. 1209.

In the light of the results obtained in this investigation, this explanation is certainly untenable because analyses show: (1) that the first violet salt is the *quinoid form* of the *monopotassium salt*, and not the *dipotassium salt*; and, (2) that the *colorless monopotassium salt* is the *carbinol form* of the first violet salt, and (3) that the *violet* and *blue* salts are *mono-* and *dipotassium* salts, respectively, and not *di-* and *tetrapotassium* salts as stated by Baeyer.

The explanation of the color changes that is in accord with all the facts is the following: α -Orcinolphthalein is a very weak acid but forms moderately stable sodium or potassium salts. It therefore belongs to the class of pseudo acids. Such substances Hantzsch¹ considers as existing in tautomeric forms, the one practically un-ionized acid, the other considerably ionized and which gives rise to the stable salts. Applying this to α -orcinolphthalein, we have the following explanation of the color changes: The violet color first observed is due to the formation of the *quinoid form* of the *monopotassium salt* (III, p. 1251) by the neutralization of the true acid (II) formed from the pseudo acid (I). In alcoholic solution this color disappears because alcohol favors the conversion of the colored *monopotassium salt* (III) into the colorless salt of the carbinol

¹ *Ber.*, 32, 575 (1899); 35, 210, 226, 1001 (1902); 39, 139, 1073 (1906).

acid (IV), which is practically insoluble in alcohol. On the addition of more alkali both these salts are converted into the blue dipotassium salt (V) which, in the presence of a large excess of alkali, is converted into the colorless tripotassium salt of the carbinol acid (VI). On boiling with water all these salts undergo hydrolysis to alkali and the true acid (II) which then crystallizes in the form of the pseudo acid (I) which is insoluble in water.

One difference between this explanation and that of Baeyer is that in this case the potassium is represented as replacing hydrogen of the carboxyl group. Since in the true acid (II) a weak acid group (OH) and a strong acid group (COOH) exist, the stronger group would be neutralized first, *i. e.*, the first atom of potassium would replace the hydrogen of the carboxyl group. This is in agreement with the fact that the monopotassium salt is colored or may be readily converted into the colored form by heating. According to Baeyer, however, the potassium replaces the

hydrogen of the phenol group, and the colorless salt has the lactoid structure. This structure does not agree with the fact that the colorless salt readily becomes colored on heating. This change is, however, very readily accounted for by the carbinol form assigned to the colorless monopotassium salt in the explanation given above.

Another difference between this explanation and that of Baeyer is that the pyrone ring is here represented as remaining intact. This is proved by the fact that even with a large excess of potassium hydroxide a *tripotassium* salt of the carbinol carboxylic acid (VI, p. 1251) is formed and not a *tetrapotassium* salt as represented by Baeyer (see p. 1209). A further proof that the pyrone ring is not ruptured is the fact that α -orcinolphthalein when benzoylated by the Baumann-Schotten reaction in strong alkaline solution gives a *dibenzoate* and not a *tetrabenzoate* (see pp. 1203 and 1219).

It is interesting to note that α -orcinolphthalein (see Formula I, p. 1251), in which both hydroxyl groups are *ortho* to the methane carbon atom, reacts with alkalis to form *colored* and *colorless* salts in exactly the same manner as those phthaleins in which the hydroxyl groups occupy the *para* positions to the methane carbon atom.

β -Orcinolphthalein exists in a colored modification represented by Formulas I or II.

(I). β -Orcinolphthalein. Colored.

(II).

and in a colorless modification represented by Formula II on p. 1203.

The lactoid modification is obtained by heating the hydrate, or the compound of β -orcinolphthalein with acetic acid, to 150° , the quinoid modification by heating the lactoid form to 180° , and by crystallizing the phthalein from *hot* alcohol or *hot* glacial acetic acid. As pointed out above (see p. 1228) it is the stable, and the lactoid the unstable form.

From the close resemblance in color of the quinoid form of the β -phthalein to that of the γ -phthalein, which is only known in the quinoid modification, and the fact that the α -phthalein is only known in the lactoid form, it seems highly probable that the *paraquinoid* formula is the one which best represents the structure of the *colored* modification of β -orcinolphthalein.

The difference in the action of dry ammonia gas on the two forms of the β -phthalein is rather surprising. From the resemblance of the quinoid form to the γ -phthalein it might have been expected that this modification

of the β -phthalein would have absorbed ammonia just as the γ -isomer does, while the lactoid form bearing such a close resemblance to the α -phthalein, which is only known in the lactoid form, and which does not absorb ammonia at all, might naturally have been expected to be unacted on by this gas. Just why the lactoid form absorbs ammonia and the quinoid does not it is not possible to say, but it seems to be connected with the fact that the lactoid form gives a colorless hydrate. As the compound with ammonia has no color it may have a structure like that assigned to the hydrate (see below).

Compound of β -orcinolphthalein with ammonia.
Colorless.

This substance loses a molecule of ammonia when heated and gives the lactoid form of the phthalein, just as the hydrate does when it loses a molecule of water. Its close connection with the hydrate is also shown by the fact that it loses all its ammonia in the air and takes up moisture in its stead to form the hydrate (see p. 1229).

The statement of Fischer that orcinolphthalein forms a monacetate, and of Meyer, that the β -orcinolphthalein contains one-third of a molecule of water (see p. 1206) are both incorrect. Meyer's β -orcinolphthalein was evidently an impure product.

β -Orcinolphthalein hydrate is colorless and gives the colorless lactoid modification of the phthalein when heated to 150° . It is hence represented as derived from the lactoid modification:

β -Orcinolphthalein hydrate.

The diacetate, dibenzoate and the compound of β -phthalein with acetic acid are also colorless and are represented by lactoid formulas analogous to those given for the corresponding α -compounds (see p. 1249).

γ -Orcinolpthalein in the free condition is only known in the *colored* modification represented by the quinoid Formula I.

The *ortho quinoid* formula (II) assigned to this phthalein by Kehrman is probably incorrect. If, as Kehrman assumes, the pyrone oxygen becomes tetravalent, *i. e.*, assumes basic properties it would unite with the stronger acid group, *i. e.*, with the carboxyl. If, then, the *ortho quinoid formula* be assumed, Formula III is preferable to II.

From the great resemblance of γ -orcinolpthalein to fluorescein (see pp. 1234, 1237, 1238 and 1239) it seems much more probable that both substances have the *para-quinoid* structure. From the structural formula (I) for γ -orcinolpthalein given above it will be seen that it is represented as a dimethyl fluorescein. Like fluorescein, γ -orcinolpthalein has both *acid* and *basic* properties. It unites with dry ammonia gas to form a *colored diammonium salt* (see p. 1238), and it is the only one of the orcinolpthaleins which acts in this way. It is also the only one of the orcinolpthaleins to combine with dry hydrochloric acid gas to form a *colored hydrochloride*. It is thus *at the same time the most acid and the most basic* of the orcinolpthaleins.

γ -Orcinolpthalein hydrate, the compound with methyl alcohol, the diacetate, and the dibenzoate are all colorless and hence are all derivatives of the lactoid tautomeric modification (see Formula III on p. 1203) and must therefore be assigned lactoid formulas analogous to those given for the corresponding α - and β -compounds (see pp. 1249 and 1253).

As the γ -orcinolpthalein hydrate loses water and the compound with methyl alcohol loses alcohol when heated and form the *yellow anhydrous*

phthalein, they might be regarded as carbinol forms of this phthalein as shown below:

The ease with which the hydrate loses water (see p. 1236), however, would seem to favor the assumption that the two hydroxyl groups from which the water is formed are combined with the same carbon atom as shown in the formula given for the hydrate (see p. 1253).

The hydrochlorides of the orcinolphthaleins are all colored and are therefore derivatives of the quinoid forms of these substances. They may be assigned the ordinary oxonium Formula I, the carbonium Formula II, or the ortho quinoid oxonium Formula III, analogous to those proposed by Kehrman for the oxonium salts of the methylated orcinolphthaleins.¹

We may also assign the *o*-quinoid structure instead of the above *p*-quinoid (Formulas I and II) to this hydrochloride.

The hydrochlorides of the isomeric α - and γ -phthaleins may be represented by formulas analogous to the above, bearing in mind that in the case of the γ -compound only the *p*-quinoid structure can be assigned to the ordinary oxonium salt and carbonium salt, while in the case of the α -orscinolphthalein only the *o*-quinoid structure is possible.

¹ *Ber.*, 45, 3506 (1912).

The formulas for the orcinoltetrachlorophthalein diacetates are derived by simple replacement of the phenol hydrogens of the above formulas by acetyl groups in each case.

It is interesting to note that in each case in which chlorine or bromine atoms have been introduced into the phthalein molecule, the tendency to assume the free quinoid form is reduced. This is in accord with the following observation of Orndorff and Hitch. "Fluorescein in the free state exists only in the *colored* quinoid form. No colorless free fluorescein has ever been prepared. Tetrachlorofluorescein, on the other hand, has been obtained in two modifications, *colored* and *colorless*, but the colored form is the more stable. Eosin in the free state is flesh colored, and may be a mixture of the two forms, while the free tetrachloroeosin is colorless or very slightly colored. The colored modification has not yet been prepared."

In the case of γ -orcinolphthalein dry ammonia acts on this compound with the formation of a colored diammonium salt which probably has the following formula:

Diammonium salt of γ -orcinolphthalein.

In the case of the tetrabromo- β -orcinolphthalein and tetrabromo- γ -orcinolphthalein four molecules of ammonia are absorbed, which is probably best represented by such a formula as the following:

Compound of tetrabromo- γ -orcinolphthalein
with four molecules of ammonia.

The successive steps of polyammonium salt formation have been worked out by Orndorff and Hitch² in connection with tetrachlorofluorescein and tetrachloroeosin.

Summary.

The results obtained in this investigation may be briefly summarized as follows:

¹ THIS JOURNAL, 36, 680 (1914).

² *Ibid.*, pp. 717 and 722.

1. The methods of preparing the orcinolphthaleins and of separating the isomers have been improved. The effect of conditions of preparation on the amounts of the isomers formed has also been studied.

2. The action of ammonia on γ -orcinolphthalein, on tetrabromo- β -orcinolphthalein, and on tetrabromo- γ -orcinolphthalein has been investigated.

3. The *colorless* and *colored* potassium salts of α -orcinolphthalein have been again prepared and analyzed and an explanation of the color changes of α -orcinolphthalein with alkalis more in accord with the facts than that proposed by Baeyer, has been suggested.

4. α -Orcinolphthalein exists only in the colorless form, while both colored and colorless forms of the isomeric β -compound have been prepared. The γ -phthalein is only known in the colored form. The tetrabromo-orcinolphthaleins and the orcinoltetrachlorophthaleins exist only in the colorless forms.

5. The colored compounds of the orcinolphthaleins with hydrochloric acid have been isolated and analyzed.

6. Colorless hydrates, acetyl and benzoyl derivatives, and colorless compounds of the orcinolphthaleins with solvents have also been prepared.

7. The three tetrabromo-orcinolphthaleins and the three orcinoltetrachlorophthaleins and their diacetates have been made and studied.

8. The absorption spectra of the orcinolphthaleins, of the tetrabromo-orcinolphthaleins, of the orcinoltetrachlorophthaleins and of the tetrabromo- γ -orcinoltetrachlorophthaleins have been investigated and the transmission curves plotted.

ITHACA, N. Y.

[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF THE UNIVERSITY OF ILLINOIS.]

***o*- AND *p*-CHLOROBENZOYLACETIC ESTERS AND SOME OF THEIR DERIVATIVES.**

BY LAMBERT THORP AND E. R. BRUNSKILL.

Received March 16, 1915.

The work presented in this article is a continuation of that begun by one of us upon the halogenated benzoylactic esters,¹ and had for its object a study of the effect of negative substituents in the aromatic nucleus upon the ease of alkylation and upon the course of the saponification of the substituted benzoylactic esters. In regard to ease of alkylation the chlorobenzoylactic esters stand between benzoylactic ester and its nitro derivatives, a condition of affairs which might be expected *a priori* from other well-known instances of the effect of a substitution of a nitro group for a chlorine atom, such as the relative instability of chloroacetic and nitroacetic acids with respect to the loss of carbon dioxide, the difference

¹ THIS JOURNAL, 35, 270 (1913).

in the orientating influence of the halogen atom and the nitro group upon the entrance of a second substituent into the benzene ring, the more pronounced effect of the nitro group upon the reactivity of a halogen atom in the aromatic nucleus, etc.

The ketonic decomposition of *o*-chlorobenzoylacetate, by means of dilute sulfuric acid, is effected with the same degree of smoothness as obtains in the case of benzoylacetate itself, although with even dilute alkali the acid decomposition appears to predominate in the case of certain derivatives of *p*-chlorobenzoylacetate.

Experimental.

***o*-Chlorobenzoylacetate Ethyl Ester.**—To one-half (160 cc.) of a solution of sodium ethylate, prepared by dissolving 20.7 g. of sodium (2 equiv. wts.) in 320 cc. of absolute alcohol, 58.5 g. (1 mol) of acetoacetic ester were added. The solution of sodium acetoacetic ester, so obtained, was cooled to 5°, and then 28.25 cc. (0.5 mol) of *o*-chlorobenzoyl chloride were gradually admitted from a buret, the temperature of the reaction mixture being maintained under 12°. It is important that the solution be constantly stirred during this addition. After the lapse of half an hour 80 cc. of the sodium ethylate solution were added and, when the temperature of the mixture had become sufficiently low, 14.12 cc. of the acid chloride were dropped in as before. In this way, always employing one-half of the remaining sodium ethylate and *o*-chlorobenzoyl chloride, the operation was completed after five successive additions. In order that the separation of the sodium salt might be complete, the reaction mixture was allowed to remain in a cold place for 24 hrs. The salt was filtered with the aid of suction, and washed several times with dry ether. Yield, 123 g. Whereas the sodium salts of other tautomeric esters of this series are distinctly yellow in color, the sodium salt of *o*-chlorobenzoylacetate is pure white. When warmed with dilute ammonia solution it is decomposed in accordance with the scheme:

One hundred and twenty grams of the sodium salt of *o*-chlorobenzoylacetate were dissolved in 600 cc. of water, 54 g. of ammonium chloride and 60 cc. of concentrated aqueous ammonia were added, and the solution maintained at a temperature of 40–50° for 2–3 hrs., with frequent shaking. The product, which had separated as a heavy, yellow oil, was extracted with ether. The ethereal solution was dried over calcium

chloride, the ether removed, and the residue placed over sulfuric acid *in vacuo*. The yield of ester amounted to 70 g.

o-Chlorobenzoylacetic ester is a pale yellow, viscous liquid, heavier than water, and possessing a faint, though pleasant, aromatic odor. It is only very slightly soluble in water, but miscible with the common organic solvents. It cannot be distilled under 30 mm. pressure without suffering decomposition.

0.4364 g. subs. required 20.4 cc. 0.1 *N* AgNO₃. Calc. for C₁₁H₁₁O₂Cl: Cl, 15.6; found: 15.1.

Ketonic Decomposition of *o*-Chlorobenzoylacetic Ester. *o*-Chloroacetophenone.—In a flask, provided with a reflux condenser, a mixture of 54 g. of the ester, 240 cc. of water and 60 cc. of concentrated sulfuric acid was boiled until the evolution of carbon dioxide had apparently ceased, a condition which seemed to have been realized after 10–12 hrs. The mixture was cooled, and the ketone, which floated as an oily layer on the surface of the acid, was taken up with ether. In order to remove any unchanged ester the ethereal solution was shaken with 10% potassium hydroxide solution; it was then washed with water, separated and dried over calcium chloride. After the ether had been removed the residual ketone distilled entirely between 223 and 230°. After further fractionation, a pure product, boiling at 227–228° under 738 mm., was obtained in a yield of 80% of the theoretical.

o-Chloroacetophenone is a colorless liquid, very slightly soluble in water, and with a very agreeable, aromatic odor. The index of refraction was determined by means of an Abbé refractometer.

$n_{D_{25}^{\circ}} = 1.685$. Specific gravity: $d_{25}^{25} = 1.1884$.

0.2000 g. subs. required 12.92 cc. 0.1 *N* AgNO₃. Calc. for C₈H₇OCl: Cl, 22.94; found: 22.88.

***o*-Chloroacetophenone Oxime.**—To a solution of 3 g. of hydroxylamine hydrochloride and 2 g. of sodium hydroxide in 10 cc. of water, 5 g. of the ketone were added, and then sufficient alcohol, 20 cc., to make the mixture homogeneous. The oxime began to crystallize from the solution after the latter had remained at room temperature for 3 hrs., and after 24 hrs. the separation appeared to be complete. The product was filtered, and hot water added to the filtrate, whereupon a further quantity of oxime was obtained. Recrystallization from 50% alcohol furnished a pure product in a yield of 90% of the theoretical.

o-Chloroacetophenone oxime crystallizes in the form of beautiful, silky needles which melt at 103°. The substance is very slightly soluble in cold water, more readily in hot water; slightly soluble in ligroin; easily soluble in alcohol or benzene; very easily soluble in ether or chloroform.

0.2448 g. subs. gave 19.0 cc. N₂ (24°, 743 mm., over KOH). Calc. for C₈H₇ONCl: N, 8.27; found: 8.56.

Nitration of *o*-Chloroacetophenone.—One hundred grams of nitric acid (sp. gr. 1.52) were cooled to 0°, and then 10 g. of *o*-chloroacetophenone were added gradually by means of a dropping funnel, the mixture being constantly stirred and the temperature maintained below 5°. After the solution had been allowed to remain in the freezing mixture for 3 hrs. it was poured into 500 g. of ice water, whereupon the nitro compound separated as a white, flocculent precipitate. The product was filtered, washed thoroughly with water and then recrystallized from alcohol. Yield, 85% of the theoretical.

The orientation of the nitro group in the nitrochloroacetophenone was effected by oxidation with a 2% potassium permanganate solution. The nitrochlorobenzoic acid obtained by this oxidation process showed a melting point of 164.7°. To the acid whose structure is represented by Formula I the literature assigns a melting point of 165°; consequently the ketone must have the nuclear substituents in the positions as represented by Formula II:

2-Chloro-5-nitroacetophenone crystallizes from alcohol in the form of small, colorless prisms, and has a melting point of 62°. It is insoluble in water, very slightly soluble in ligroin, slightly soluble in cold alcohol or ether, readily soluble in benzene, chloroform or hot alcohol.

0.2423 g. subs. gave 0.1752 g. AgCl. Calc. for $C_8H_5O_2NCl$: Cl, 17.77; found: 17.88.

***p*-Chlorobenzoylactic Ester.**—This ester was obtained in a manner analogous to that for the preparation of the corresponding ortho compound, as outlined above. It was found advantageous, however, to employ the *p*-chlorobenzoyl chloride in ether solution since, under these circumstances, the separation of the sodium salt of *p*-chlorobenzoylacetacetic ester is much facilitated. The quantities of the various substances used were as follows: acetoacetic ester, 37 g.; *p*-chlorobenzoyl chloride, 50 g. in 90 cc. of anhydrous ether; sodium, 13.12 g.; absolute alcohol, 200 cc. The yield of sodium salt was 90 g. This substance is of a yellow color, and much less soluble in water than the corresponding ortho compound.

One hundred and twenty grams of the sodium salt of *p*-chlorobenzoylacetacetic ester were suspended in 600 cc. of water, 30 g. of ammonium chloride and 60 cc. of concentrated aqueous ammonia were added, and the mixture maintained at a temperature of 40–45° for 3 hrs., with continual shaking. The product was extracted with ether, the ethereal solution dried over calcium chloride, and the ether distilled. In this way the ester was obtained as a yellow, viscous oil, which, upon being cooled in a freezing

mixture, solidified to a mass of crystals. The crystals were freed from traces of adhering mother liquor by means of a porous plate, and then recrystallized from dilute alcohol.

p-Chlorobenzoylacetate ester crystallizes in the form of colorless, flat prisms, and has a melting point of 38°. It is insoluble in water, readily soluble in alcohol, ether, benzene or ligroin.

0.4387 g. subs. gave 0.2880 g. AgCl. Calc. for $C_{11}H_{11}O_2Cl$: Cl, 15.67; found: 15.79.

Potassium Salt of *p*-Chlorobenzoylacetate Ester.—Five grams of *p*-chlorobenzoylacetate ester were treated with two equivalent weights of potassium hydroxide in 10% solution at the ordinary temperature. Upon stirring the mixture the potassium salt separated out as a white, voluminous mass, which was filtered off and recrystallized from absolute alcohol. The salt is slightly soluble in water, easily soluble in alcohol. It melts with decomposition at 265°.

0.2132 g. subs. gave 0.0682 g. K_2SO_4 . Calc. for $C_{11}H_{10}O_2ClK$: K, 14.37; found: 14.78.

***p*-Chlorobenzoylacetate Acid.**—Three and one-half grams of *p*-chlorobenzoylacetate ester were allowed to react with 2.4 g. (3 mols) of potassium hydroxide in 50 cc. of water at the ordinary temperature for a period of 3 days. At the end of this time the solution was filtered, and then extracted with ether in order to remove traces of unchanged ester and *p*-chloroacetophenone. From the cold solution the *p*-chlorobenzoylacetate acid was precipitated by means of dilute sulfuric acid. The substance was recrystallized from a mixture of ether and ligroin.

p-Chlorobenzoylacetate acid is very slightly soluble in water; slightly soluble in benzene or ligroin; readily soluble in alcohol or ether.

When heated gradually the substance decomposes into *p*-chloroacetophenone; but when quickly brought to a temperature in the vicinity of its melting point it melts at 232°.

0.0784 g. subs. gave 0.0568 g. AgCl. Calc. for $C_9H_7O_2Cl$: Cl, 17.88; found: 17.89.

Alkylation of *p*-Chlorobenzoylacetate Ester.

Phenacyl *p*-Chlorobenzoylacetate Ethyl Ester, $ClC_6H_4.CO.CH(CH_2.CO.C_6H_5).COOC_2H_5$.—To a solution of sodium ethylate, prepared from 2.05 g. of sodium and 35 cc. of absolute alcohol, 20 g. of *p*-chlorobenzoylacetate ester were added. The solution of the sodium salt of *p*-chlorobenzoylacetate ester was cooled, and then treated gradually with one equivalent weight (17.6 g.) of phenacyl bromide. The mixture became warm, and sodium bromide separated. The reaction was driven to completion by warming the contents of the flask on the water bath for fifteen minutes. Water was added to dissolve the sodium bromide, and the reddish oil which separated was taken up with ether. The ethereal solution was dried over calcium chloride, filtered, and the ether removed. The residual oil, after being allowed to remain in a cold place for several days, was

transformed into a crystalline mass. The crystals were pressed out on a porous plate, and then recrystallized from dilute alcohol. The yield was 50% of the theoretical.

Phenacyl *p*-chlorobenzoylacetate ethyl ester crystallizes in the form of colorless prisms, and has a melting point of 63°. It is insoluble in water, slightly soluble in ligroin, fairly soluble in alcohol, readily soluble in ether, benzene or chloroform.

0.2238 g. subs. gave 0.1342 g. AgCl. Calc. for $C_{17}H_{17}O_4Cl$: Cl, 10.33; found: 10.36.

4-Chlorodiphenacyl, $C_6H_5.CO.CH_2.CH_2.CO.C_6H_4Cl$.—The ketonic decomposition of phenacyl *p*-chlorobenzoylacetate, by means of dilute alkali, is not effected with the same smoothness as obtains in the case of the correspondingly substituted, nonhalogenated benzoylacetate esters, the yield of ketone being diminished by the greater tendency of the former ester to undergo the acid decomposition.

Thirty-five grams of phenacyl *p*-chlorobenzoylacetate were added to a solution of 13.6 g. of potassium hydroxide (2 mols) in a mixture of 300 cc. of water and 100 cc. of alcohol, and the solution boiled under a reflux condenser. After 2 hrs. boiling the contents of the flask were cooled, and the product filtered off. Several recrystallizations from alcohol, with the aid of bone black, gave a pure product, melting at 114.5°. The yield was poor.

4-Chlorodiphenacyl crystallizes in the form of colorless leaflets of pearly luster. It is insoluble in water, slightly soluble in ligroin, fairly soluble in alcohol or ether, readily soluble in benzene or chloroform.

0.3378 g. subs. gave 0.1814 g. AgCl. Calc. for $C_{16}H_{13}O_2Cl$: Cl, 13.02; found: 13.28.

***p*-Chlorophenacyl Benzoylacetate Ester**, $C_6H_5.CO.CH(CH_2.CO.C_6H_4Cl).COOC_2H_5$.—This ester was prepared in order to determine the relative yields of 1,4-diketone produced in the saponification of this and of the isomeric ester described above.

Thirty-eight grams of *p*-chlorophenacyl bromide were added gradually to a solution of the sodium salt of benzoylacetate ester, prepared from 3.65 g. of sodium, 80 cc. of absolute alcohol and 30 g. of benzoylacetate ester. The reaction was completed by warming on the water bath for half an hour. The alcohol was distilled, and then water added to dissolve the sodium bromide. The oil which separated was extracted with ether, the ethereal solution dried over calcium chloride, and the greater part of the ether removed on the steam bath. In order to eliminate the last traces of ether the ester was placed *in vacuo* over sulfuric acid, a procedure which caused the transformation of the substance into a crystalline mass. The product was pressed out on a porous plate, and then recrystallized from alcohol. The yield was 75% of the theoretical.

p-Chlorophenacyl benzoylacetate ester crystallizes in the form of colorless

needles which have a melting point of 92° . It is insoluble in water, fairly soluble in alcohol, ether or ligroin, readily soluble in benzene or chloroform.

0.2084 g. subs. gave 0.0892 g. AgCl. Calc. for $C_{19}H_{11}O_4Cl$: Cl, 10.33; found: 10.58.

Saponification of 9 g. of the ester by means of a solution of 3.2 g. of potassium hydroxide in a mixture of 75 cc. of water and 25 cc. of alcohol yielded 50% of the theoretical amount of a substance, identical in melting point, and undistinguishable in other physical properties from the 4-chlorodiphenacyl, described above.

URBANA, ILL.

A COMPARISON OF THE OPTICAL ROTATORY POWERS OF THE ALPHA AND BETA FORMS OF CERTAIN ACETYLATED DERIVATIVES OF GLUCOSE.

By C. S. HUDSON AND J. K. DALE.¹

Received March 5, 1915.

If the alpha and beta forms of glucose pentacetate have the isomeric structures, as generally accepted,

the molecular rotations of the substances may be regarded as having the values $(A + B)$ for one form, and $(-A + B)$ for the other, according to the considerations which have been presented by one of us in a previous article.² The quantity A represents the rotation which is due to the end asymmetric carbon atom, and B denotes the rotation of the remainder of the structure. In similar manner, the rotations of the alpha and beta forms of tetracetyl methylglucoside,

may be written $(A' + B)$ and $(-A' + B)$, where A' is of different value from A , on account of the replacement of the acetyl by the methyl radical, but B remains of constant value. The deduction may be drawn that the

² THIS JOURNAL, 31, 66 (1909).

sum of the molecular rotations of the two pentacetates (2B) is presumably equal to the sum of those of the two tetracetyl methylglucosides (2B), and this conclusion can be tested by experiment. Schliephacke¹ has calculated the data and finds that the sum is 39,700 for the pentacetates and 54,900 for the tetracetyl methylglucosides, the rotations of the four substances being measured in benzene solution. The disagreement is clear, and Schliephacke concludes that the foregoing theoretical views do not apply to the acetylated derivatives of glucose. In this connection, however, it is to be noticed that one of the four substances, namely, α -tetracetyl methyl glucoside, has been found by Moll van Charante² to form a crystalline compound with benzene and to have in benzene solution a specific rotation (173°) much larger than in alcoholic solution (137°). The corresponding beta form was found to have nearly identical rotations

³ The molecular weights which are used are, 390 for glucose pentacetate and 362 for tetracetyl methylglucoside.

⁴ Quoted from Koenigs and Knorr, *Ber.*, 34, 970 (1901).

⁵ Moll van Charante (*Loc. cit.*) found this value to be $[\alpha]_D^{20} = +137.3^\circ$.

in the two solvents.¹ It has seemed to us desirable to compare the rotations of the four substances in several solvents other than benzene since the relations seem to be complicated in the case of that solvent by the formation of a compound with one of the substances. The pentacetates of glucose and the tetracetates of methylglucoside were prepared as described in detail further on and the specific rotations of the pure substances were found to have the following values (Table I). The measurements refer to a temperature of 20°, sodium light, circular degrees of rotation, and the concentrations which are recorded signify the grams of substance which were contained in 100 cc. of solution, the weighings having been made in air with brass weights. The tube length in all cases is 4 decimeters. The chloroform used was *chloroformum purificatum*, U. S. P.

Tanret² has found for the specific rotation of α -glucose pentacetate the value +99° in benzene solution, 8 g. per 100 cc., and +101.7° in chloroform, 9 g. per 100 cc., and for the beta form of glucose pentacetate, he has found +2.8 in benzene, 8 g. per 100 cc., and +3.7 in chloroform, 14 g. per 100 cc. Our measurements confirm these values except in the case of the alpha form in benzene solution. Since we obtain for this substance in chloroform the same value as Tanret, it appears to us that his value in benzene must be high.

The data are now at hand for a comparison of the sums of the molecular rotations of the alpha and beta forms of glucose pentacetate and tetracetyl methylglucoside.

TABLE II.
Sum of the molecular rotations of the alpha and beta forms.

Substance.	Chloroform.	Benzene.	Acetic acid.		Absolute alcohol.	Absolute methyl alcohol.
			99.5%.	50%.		
Glucose pentacetate....	41,100	38,900	44,000	43,400	40,100	42,700
Tetracetyl methylglucoside.....	40,700	55,240	41,400	37,700	40,600	41,300

The divergence of the sums for benzene solution has already been discussed. The difference in the values in 99.5% acetic acid is 2,600 in molecular rotation or approximately 7° in specific rotation, which seems larger than the uncertainty of the four measurements, and the divergence between the sums becomes greater when the proportion of water in the solvent is increased (50% acetic acid). In methyl alcoholic solution the sums differ only slightly beyond the limits of experimental error. The

¹ There is evidently a numerical error in Moll van Charante's calculation of the specific rotation of the β -form in alcohol from the measurements which he records, and, likewise, the value in benzene is incorrectly quoted from Koenigs and Knorr, but, nevertheless, the conclusion that the β -form has nearly identical rotations in benzene and alcohol is correct, according to our measurements in Table I.

² *Bull. soc. chim.*, 13, III, 261 (1895).

difference in chloroform solution is only 400 in molecular rotation or about 1° in specific rotation, which constitutes good agreement with the theory. The agreement between the sums in absolute alcoholic solution is also good.

Concerning the Rotatory Powers of the Two Octacetates of Cellose.—

The difference between the molecular rotations of the alpha and beta forms of glucose pentacetate is +38,100 in chloroform solution. According to the theory, the difference is the quantity $2A$, which should presumably have the same value for all the acetylated aldoses, in which the end asymmetric carbon atom is acetylated. The octacetate of cellose has been prepared in two crystalline forms, of specific rotation in chloroform solution $+41^\circ$ and -8° .¹ Assuming that these are the alpha and beta forms, respectively, their molecular difference ($2A$) becomes 33,200 which is smaller than the difference for the two pentacetates of glucose by 4,900 or approximately 7° in specific rotation, since the molecular weight of cellose octacetate is 678. The considerable divergence suggests that the α - and β -cellose octacetates may not yet have been obtained in a pure or fully separated condition.

Experimental.

Preparation of the α - and β -Pentacetates of Glucose and their Correlation with the Alpha and Beta Forms of Glucose.—The alpha and beta forms of glucose pentacetate have been correlated with the alpha and beta forms of glucose by the experiments of Behrend and Roth² in 1904 and of Behrend³ in 1907, which show that the acetylation of α -glucose in pyridine solution at zero degrees by the action of acetic anhydride yields α -pentacetate, while β -glucose, under the same conditions, gives rise to β -pentacetate. Recently, we have observed that a similar correlation may be obtained when glucose is acetylated with acetic anhydride and zinc chloride, provided the temperature is kept near zero. Before our experiments on this subject are described, it may be well to record the results which we obtained in repeating the work of Behrend and Roth, since our confirmatory data furnish a more nearly quantitative proof of the correlation in question.

Fifty grams of acetic anhydride were mixed with sixty-seven grams of commercial pyridine bases, the mixture cooled to 0° , 10 g. of pure crystalline α -glucose added and the mixture kept at 0° with occasional shaking during seven hours. The sugar had then dissolved completely. After standing seventeen hours longer at room temperature, the solution was poured into ice water and upon vigorous stirring the pentacetate crystallized in a few minutes. In three experiments, there were obtained from 10 g.

¹ Schliemann, *Ann.*, 378, 372 and 374 (1911).

² *Ann.*, 231, 369 (1904).

³ *Ibid.*, 353, 109 (1907).

of α -glucose 19.0, 19.5 and 18.5 g. of pentacetate with specific rotations in chloroform solution of 91.3° , 90.9° and 92.1° . The weight of pentacetate which is the equivalent of 10 g. of glucose is 21.7 g.

In another experiment, the same quantities of α -glucose, acetic anhydride and pyridine were kept at 0° for 24 hrs. There were obtained 19.8 g. of pentacetate with a specific rotation of 94° in chloroform. Since the specific rotation of pure α -glucose pentacetate in chloroform is about 101.6° , while that of the beta is only 3.9° , it is evident that the crystalline product consisted largely of the alpha isomer.

β -Glucose acetylates more readily than the alpha isomer. The β -glucose used had a specific rotation of $20-21^\circ$. With the same amounts of sugar, acetic anhydride and pyridine as were used in acetylating α -glucose, there were crystallized after acetylation at 0° during 3, 5, 6 and 24 hours, respectively, 14, 18, 19.5 and 20.5 g. of pentacetate of specific rotations varying between $+5.5$ and $+5.8$ in chloroform. It is evident that the product was almost wholly β -pentacetate.

It was found that powdered glucose can be acetylated readily at 0° by a solution of zinc chloride in acetic anhydride. Four grams of fused zinc chloride were dissolved in 40 g. acetic anhydride, the solution was cooled to 0° , 10 g. of pure α -glucose were added, a little at a time, and the mixture was kept at zero with an occasional shaking for five hours. During this time most of the sugar dissolved but there remained some which had not been attacked; the weight of this portion, after filtering it off, was found to be 2.85 g. The filtrate crystallized in a few minutes after falling into water and yielded 7.15 g. of dry pentacetate, of specific rotation 92° in benzene. The water from which these crystals were obtained was then shaken out with chloroform, and by evaporating the chloroform solution nearly to dryness and pouring it again into water, a second lot of crystalline pentacetate was obtained, showing a specific rotation of 86° and weighing 3.64 g. when dry. An extraction of the second water with chloroform yielded 2.26 g. of a very viscous sirup which did not crystallize. Summing up these weights, there were obtained 13.05 g. of acetylated material from 7.15 g. of sugar, the latter being equivalent by theory to 15.44 g. pentacetate. Since the specific rotation of α -glucose pentacetate in benzene is about 96.7° , while that of the β -pentacetate in benzene is only 2.7° , it is evident that the crystalline product consisted largely of the alpha isomer.

In a second similar experiment, the time of reaction was increased to 45 hours with the result that only 0.33 g. glucose remained undissolved. There were obtained 15.20 g. of pentacetate of specific rotation 78° , 3.03 g. of 59° , and 1.30 g. of sirupy residue, making 19.53 g. of acetylated product against 19.89 g. of pentacetate by theory. There is evidence from the rotatory powers of the crystals that a partial change of the α .

pentacetate to the β form took place during the prolonged time of the reaction; this change is just detectable in the first experiment. It has been found during numerous preparations of this substance that 10 g. of pure α -glucose will yield under constant stirring of the acetylation mixture for 8 hours about 13 g. of pentacetate of specific rotation 83° , from which the pure α form may be readily obtained by the usual recrystallization from alcohol.

With the same proportions of sugar, zinc chloride and acetic anhydride that are recorded in the experiments just mentioned, 10 g. of crystalline β -glucose, of specific rotation 21° , after 5 hours' reaction at 0° , yielded 2.73 g. undissolved sugar, 10.75 g. pentacetate of rotation 8.7° , 2.22 g. of 18° , and 1.06 g. of viscous sirup, making a total of 14.03 g. of acetylated product against 15.75 g. of pentacetate by theory. The crystals from this experiment yielded pure β -pentacetate on recrystallization. In a second similar experiment the time of reaction was extended to 24 hours and there were found 0.43 g. sugar remaining undissolved, 15.10 grams pentacetate of rotation 14° , 3.43 g. of rotation 43° , and 1.20 g. of sirup, making 19.73 g. of acetylated product against 20.73 g. pentacetate by theory. It is again noticeable from the rotations of the product that the longer duration of the reaction causes isomeric change, in this instance transforming some of the β -pentacetate into the alpha form. It has been found that 10 g. of crystalline β -glucose will yield, with eight hours' stirring in the acetylation mixture, about 17 g. of pentacetate of specific rotation 17° , from which the pure β -pentacetate may be readily obtained by recrystallization from alcohol.

These acetylations of α - and β -glucose, with acetic anhydride and zinc chloride, correlate these substances with the α - and β -pentacetates of glucose, respectively, and confirm the similar correlation by Behrend, who used pyridine as the catalyst.

The purification of the samples of the pentacetates which were used in making the measurements recorded in Table I was accomplished by recrystallizing from 95% alcohol until the rotation became constant. The crystals were dried by raising the temperature gradually to 100° . The pure alpha pentacetate melted at $112-113^\circ$, corrected.

Two acetyl estimations made by boiling in a quartz flask with reflux condenser 0.5 g. of pentacetate with 90 cc. of 0.3 *N* sulfuric acid during three hours gave 76.73% and 76.97% acetic acid; calc. 76.93%.

The pure beta pentacetate melted at 132° , corrected, and yielded 77.16% acetic acid after hydrolysis. Both pentacetates were found to yield the theoretical amount of glucose after the hydrolysis of 5 g. of pentacetate with 50 cc. of 5% sulfuric acid during two hours on the steam bath, the estimation of the glucose being taken from a measurement of the rotation of the hydrolyzed solution.

Preparation of α -Tetracetyl Methyl Glucoside.—This substance was prepared by acetylating α -methylglucoside with acetic anhydride and sodium acetate, according to the directions of Koenigs and Knorr.¹ It was recrystallized from 95% alcohol until a constant specific rotation was obtained. It melted at 100–101° corrected.

Preparation of β -Tetracetyl Methylglucoside.—This compound has been prepared by Koenigs and Knorr² from β -bromoacetyl glucose and from β -acetonitroglucose, and Moll van Charante³ has prepared it from β -methylglucoside. We followed Koenigs and Knorr's procedure slightly modified, using β -bromoacetyl glucose. Twenty-five g. of β -bromoacetyl glucose were dissolved in 200 cc. methyl alcohol. To this were added 12.5 g. silver nitrate dissolved in 200 cc. methyl alcohol and 50 cc. water. The filtrate from the silver bromide precipitate was treated with hydrogen sulfide and then shaken with barium carbonate. The filtrate from this was evaporated to a thick syrup on the steam bath under diminished pressure. On cooling, it crystallized to an almost solid mass. It was recrystallized from absolute methyl alcohol until the specific rotation was constant. The yield was 13.5 g., having a melting point of 104–105° (corr.).

THE ISOMERIC OCTACETATES OF LACTOSE.

By C. S. HUDSON AND J. M. JOHNSON.⁴

Received March 5, 1915.

Schutzenberger and Naudin⁵ acetylated lactose by boiling it with acetic anhydride but did not obtain a crystalline product. Herzfeld⁶ crystallized lactose octacetate by acetylating the sugar with acetic anhydride and anhydrous sodium acetate (the Liebermann⁷ method), and found the substance to melt at 86°, but did not learn its rotatory power. Schmöger⁸ prepared the octacetate by this method, reported a higher melting point, 95–100°, and observed a specific rotation of -3.5° in chloroform. Fischer and Armstrong⁹ found this octacetate to melt at 106°.

⁹ *Ibid.*, 35, 841 (1902).

regarded it as a mixture of two isomers, but were unable to separate it into its assumed components.

We attempted to prepare crystalline lactose octacetate by the methods which have been described by these different authors, and also by the method which Kremann¹ has used, but the products did not crystallize. Finally, a method was devised by which the octacetate may be readily prepared in crystals.

Four hundred cc. of acetic anhydride were heated to 100° in a flask of several liters' capacity and 25 g. of anhydrous sodium acetate were added. The mixture was heated nearly to the boiling point of the solution and there was added to it, a little at a time, 100 g. of commercial milk sugar, which consists principally of the monohydrated alpha form of lactose. After a small amount of the sugar had been added, a vigorous reaction began, accompanied by boiling of the acetic anhydride. The gas flame under the flask was then turned off and the addition of the sugar continued, a small amount at a time, until all was in solution, the reaction furnishing enough heat to keep the acetylation going to completion. After all the lactose had dissolved, the solution was boiled for ten minutes and poured into a large volume of cold water. The insoluble viscous mass which precipitated was stirred with the water, allowed to settle, the water poured off and fresh water added from time to time. After standing over night under water, the mass solidified and was broken up with a rod. It was then filtered on a Buchner funnel, washed well with water and dried in the air. The product was ground, and extracted with warm ether by decantation until all ether-soluble material was removed. The residue, which was by far the larger portion of the product, was then dried from all ether and dissolved in hot 95% alcohol. On cooling and stirring frequently, a spontaneous crystallization was invariably obtained. The compound may also be recrystallized from chloroform by the addition of alcohol or ether, or from benzene by adding ether. The recrystallization from alcohol was repeated until a constant value for the specific rotation was obtained, and the yield of the purified product was about 55% of the theoretical.

The rotatory power of this octacetate in chloroform solution is to the left, and our measurements (see Table I) on the carefully purified material show that the concentration influences the specific rotation appreciably. Schmöger's value comes within the range of our results, but the concentration of his solution is not recorded.

The melting phenomena which are exhibited by the substance are peculiar, as is to be expected from the fact that observers have obtained melting points as far apart as 86° (Herzfeld) and 106° (Fischer and Armstrong). In our first observations on the carefully purified and dried

¹ *Monatsh.*, 23, 483 (1902).

octacetate, the microscopic crystals appeared to melt from 95° to 99° , but it was noticed that the mass kept a white appearance to 104° . This behavior was understood when the crystals were observed under magnification during the process of melting, because it was then seen that each crystal distinctly melted at about 90° , but the melt is so viscous at that temperature that the drops do not coalesce, or only very slowly. When they do unite, as the temperature rises toward 100° , air bubbles are included in the melt and give it a white appearance which vanishes as the viscous liquid becomes more fluid at or about 104° . We regard this lactose octacetate, therefore, as melting at about 90° , and fairly sharply, considering that the melt is very viscous and the heat transfer slow in consequence.

For analysis; the material was dried in a vacuum oven at 70° to constant weight. 0.6792 and 0.5513 g. subs. gave 1.2241 and 0.9951 g. CO_2 and 0.3454 and 0.2808 g. H_2O . Found: 49.16% and 49.23% C; 5.70% and 5.71% H; calc. for $\text{C}_{12}\text{H}_{14}\text{O}_{11}(\text{CH}_3\text{CO})_8$: 49.54% C and 5.65% H.

The acetyl percentage was measured by boiling 0.5 g. samples with 50 cc. of $N/3$ sulfuric acid under a reflux condenser for three hours, and titrating with 0.1 N sodium hydroxide solution, using phenolphthalein as indicator. The reliability of the method was tested in numerous blank determinations, both with and without the addition of lactose. By varying the time of hydrolysis, the latter was shown to be complete in three hours. Using 0.5 g. samples, the percentages of acetyl (CH_3CO) found in two experiments were 50.75 and 50.71 while the theory requires 50.74%.

Preparation of an Isomeric Crystalline Octacetate of Lactose.—When lactose octacetate of m. p. 90° was dissolved in glacial acetic acid containing a small amount of zinc chloride, there was observed at 20° a slow change of rotation day by day to the right. The speed of this change could be hastened by heating the solution on the steam bath. A similar change of rotation towards the right was observed when acetic anhydride containing zinc chloride was used as the solvent, and in this case a new crystalline product was isolated by the following procedure:

Fifty grams of lactose octacetate (m. p. 90°) and 5 g. of fused zinc chloride were dissolved by warming in 250 cc. acetic anhydride, and then heated thirty minutes on the steam bath. The mixture was cooled, poured into a large volume of cold water and allowed to stand under the water over night. The hard mass was filtered off, ground in a mortar, dried in the air, and dissolved in ether. With an occasional scratching of the glass vessel the ether solution was brought to crystallization after a day or so at 20° . These crystals were then recrystallized from 95% alcohol, at first with some difficulty, but after several recrystallizations with ease. A yield of 56% was obtained. A compound differing from the original octacetyl lactose in many physical properties was thus prepared. It melts sharply at 152° , consists of fine felted needles, is more soluble in ether and in alcohol than the parent substance and, like the latter, is very

soluble in chloroform, benzene and ethyl acetate, difficultly soluble in water and almost insoluble in petroleum ether. Determination of the acetyl value, elementary analysis, and the regeneration of lactose showed this compound to be an octacetyl lactose. Milk sugar was regenerated from it by pouring cold alcoholic potash on a suspension of the substance in alcohol, filtering off the lactose, recrystallizing, and identifying the sugar by its cupric reducing power, its specific rotation, its solubilities and its failure to ferment with yeast.

0.3202 and 0.4732 g. subs. gave 0.5810 and 0.8573 g. CO_2 and 0.1626 and 0.2372 g. H_2O . Found: 49.49% and 49.41% C; 5.69% and 5.62% H.

Calc. for $\text{C}_{12}\text{H}_{14}\text{O}_{11}(\text{CH}_3\text{CO})_8$: 49.54% C and 5.65% H.

The acetyl percentage, estimated as previously described, showed 50.84% and 50.66% CH_3CO ; calc.: 50.74%.

This isomeric octacetyl lactose is also formed in small amount along with the earlier discovered octacetate during the acetylation of lactose with acetic anhydride and anhydrous sodium acetate. We obtained a small quantity of the new isomer in crystals from the ether extraction which has been mentioned in connection with the description of the preparation of octacetyl lactose of m. p. 90° .

Determinations of the specific rotation of the new isomeric octacetyl lactose are recorded in Table I and show that the substance is strongly dextrorotatory, distinguishing it from the earlier discovered lactose octacetate which is levorotatory.

² 1° Verltzke = 0.346° Angular.

³ None could be observed and the limit of detection was somewhat less than 0.05° V.

The Equilibrium between the Two Isomeric Octacetates.—Two and one-half grams of the older isomer were dissolved in glacial acetic acid containing zinc chloride, the solution was made up to 50 cc. and allowed to stand at 20° during five months. There was a slow change in the rotation as read in a 200 mm. tube with a Ventzke instrument from +0.7° to +15.3°. A corresponding solution of the new isomer changed in rotation during the same time from +17.6° to +15.2°. Equilibrium was thus reached between the two forms in glacial acetic acid under the specified conditions when about 86% of the new isomer was present.

Five grams of the older isomer and 0.5 g. ZnCl_2 when made up to 50 cc. with acetic anhydride at 20° gave a specific rotation of +4.3°. This solution was heated at 100° for 30 minutes, cooled to 20° and the specific rotation was found to be +51.9°, and the value was not changed by a further heating for ten minutes. Five grams of the new isomer were treated in the same manner and the specific rotation was found to change from +64.0° to +52.8°, at which value it became constant. The point of equilibrium at 100° is then about +52°, which shows that about 81% of the new isomer is present in the equilibrium mixture in acetic anhydride.

Preparation of Bromoacetyl Lactose from the New Lactose Octacetate.—Five grams of lactose octacetate of specific rotation -4° were dissolved in 7 cc. warm acetic anhydride, the mixture cooled, 7 cc. acetic acid saturated with hydrobromic acid gas were added, and the solution kept at room temperature until its polariscopic reading became constant, which required about forty minutes. The solution was then poured into ice water and treated according to Fischer's¹ directions for the preparation of heptacetyl bromolactose. We obtained 3 g. of recrystallized substance of m. p. 139–141°, and specific rotation +105° in chloroform, which was evidently identical with Fischer's preparation which melted at 141–142° and had a specific rotation in chloroform of +104.9°. When the new lactose octacetate of specific rotation +53° was treated by the same procedure, there were obtained 2 g. of recrystallized substance melting at 139–141° and having a specific rotation of +104° in chloroform solution. From the two lactose octacetates, therefore, the same heptacetyl bromolactose was obtained.

Molecular Weights of the Isomeric Octacetates in Benzene.—The freezing temperatures of solutions of the new isomeric octacetate containing per hundred grams of benzene 1.34, 1.58, and 3.38 g. substance, respectively, were found to be 0.099°, 0.113°, and 0.242° below that of the solvent, indicating on an average the molecular weight of 692, in comparison with the theoretical value 678. The freezing-point depressions of solutions of the earlier discovered octacetate gave the value 611.

The Structural Formulas and Nomenclature of the Isomeric Oct-

¹ *Ber.*, 43, 2530 (1910).

acetates.—The existence of isomeric pairs of the fully acetylated derivatives of all the aldose and ketose sugars, corresponding to the well-known alpha and beta forms of glucose pentacetate and of cellose octacetate, respectively, is to be expected. The isomerism of the two lactose octacetates presumably depends upon the space arrangement about the terminal asymmetric carbon atom, which may take the two forms

On this view, the two lactose octacetates are the derivatives, respectively, of the well-known alpha and beta forms of lactose, and the octacetate of stronger dextro rotation, which is the new isomer, is to be named in accordance with the naming of the forms of lactose, the alpha form, the older isomeric octacetate being the beta form. This naming of the octacetates is supported by the following comparison of their rotatory powers with those of the alpha and beta forms of glucose pentacetate, since the α - and β -pentacetates have been correlated with the alpha and beta forms of glucose by the experiments of Behrend and Roth. Writing the molecular rotations¹ of α - and β -glucose pentacetates as $(A + B)$ and $(-A + B)$, respectively, the molecular rotations of the corresponding α - and β -octacetates of lactose may be written $(A + B')$ and $(-A + B')$, respectively. It follows that the difference of the molecular rotations of the first pair of substances ($2A$) is equal to that of the second pair, a conclusion which may be tested experimentally from the data recorded in Table II.

The differences of the molecular rotations of the α - and β -glucose pentacetates in several solvents are quoted from the foregoing article by Hudson and Dale, and those of the α - and β -lactose octacetates are obtained from the averaged values of Table I, multiplied by 678, the molecular weight of the octacetate.

TABLE II.
Difference of the molecular rotations of the alpha and beta forms.

Substance.	Chloroform.	Benzene.	Acetic acid.	
			99.5%.	50%.
Glucose pentacetate.....	38,100	36,700	40,800	41,000
Lactose octacetate.....	39,400	34,300	40,600	41,600

The numbers agree closely in the two strengths of acetic acid and also the agreement in chloroform solution is a satisfactory one, since the difference between the two values corresponds to less than 2° in specific rotation. The values in benzene solution are farther apart, and confirm Hudson and Dale's conclusion that benzene is not a suitable solvent for such comparisons.

THE ISOMERIC ALPHA AND BETA OCTACETATES OF MALTOSÉ AND OF CELLOSE.

By C. S. HUDSON AND J. M. JOHNSON.¹

Received March 12, 1915.

In continuation of the work which we recently described² regarding the preparation of the new alpha lactose octacetate by heating the well-known beta octacetate in acetic anhydride solution with a small amount of zinc chloride, we have applied the method to the octacetate of maltose which is described in the literature and have transformed it likewise to an isomeric crystalline octacetate. The new maltose octacetate rotates to the right in chloroform solution $+122^\circ$, in comparison with the value $+63^\circ$ for the octacetate from which it was prepared, and on this account we have chosen to designate the new substance as the alpha form, and the earlier discovered octacetate as the beta isomer.

Preparation of β -Maltose Octacetate.—By acetylating maltose with acetic anhydride and sodium acetate, Herzfeld³ first prepared crystals of this substance, but the earliest accurate description of it was given some years later by Ling and Baker,⁴ who found it to melt at $158-9^\circ$, and to show a specific rotation of $+62$ in chloroform solution. We prepared from pure maltose without difficulty a considerable quantity of this octacetate by the Liebermann method and recrystallized it until the specific rotation became constant. The substance melted at $159-60^\circ$ corr. and exhibited the specific rotations which are recorded in a part of Table I.

Preparation and Description of the New Isomeric α -Maltose Octacetate.—One hundred grams of β -maltose octacetate, of m. p. 159° , were dissolved in 250 cc. of acetic anhydride containing 5 g. of zinc chloride, and the solution was heated on the steam bath until its rotation became constant, which required about eleven minutes only. During this heating the specific rotation changed from the initial value of $+59.8^\circ$ to $+110.4^\circ$, and it was concluded that this large increase in dextrorotation indicated that most of the original β -octacetate had changed to the hypothetical alpha form. Repeated attempts were made to crystallize the new isomer and this was at last accomplished by the following procedure: The solution which had reached constant rotation was poured into cold water and allowed to stand with an occasional renewal of the water until the viscous insoluble mass of acetylated sugar became hard. After drying and powdering the solid mass, it was dissolved in a very small amount of 95% alcohol so as to form a thick sirup. After standing for some weeks

¹ Contribution from the Carbohydrate Laboratory, Bureau of Chemistry, United States Department of Agriculture.

³ Ber., 13, 267 (1880); Ann., 220, 215 (1883).

⁴ J. Chem. Soc., 67, 212 (1895); Ber., 28, 1019 (1895); cf. Herzfeld, *Ibid.*, 28, 440 (1894).

at room temperature, this sirup crystallized and by seeding with this material freshly prepared sirups could be brought to rapid crystallization. The new compound was recrystallized from alcohol until the rotatory power reached a constant value. The pure crystals melted at 125° corr. after thorough drying at 70° in a vacuum oven.

0.2112 and 0.2073 g. subs. yielded 0.3832 and 0.3755 g. CO_2 , and 0.1098 and 0.1065 g. H_2O , corresponding to 49.54 and 49.40% C, 5.82 and 5.75% H, respectively. Calc. for maltose octacetate: 49.54% C and 5.65% H.

An acetyl estimation was made by boiling in a quartz flask with reflux quartz condenser 0.5 g. substance with 100 cc. 0.25 *N* sulfuric acid during six hours and it indicated 50.62% acetyl (CH_3CO), and duplicate experiments in which the boiling lasted only three hours gave 50.68 and 50.72% acetyl, respectively. These three values agree with the theoretical 50.74% for a maltose octacetate.

The molecular weight of the compound was determined from the lowering of the freezing point of its solutions in benzene. Six experiments with different concentrations showed depressions between 0.090 and 0.235° , which indicated values for the molecular weight ranging between 664 and 694, in comparison with 678, the theoretical value for maltose octacetate. Ling and Baker (*l. c.*) have found 633 in a measurement of the molecular weight of β -maltose octacetate in benzene by the freezing-point method.

Table I records the specific rotatory power of the new octacetate in several solvents, in comparison with the rotation of the β -octacetate. The tube length in all cases is 4 dcm., the readings are expressed in circular degrees for sodium light, and the concentration in grams per 100 cc. of solution, the weighings being made in air with brass weights. The chloroform used was *chloroformum purificatum*, U. S. P.

The Rotatory Powers of the Alpha and Beta Forms of Cellose Octacetate.—It has been mentioned by Hudson and Dale¹ that the difference between the molecular rotations of the two isomeric octacetates of cellose as given in the literature does not accord with the difference for the two

¹ THIS JOURNAL, 37, 1264 (1915).

glucose pentacetates. We have investigated this disagreement and find that the recorded value of the specific rotation of β -cellose octacetate is too small and that the correct values for the two octacetates agree well with those of the glucose pentacetates. Skraup and Geinsperger¹ found the specific rotation of α -cellose octacetate to be $+43.6$ and the value -30 was found for the beta form, both in chloroform solution. Hardt-Stremayr² working later in the same laboratory, found $+42.7^\circ$ and $+42.9^\circ$ for the alpha octacetate in chloroform, and expressed the opinion³ that Geinsperger's value -30 should read $+30$ and that it really referred to an impure sample of the alpha form. Schliemann⁴ has purified the alpha form by numerous recrystallizations from alcohol and from benzene and has found the value $+41.5$ for its rotation. He found the value -8° for the β -octacetate in chloroform.

We have prepared α -cellose octacetate by the usual method of treating filter paper with acetic anhydride and a small amount of concentrated sulfuric acid. The acetate was recrystallized from hot 95% alcohol until the specific rotation became constant and the following values were found: 9.85 g. per 100 cc. in chloroform $[\alpha]_D^{20} = +41.95^\circ$, 5.85 g. per 100 cc., $+40.87^\circ$, the chloroform used being *chloroformum purificatum*, U. S. P. The melting point of the compound was 229.5° corr. From this acetate cellose was regenerated by saponification with alcoholic potash, and the crystalline sugar was then acetylated with acetic anhydride in the presence of anhydrous sodium acetate. The product was poured into cold water and soon crystallized. It was found that sixteen successive recrystallizations, first from alcohol and then from mixtures of chloroform and alcohol and of chloroform and ether, were required in order to fully purify the octacetate and obtain material which did not change in rotatory power after further recrystallization. From 75 g. of cellose, 111 g. of octacetate were obtained as the first product. Its rotation was -7.5° in chloroform, which agrees with Schliemann's observation. After the sixteen recrystallizations, 19 g. of pure material, of melting point 202° corr., were in hand. 10.88 g. of this β -octacetate per 100 cc. of its chloroform (*chloroformum purificatum*, U. S. P.) solution rotated to the left, $[\alpha]_D^{20} = -14.48$, and 5.10 g. per 100 cc. gave the value -14.74° .

Transformation of β -Cellose Octacetate to the Alpha Isomer.—Maquenne and Goodwin⁵ mention that β -cellose octacetate can be changed to the alpha isomer by heating in acetic anhydride solution with a small quantity of sulfuric acid. We have carried out this transformation by

¹ *Monatsh.*, 26, 1471 (1905).

² *Ibid.*, 28, 73 (1907).

³ *Loc. cit.*, p. 68.

⁴ *Ann.*, 378, 366 (1910).

⁵ *Bull. soc. chim.*, [3] 31, 856 (1904).

heating an acetic anhydride solution of the beta form with a small amount of zinc chloride. 2.96 g. of the β -acetate dissolved in the cold in 50 cc. acetic anhydride containing a trace of zinc chloride read $[\alpha]_D^{20} = -4.8^\circ$, and after fifteen minutes' heating on the steam bath, its rotation became constant at $+44.9^\circ$. From this solution, by pouring into water and recrystallizing, there were obtained 1.9 g. of α -cellose octacetate of m. p. $221-3^\circ$ and specific rotation $+40.5$ in chloroform. Likewise, the beta form was transferred to the alpha by heating with acetic anhydride containing some sulfuric acid, as mentioned by Maquenne and Goodwin, but the yield was very much smaller, due probably to the hydrolyzing action of the acid. Hardt-Stremayr¹ sought to transform the α -octacetate to the beta by the same methods but without success. Evidently the equilibrium in acetic anhydride solution between the two isomers is so far towards the side of the alpha form that it alone has been obtained from the mixture. The recorded rotatory power of the transformed solution also indicates that the point of equilibrium is far towards the side of the α -octacetate. This transformation of the β - to the α -octacetate makes it clear that the production of α -cellose octacetate by the acetolysis² of cellulose with acetic anhydride and sulfuric acid does not throw any light upon the question whether cellulose is a condensation product from α -cellose or β -cellose, because either form of the sugar must yield the same α -octacetate in the presence of the reagent mentioned.

Comparison of the Rotations of the Pentacetates of Glucose and the Octacetates of Lactose, Maltose and Cellose.—We have previously shown that the difference between the molecular rotations of the α - and β -glucose pentacetates in chloroform solution agrees with the difference for the α - and β -lactose octacetates, as is suggested by theoretical considerations. The data are now at hand for an extension of this comparison to the octacetates of maltose and of cellose. Since these have the same molecular weight as lactose octacetate, it is sufficient to compare the specific rotations of the substances. In chloroform solution α - and β -lactose octacetates rotate $+53$ and -4 , respectively, the difference being 57° , α - and β -maltose octacetates rotate $+122^\circ$ and $+63^\circ$, with a difference of 59° , and α - and β -cellose octacetates rotate $+41$ and -15 , giving the difference 56° . These differences agree closely and also, as may be understood from what precedes, agree with the value which can be calculated from the observed difference between the rotations of the α - and β -glucose pentacetates, which have the values $+102$ and $+4$, respectively. Their specific rotation difference is thus 98° and since their molecular weight

¹ *Loc. cit.*

² The term acetolysis is coming into use to designate the splitting and simultaneous acetylation of polysaccharides, in the same sense that hydrolysis indicates the splitting and simultaneous hydration.

is 390, in comparison with 678 for the biose octacetates, the calculated difference for the latter becomes $98 \times (390/678) = 56^\circ$. As has been shown from theory, the value of this difference is a measure of the rotatory power of that end asymmetric carbon atom which is common to all the acetylated aldose sugars. The close numerical agreement, among the four acetylated sugars here described, may be interpreted to mean that the differences in structure which distinguish them do not appreciably affect the rotatory power of this end asymmetric carbon atom. Possibly this may be due somewhat to the fact that the three bioeses are derivatives of glucose, and have much of their structure in common with that sugar.¹

WASHINGTON, D. C.

THE ISOMERIC PENTACETATES OF MANNOSE.

BY C. S. HUDSON AND J. K. DALE.²

Received March 12, 1915.

The possibility of the existence of two isomeric pentacetates of *d*-mannose has been foreshadowed by Franchimont's³ recognition of the two pentacetates of glucose, the beta form of which was discovered by him⁴ in 1879 and the alpha form by Erwig and Koenigs⁵ in 1889. Mannose may be readily acetylated by any of the customary reagents but it is only within the last two years that methods have been applied which result in a crystallization of the acetylated sugar. E. Fischer and Oetker⁶ have prepared crystalline mannose pentacetate by acetylating β -mannose at low temperature (0°) with a mixture of acetic anhydride and pyridine (Behrend's method), and have regarded the substance, which they found to melt at 117.5° and to have a specific rotation of -24.9 in chloroform solution, as the β -pentacetate because of its preparation from β -mannose by the above mentioned method and its levorotation. Shortly before the appearance of Fischer and Oetker's description of the β -pentacetate, our colleague, Mr. H. L. Sawyer, succeeded in crystallizing from the products of the action of acetic anhydride and zinc chloride on β -mannose at 0° a mannose pentacetate which he found to melt at $117-118^\circ$ and

¹ The transformation of galactose pentacetate of m. p. 142° by heating with acetic anhydride and zinc chloride has yielded an isomeric crystalline pentacetate, of m. p. about 96° , which is being examined further. The expected isomeric form of xylose tetracetate has also been crystallized, found to melt at 59° and to have the specific rotation to the right of $+88$ in chloroform. This work will be published in detail later.—C. S. Hudson.

⁶ *Ibid.*, **46**, 4020 (1913).

to show a specific rotation of -25.3 in chloroform.¹ The substance is evidently the same as that which Fischer and Oetker have prepared, and the fact that it may be obtained from β -mannose at 0° by acetylation with acetic anhydride mixed with ZnCl_2 , as well as with pyridine as a catalyst, increases the probability that the substance is the beta form. Recently we have transformed this pentacetate into the isomeric alpha form by heating it in acetic anhydride solution with a small amount of ZnCl_2 . Although the spontaneous crystallization of the new pentacetate was very difficult to accomplish, an examination of the solubilities of the first crystals which were obtained suggested a method of operation by which the substance may be prepared with ease as beautiful crystals.

Preparation of the β -Pentacetate of Mannose by the Action of Acetic Anhydride and ZnCl_2 .²—Four grams of fused zinc chloride were dissolved in 40 g. of acetic anhydride, the solution was cooled to zero and 10 g. of very pure β -mannose were added a little at a time, the mixture being kept at zero with occasional shaking until all the sugar went into solution, which required about twenty-four hours. Ice water was then added and after a time the insoluble viscous phase crystallized. On recrystallization from 95% alcohol, β -mannose pentacetate was obtained in a yield of 45–50% of the theoretical. The substance was successively recrystallized from 95% alcohol until the specific rotation became constant. A solution consisting of 2.1073 g. pentacetate made up to 25 cc. with chloroform (*chloroformum purificatum*, U. S. P.) gave a negative rotation, -4.26 circular degrees, in a 200 mm. tube, hence $[\alpha]_D^{20} = -25.3^\circ$. A similar solution containing 4.534 g. pentacetate gave a specific rotation of -25.1° . The melting point of the substance was $117-8^\circ$ corr. These values agree with those found by Fischer and Oetker. An acetyl estimation, which was made by boiling in a quartz flask with reflux condenser half a gram of the pentacetate with 100 cc. of 0.25 *N* sulfuric acid during three hours, indicated 76.78% acetic acid, and in duplicate 77.22%, against 76.93% as the theoretical value for a mannose pentacetate.

Transformation of β -Mannose Pentacetate to the New Isomeric Alpha Form.—When the β -pentacetate was dissolved in acetic anhydride containing a small amount of ZnCl_2 , the rotation was found to change towards the right very slowly at room temperature but rapidly on the steam bath. After a constant value was reached, the solution was poured into cold water and the oily substance which separated was then thoroughly washed with cold water. The material was found to be soluble in hot water and such a solution on cooling and long standing slowly deposited crystals which proved to be the isomeric α -pentacetate. Further experiments have

¹ Unpublished communication.

² The directions for this preparation are based upon hitherto unpublished work by Mr. H. L. Sawyer and myself.—C. S. Hudson.

shown the following to be a more convenient method for the preparation of the substance. Twenty grams of β -pentacetate are dissolved in 30 cc. of acetic anhydride containing about 1 g. of fused zinc chloride and the solution is heated on the steam bath until no further change in the rotation is noticed, which requires about thirty minutes. The solution is cooled, mixed with 500 cc. of ice water, and the acid is neutralized with sodium bicarbonate. A thick, gummy substance separates and is removed, washed in cold water, and dissolved in boiling water. On cooling, the solution slowly deposits about 7 g. of crystals of the α -pentacetate in nearly pure condition. The substance has been recrystallized from water until the specific rotation became constant. The melting point of the pure material, dried in a vacuum desiccator over CaCl_2 and KOH , is 64° corr.

0.2246 and 0.3149 g. subs. yielded 0.4044 and 0.5681 g. CO_2 and 0.1164 and 0.1623 g. H_2O , in duplicate corresponding to 49.10 and 49.20% C and 5.79 and 5.77% H, respectively. Calc. for a mannose pentacetate 49.21% C and 5.68% H.

Acetyl determinations, made by boiling in a quartz flask with a reflux condenser 0.5 g. substance with 100 cc. 0.25 H_2SO_4 during three hours gave 77.11 and 77.18% acetic acid, which agree with the theoretical value for a mannose pentacetate, 76.93%.

In chloroform (*chloroformum purificatum* U. S. P.) solution 0.9197 g. of the α -pentacetate per 25 cc. of the solution gave a reading to the right, $+4.04$ circular degrees, in a 2 dcm. tube with sodium light, or $[\alpha]_D^{20} = +54.9^\circ$. A duplicate measurement, in which 1.2007 g. pentacetate were used, gave $[\alpha]_D^{20} = +55.1^\circ$.

Comparison of the Rotatory Powers of the Alpha and Beta Forms of Mannose Pentacetate with those of the Glucose Pentacetates.—If the molecular rotations of the α - and β -pentacetates of glucose are written $(+A + B)$ and $(-A + B)$, respectively, those of the corresponding mannose pentacetates may be considered, as a first approximation, to be $(+A + B')$ and $(-A + B')$, where B and B' have different values. It follows that the difference of the rotations of the mannose pentacetate pair is $2A$, which is equal to the difference for the glucose pentacetates. We have previously¹ found the molecular rotations of the glucose pentacetates in chloroform solution to be $+39,600$ for the alpha form and $+1,500$ for the beta, hence the difference is $38,100$. The difference in the specific rotations of the mannose pentacetates in the same solvent is $(55.0 + 25.2) = 80.2^\circ$, which corresponds to a molecular rotation difference of $+31,300$, since the molecular weight of the pentacetate is 390. There is thus some lack of agreement between these values, corresponding to 17° in specific rotation, which suggests that the change from the glucose chain, of rotation B, to the mannose chain, of rotation B', may somewhat change the value of A. On the other hand, the agreement with theory appears sufficient to justify the nomenclature which has been adopted for the two pentacetates of mannose.

CRYSTALLINE *D*-FRUCTOSE PENTACETATEBy C. S. HUDSON AND D. H. BRAUNS.¹

Received March 12, 1915.

Progress in the investigation of fructose has always been impeded by the difficulty of crystallizing its derivatives. According to the accepted view of the constitution of fructose, its molecule contains five hydroxyl groups and therefore a pentacetate or two isomeric pentacetates, in case alpha and beta forms of fructose are postulated, should exist. Winter² acetylated fructose according to the Liebermann method with acetic anhydride and anhydrous sodium acetate, but did not obtain a crystalline product. Erwig and Koenigs³ also prepared an amorphous resin by the action of acetic anhydride and zinc chloride on fructose. They obtained analytical data which agree with the formula of a pentacetyl fructose, but since the substance was amorphous, its chemical individuality is doubtful. It would appear probable from the method of preparation that it was a mixture of isomeric pentacetates of fructose. Panormov⁴ prepared from fructose by a modification of Baumann's method of benzylation an amorphous product which had the composition of a penta-benzoylfructose, but its failure to crystallize prevented in this case also the establishment of convincing direct proof that five hydroxyl groups are present in fructose. Several years ago, one of us⁵ prepared a crystalline tetracetate of fructose, but the expected pentacetate was not obtained. Recently we have succeeded in preparing a pentacetate of *D*-fructose which crystallizes very readily, as is the case with fructose tetracetate.

Forty grams of very pure recrystallized *D*-fructose are added in the form of fine powder to a mixture of 240 cc. acetic anhydride and 10 cc. concentrated sulfuric acid, which is cooled by an ice and salt bath and vigorously stirred by a motor driven glass paddle. When the fructose is dissolved, which requires about an hour, the mixture is shaken with about 500 cc. of ice water, neutralized in a large dish with sodium bicarbonate, separated from the excess of solid bicarbonate by filtration, and the residue on the filter is washed with chloroform to dissolve the adhering acetylated sugar. The filtrate is extracted with chloroform for the same purpose. The chloroform solutions are mixed, dried with calcium chloride and distilled *in vacuo* to a small volume, 30-50 cc. This solution is then spread in a thin layer on a flat crystallizing dish and a strong current of air is passed over the yellowish fluid until the odor of chloroform disappears, and that of acetic anhydride becomes noticeable.

³ *Ber.*, 23, 672 (1890).

⁴ *J. Russ. Phys. Chem. Soc.*, 1, 375 (1891).

⁵ Brauns, *Verslag v. d. Koninkl. Akad. v. Wetensch.*, Amsterdam, 1908, 577.

The sirup is then placed in a vacuum desiccator near potassium hydroxide and on stirring at intervals, it soon crystallizes to a solid mass. This is stirred in a mortar with some ether and filtered by suction, yielding about 16 g., or 20% of the theoretical, of pure *d*-fructose pentacetate of correct melting point and specific rotation. The substance may be easily recrystallized from ether and by slow evaporation brilliant, clear crystals may be obtained, measuring about 1 cm. in length and several mm. in width.

Fructose pentacetate melts at 108–109°. It is colorless, odorless and has a bitter taste. It is slightly soluble in cold water, insoluble in petroleum ether and readily soluble in benzene, chloroform, ether and alcohol. In comparison with fructose tetracetate, its solubility in ether and in alcohol is greater.

0.2919 and 0.2302 g. gave 0.5267 and 0.4147 g. CO₂ and 0.1515 and 0.1195 g. H₂O, corresponding to 49.21 and 49.13% C and 5.81 and 5.81% H; calc. for C₈H₇O(C₂H₅O₂)₅: 49.21% C, and 5.68% H.

The quantitative saponification of fructose pentacetate requires care, because the liberated fructose is so readily attacked by acid or alkali. Erwig and Koenigs¹ found the sugar to be slightly attacked by three hours' boiling with 0.1 *N* sulfuric acid. We observed a similar action and after trying various modifications, discarded the method of acid hydrolysis. It was found, however, that fructose pentacetate may be saponified readily by shaking at 0° with 0.1 *N* sodium hydroxide, a reagent which does not produce from fructose, under the same conditions, detectable amounts of acid, according to control experiments.

By shaking 0.4000 g. powdered fructose pentacetate with 75 cc. 0.1 *N* sodium hydroxide during two hours at 0° and titrating with 0.1 *N* sulfuric acid and phenolphthalein, the amount of acetic acid produced was found to be 73.99%. In a similar experiment of 3½ hours' duration, the value 77.20% was found, and in a third, lasting 5 hours, the value was 76.87%. The theoretical quantity for a fructose pentacetate is 76.93%. Evidently the saponification is complete after 3½ hours. The solution was levorotatory after saponification, indicating the regeneration of fructose.

The molecular weight of the fructose pentacetate was determined by the lowering of the freezing point of benzene. In three experiments, 1.789, 1.928 and 3.359 g. fructose pentacetate per 100 g. benzene gave the respective depressions, 0.226°, 0.242° and 0.415°, from which the values 396, 398 and 404 are calculated for the molecular weight in comparison with the theoretical value 390.

Fructose pentacetate can be obtained from benzene solution with one molecule of benzene of crystallization. This substance melts at 90° and on standing in the air readily loses benzene, which was recognized by its odor. On drying at ordinary temperature during one week, the substance lost 14.1% in reaching constant weight. Further drying at 70° did not decrease its weight. The formula C₁₈H₂₈O₁₁·C₆H₆ corresponds to 16.6% benzene.

The specific rotation of the fructose pentacetate was measured in chloro-

¹ *Loc. cit.*

form and in benzene solution. 2.500 g. fructose pentacetate without recrystallization were made up to 50 cc. with chloroform (*chloroformum purificatum*, U. S. P.), and the solution polarized in a 2 dcm. tube at 20° with sodium light 12.04 circular degrees to the left, hence $[\alpha]_D^{20} = -120.4^\circ$. After one recrystallization from ether 2.500 g. fructose pentacetate made up in the same manner rotated 12.09 circular degrees to the left, hence $[\alpha]_D^{20} = -120.9^\circ$. After a second recrystallization from ether, the material still rotated -120.9° , which is taken as the specific rotation of the pure substance. 1.000 g. of pure fructose pentacetate made up to 50 cc. with benzene rotated, under the above mentioned conditions, 4.22 circular degrees to the left, hence $[\alpha]_D^{20} = -105.5$ for its solution in benzene.

WASHINGTON, D. C.

THE VOLATILE OILS OF THE GENUS SOLIDAGO.

BY EMERSON R. MILLER AND JEMISON MIMS MOSLEY.

Received March 8, 1915.

The genus *Solidago*, commonly known as Golden-rod, is one of the larger genera of the plant family Compositae. It is quite widely and favorably known for the beauty which the golden-yellow flowers lend to late summer and early autumn, but is more or less unpopular as an alleged cause of hay fever.

Although a very large genus, numbering about seventy-five species in the United States alone, it has been of comparatively little practical value and consequently has received little attention at the hands of the phytochemist.

Of the four or five species which have been distilled, two, *Solidago canadensis* and *S. odora*, give a very fair yield of volatile oil and may, possibly, become of some economic importance. Only two of the oils thus far distilled, those of *Solidago canadensis*¹ and *S. nemoralis*² have received anything like a thorough chemical investigation.

The Volatile Oil of *Solidago Rugosa*.

Solidago rugosa Mill. is an American species found in damp thickets and on the borders of fields from Newfoundland to Ontario and south-westward to the Gulf of Mexico. It grows from one to six feet high.

In 1893 Oberhauser³ made a chemical examination of the flowering plant and reported, among other things, a volatile oil present to the extent of 0.996%. The flowers and leaves were separately distilled with water. From the flowers he obtained a colorless oil having $d_{15} = 0.8486$; from the leaves a straw-colored oil having $d_{15} = 0.8502$. Both oils had an

¹ Report of Schimmel & Co., April, 1894, p. 57.

² THIS JOURNAL, 36, 2538 (1914).

³ Am. J. Pharm., 65, 122 (1893).

odor resembling organum. Reactions with iodine and bromine indicated the presence of large amounts of terpenes. "On careful heating each began to boil at 130°."

From plants of this species collected near Auburn, Ala., we obtained by steam distillation of the fresh material a small amount of a light yellow oil, the yield being about 0.4%. The plants were in full bloom and were on the average three to four feet high. The material was carefully examined and was known to be free from other plants. Our determination of the plants was confirmed by comparison with specimens in the herbarium of the Alabama Polytechnic Institute.

The following physical and chemical properties were determined: d_{25}^{25} , 0.8620; α_D , -12.8° ; n_D^{25} , 1.4813; saponification number, 4.22; saponification number after acetylation, 10.97. These values correspond to 1.47% of ester calculated as bornyl acetate and 1.67% of free alcohol calculated as borneol.

After saponification the oil was fractionated under diminished pressure, then under atmospheric pressure. The results are given in Table I.

TABLE I.

No. of fraction.	Boiling temperature.	d_{25}^{25} .	α_D . (100 mm. tube.)	n_D^{28} .
1.....	Below 165°	0.8520	— 3.78°	1.4688
2.....	165–170°	0.8560	+ 8.32°	1.4700
3.....	170–175°	0.8530	+ 24.04°	1.4725
4.....	175–180°	0.8510	1.4745
5.....	180	0.9200	1.4764
6.....	Residue			

From Fraction 1, which formed the greater part of the oil, there was prepared a nitrosyl chloride, m. p. 103°. As will be seen the boiling temperature, specific gravity, and index of refraction of this portion of the oil all agree closely with those of α -pinene and there can scarcely be any doubt that the oil is composed mainly of that terpene. For similar reasons it may be said that Fraction 4 is most probably composed mainly of limonene. The higher specific gravity of the two intervening fractions shows conclusively that a third compound, probably β -pinene, is present. Fraction 5 contained the alcohol resulting from saponification. That a saponification number of 10.97 was obtained after acetylation is, however, not absolute proof that a free alcohol was present, since it has been shown by Bouchardat and Lafont¹ and by Sievers² that unsaturated hydrocarbons may be acetylated.

The Volatile Oil of *Solidago Odora*.

Solidago odora Ait., commonly known as Sweet Scented Golden-rod or Blue Mountain Tea, is a native of the United States, growing in dry

¹ *Compt. rend.*, 102, 171 (1886).

² University of Wisconsin, Science Series, *Bull.* 434 (1911).

or sandy soil on the borders of thickets and in open woods from New Hampshire to Florida, westward to Missouri and Texas. The stem is $1\frac{1}{2}$ to $3\frac{1}{2}$ feet high. The whole plant is strongly aromatic, having a pleasant odor resembling that of anise and a sweetish aromatic taste.

The leaves and flowering tops of this plant were official in the United States Pharmacopoeia from 1820 to 1870, being placed in the secondary list of the *Materia Medica*. At times it has occupied a rather important place among medicinal plants, having been used to cover the taste and odor of disagreeable medicines, also as a stimulant, carminative and stomachic. It has been much used as a domestic remedy to produce diaphoresis, allay colic and promote menstruation.

Golden-rod oil has been an article of commerce, in a small way, for many years, although it has probably been nothing more than a nondescript oil distilled from a mixture of weeds without any attempt at selection. "While a little true, scented golden-rod oil has probably been distilled here and there in an experimental way, we have never seen more than a few ounces at a time purporting to be such."¹

In 1891 Schimmel & Co.² obtained from *Solidago odora* by steam distillation a sample of oil which they described as strongly aromatic but not especially pleasant; density, 0.963.

In 1906 the same firm³ obtained from the United States two volatile oils, one of which they considered to be oil of *Solidago odora* and was described as follows: light yellow color, pleasant refreshing aroma; d_{15}° , 0.8904; α_D , $-15^{\circ} 14'$; ester number 34.2, after acetylation 59.9; did not dissolve to a clear solution in 10 volumes of 90% alcohol. By using 95% alcohol the solution was clear at first only. Turbidity was produced by addition of more than 1.5 volumes of 95% alcohol. Judging from the odor of the oil they considered the ester content to be composed mainly of bornyl acetate, the ester number found corresponding to about 12% of that ester.

Making all due allowance for variations known to occur in oils from the same source, the marked differences between the physical and chemical constants of the oil described by Schimmel & Co. and the oil distilled by us make it evident that the two were not obtained from plants of the same species.

The oil used in our investigation was obtained by steam distillation from fresh material consisting of the greater part of the flowering plant carefully examined and known to be free from other plants. The plant is easily distinguished from the other species of this genus by its linear-lanceolate, entire, shining leaves and their anise-like odor.

The results obtained on this oil are given in Table II. By reference to the table it is seen that the yield was above 1% in every case but two. Botanists describe a variety of *Solidago odora* characterized by having odorless leaves. We found a few plants of this kind, but it seems hardly probable that they were present in sufficient quantity to account for this low yield.

In the case of Sample 5, where the yield was unusually high, the material was collected mainly in open fields which had been cultivated. These plants were decidedly more branched and consequently possessed a much larger quantity of leaves and flowers in proportion to stem. As there is very little oil in the stem this would, of course, give a larger percentage of oil. Sample 10 was obtained from plants which had been transplanted and cultivated in an open field. The plants were harvested about the 12th of September and after drying were shipped to Madison, Wisconsin, where they were distilled about three months later. The yield would undoubtedly have been considerably higher if the plants had been collected two weeks later and distilled in the fresh condition.

The greater part of the oil used in this investigation consisted of the first nine samples which were mixed after the optical rotation of each had been determined. The color of the oil was slightly yellowish, the odor somewhat like that of anise and at the same time somewhat suggestive of safrol. The taste was warm and sweetish, very noticeably less sweet than oil of anise. The following constants were determined: d_{25}^{25} , 0.9310°; α_D , +13.72°; n_{D28} , 1.5065; saponification number, 7.9; acid number, 0.63; % of OCH_3 , 15.9. These saponification values correspond to 3.11% of ester calculated as bornyl acetate and 2.96% of free alcohol calculated as borneol. Considering the methoxy compound to be methyl chavicol, this value for OCH_3 would indicate that 75.89% of the oil consists of methyl chavicol.

For Sample 10, the oil from cultivated plants, the following constants were found: d_{15}^{25} , 0.9450°; α_D , +9.33°; n_{D21} , 1.5140; saponification number, 8.9; after acetylation, 19.4. One cc. of the oil with two drops of 90% alcohol gave a turbid mixture. One volume of the oil with 0.4 volume of 90% alcohol produced a clear mixture. One volume of the oil gave a turbid mixture after the addition of 15 volumes of the alcohol.

Action of Reagents on the Oil.—With a drop of conc. nitric acid the oil

gives a bright green color which soon changes to reddish brown. With an excess of acid a bright red color is produced. With conc. sulfuric acid a brownish purple soon becoming rose colored on the edges is produced. Conc. hydrochloric acid causes a dull red color. Glacial acetic acid dissolves it without change of color. Conc. formic acid causes a purplish color which soon changes to reddish brown. Conc. aqueous solution of potassium hydroxide produces no visible change, but when boiled with 0.5 *N* alcoholic potassium hydroxide the oil becomes very dark colored.

Test for Phenol.—5 cc. of the oil were shaken in a cassia flask with an excess of 5% aqueous solution of potassium hydroxide and the oil then brought into the graduated neck of the flask. No diminution in the volume of the oil was observed, showing the absence of phenols, or the presence of not more than traces.

Test for Aldehydes and Ketones.—With Schiff's reagent for aldehydes no color was produced within two minutes. With sodium bisulfite and hydroxylamine negative results were obtained, showing that aldehydes and ketones are either absent or present only in traces.

Test for Anethol.—Since the odor of the oil suggested the possible presence of anethol, some of the oil was kept in a freezing mixture of ice and salt for several hours, the sides of the container being repeatedly rubbed with a glass rod. No solid separated. Information obtained by fractionation of the oil also showed that anethol is either absent or present in very small amount.

Test for Methoxy Compounds. Quantitative Determination of the Methoxy Group.—The only substance known to have an odor similar to that of anethol is its isomer methyl chavicol. If this substance were the bearer of the characteristic odor the oil should give a positive result when treated according to the method of Zeisel.¹ In order to throw light on this question an estimation was made, following Perkin's² modification of the Zeisel method. The amount of silver iodide obtained corresponded to 15.9% of methoxyl. To determine whether the alkoxyl present was methoxyl or ethoxyl or possibly both, the alkyl halide formed by the action of boiling hydriodic acid on the oil was conducted into an alcoholic solution of dimethyl aniline. A beautiful, white, crystalline substance was obtained having the melting point 212–213°. The melting point given for trimethyl phenyl ammonium iodide is 212–214°, and for dimethyl ethyl phenyl ammonium iodide is 124°. Consequently the alkoxyl group in the oil must be the methoxyl group.

Saponification and Fractionation of the Oil.—The oil was heated one hour on a boiling water bath with an excess of potassium hydroxide

¹ *Monatsh.*, 6, 989 (1885).

² *J. Chem. Soc.*, 83, 1367 (1903).

in alcoholic solution, and the greater part of the alcohol removed by distillation. The liquid remaining in the distilling flask was mixed with a large volume of water, the oil which separated was removed, washed till neutral, dried with anhydrous sodium sulfate and fractionated under a pressure of 20 mm. The five fractions thus obtained were refractionated three times under atmospheric pressure. The results are given in Table III.

TABLE III.

No. of fraction.	Boiling temperature.	$d_{25}^{25^{\circ}}$	n_D	$n_D^{18.9^{\circ}}$
1.....	165–180°	0.8440	+68.56
2.....	180–210°	0.8930	+48.34
3.....	210–212°	0.9640	+ 0.25	1.5240
4.....	212–225°	0.9680	+ 0.20
5.....	225–240°

The constants given for Fraction 3 are for that fraction after it was again repeatedly redistilled. From fraction 225–240° there was obtained a fraction boiling at 236–240°. $n_D^{18.9^{\circ}}$ for this fraction was 1.5295.

Test for Pinene.—From Fraction No. 1 a nitrosyl chloride, m. p. 103° was prepared by the method of Wallach¹ and also by the method of Ehestaedt.² From this compound both a nitrol-piperidide and a nitrol-benzylamine were prepared, but their behavior in regard to melting point was such as to make the presence of pinene doubtful.

From the alcohol distilled from the saponification mixture there was obtained, by dilution with water, a small amount of a hydrocarbon having the odor of pinene. From it also a nitrosyl chloride was prepared having the m. p. 103°.

Test for Phellandrene.—Fractions Nos. 1 and 2 were tested for phellandrene by the method of Wallach and Gildemeister³ for preparing phellandrene nitrosite but with negative results in both cases.

Identification of Methyl Chavicol.—The odor of the oil is generally described as being anise like, but the odor of Fraction No. 3 suggests both anethol and safrol. Indeed, the odor of safrol is so pronounced that several persons familiar with volatile oils mistook this fraction for oil of sassafras.

Although the odor of this fraction may be considered as somewhat anise-like the absence of anethol is shown in several ways, as follows: (1) Its taste is only moderately sweet while that of anethol is decidedly sweet; (2) its boiling point is too low by 10–12°; (3) when subjected to a freezing mixture it could not be made to solidify or deposit any crystals, whereas anethol is readily crystallized when subjected to cold. On the

¹ *Ann.*, 245, 251 (1888).

² *Report of Schimmel & Co.*, April, 1910, p. 104.

³ *Ann.*, 246, 282 (1888).

other hand its odor, taste, boiling point, density, index of refraction and its being almost optically inactive all agree in suggesting methyl chavicol.

Preparation of Anisic Acid.¹—In order to obtain further knowledge of the chemical nature of this fraction, 25 g. were shaken with three liters of a warm 3% solution of potassium permanganate, the MnO_2 filtered off, the filtrate evaporated to a small volume and acidified with dilute sulfuric acid. A white solid separated, which, after recrystallization from alcohol, was obtained in brilliant needles having the melting point 184° . The melting point of anisic acid is given as 184.2° . A methoxyl estimation of the compound obtained in this experiment gave 19.95% of methoxyl; calculated for $C_6H_4 \begin{matrix} \nearrow OCH_3 (1) \\ \searrow COOH (4) \end{matrix}$, $OCH_3 = 20.39\%$. The com-

pound resulting from the oxidation of this fraction of the oil is, therefore, anisic acid and the experiment proves that that part of the oil which boils at $210-212^\circ$ consists mainly of anethol or of methyl chavicol.

Preparation of Homoanisic Acid.¹—30 g. of this fraction were shaken in the cold with 20 g. each of potassium permanganate and acetic acid in two liters of water. On completion of the reaction the liquid was made alkaline by the addition of sodium carbonate, filtered, the filtrate evaporated to a small volume, acidified with dilute sulfuric acid and extracted with ether. On evaporation of the ether there was obtained a white solid. When crystallized from hot water it was obtained in beautiful, shining plates having the melting point $85-86^\circ$. The melting point of homoanisic acid is given at 86° .

Since methyl chavicol on oxidation yields homoanisic acid and anethol does not, this experiment proves that the methoxy compound contained in this fraction of the oil is methyl chavicol.

Further Examination of the Fraction Boiling at $210-212^\circ$.—That this fraction is not composed wholly of methyl chavicol was shown in several ways. An estimation of methoxyl gave 16.98% (OCH_3); calculated for methyl chavicol, $C_6H_4 \begin{matrix} \nearrow CH_2-CH=CH_2 (1) \\ \searrow OCH_3 (4) \end{matrix}$, (OCH_3) = 20.94%. Al-

though the original oil was saponified before it was fractionated this fraction showed an ester number of 9.12, corresponding to 3.19% of ester calculated as bornyl acetate and 2.51% of combined alcohol calculated as borneol. After acetylation an ester number of 46.85 was obtained, corresponding to 13.35% of total alcohol and 10.84% of free alcohol, calculated as borneol.

Test for Camphor.—The fractions boiling at $195-210^\circ$ and $210-212^\circ$ were separately examined for camphor by the usual method of preparing

¹ Bertram and Walbaum, *Arch. Pharm.*, 235, 179, 182 (1897).

camphor oxime, but from neither fraction could any camphor oxime be separated. The experiment was repeated with both fractions but the results were also negative. This shows, therefore, that practically no camphor exists in the oil.

Identification of Borneol.—Although Schimmel & Co. expressed the view that bornyl acetate was a constituent of an American golden-rod oil which they considered to be oil of *Solidago odora*, there is nothing whatever in the odor of the genuine oil that suggests either bornyl acetate or free borneol. In fact, the amount of methyl chavicol present is so large that the odor of a considerable quantity of either the acetate or the free alcohol would be completely masked. However, since acetylation indicated the presence of a considerable amount of free alcohol in this fraction and since the boiling point is practically that of borneol, the fraction boiling at $210-212^{\circ}$ was treated as follows: 35 cc. were shaken one hour with 20 g. of potassium dichromate and 25 g. of conc. sulfuric acid in 200 cc. of water. The mixture was then made slightly alkaline with sodium carbonate and distilled with steam. 31 cc. of oil were recovered. This was boiled one hour on a water bath with 20 g. of hydroxylamine hydrochloride and 30 g. of sodium hydroxide in 250 cc. of alcohol. The mixture was then diluted with water, the oil which separated was removed and the alkaline liquid shaken out with ether. The mixture was then acidified slightly with acetic acid and again shaken out with ether. On evaporation of the ether there was obtained a thick, syrupy, brown mass, from which a small amount of a crystallized substance separated on standing. This was obtained almost colorless by pressing between porous plates. An attempt was made to recrystallize it from dilute alcohol, but, unlike camphor oxime, it was quite readily soluble. From its solution in diluted alcohol it was recovered by extraction with ether. On evaporation of the ether a syrupy liquid remained, which on standing a short time solidified to a white, crystalline mass. After drying between filter paper and then in a desiccator it melted at 45° .

Since borneol could not be identified in this way, recourse was had to the method of Haller¹ for the separation of borneol and camphor by conversion of the former into acid bornyl succinate, using, however, phthalic anhydride instead of succinic acid. 100 cc. of the fraction were heated with 15 g. of phthalic anhydride in a flask in a glycerin bath at $150-160^{\circ}$ for about fifty hours. On cooling, the oil was poured off from the phthalic anhydride which had crystallized out, then dissolved in ether and the ethereal solution shaken several times with a 5% solution of sodium carbonate. This solution was treated with sodium hydroxide and then distilled. A small amount of a white solid collected in the condensing tube. This product was crystallized from petroleum ether, sublimed

¹ *Compt. rend.*, 108, 1308 (1889).

and again crystallized from petroleum ether. It was obtained in hexagonal plates, melting point $203-204^{\circ}$. From this compound a phenyl urethane was prepared having the melting point $138-139^{\circ}$. This experiment proves that borneol is a constituent of the oil.

The bornyl phenyl urethane was crystallized from hot petroleum ether, but before it separated a few larger crystals were formed which melted at $149-150^{\circ}$. The formation of this compound seems to indicate the presence of a second alcohol in the oil.

Fractionation of the Oil from Cultivated Plants.—Sample No. 10.—After saponification this sample was fractionated under ordinary pressure. In Table IV physical constants are given for these fractions.

TABLE IV.

No. of fraction.	Boiling temperature.	$n_{D20.5}^{\circ}$	α_D .	$d_{25}^{25^{\circ}}$.
1.....	$170-176^{\circ}$	1.4735	$+62.6^{\circ}$	0.8408
2.....	$176-180^{\circ}$	1.4769	$+71.0^{\circ}$
3.....	$180-195^{\circ}$	1.4880	$+57.4^{\circ}$
4.....	$195-210^{\circ}$	1.5118	$+15.4^{\circ}$
5.....	$210-212^{\circ}$	1.5210	$+0.7^{\circ}$
6.....	$212-222^{\circ}$	1.5221	$+0.1^{\circ}$
7.....	$222-236^{\circ}$	1.5260	-0.2°	0.9840
8.....	Residue	1.5505

A nitrosyl chloride was prepared from Fraction 1 by the method of Wallach.¹ After filtering out the crystals which first separated two further quantities of the nitrosyl chloride were obtained in succession by the addition of alcohol to the filtrate. The melting points, in order, of these products were 103° , $101-102^{\circ}$, $99-101^{\circ}$. A nitrol-piperidide was apparently formed but not in sufficient quantity to permit of purification and melting-point determination.

Fractions 2 to 7 inclusive were treated with concentrated formic acid. A pronounced purplish color was produced with Fraction 2. A similar color was formed with the next four fractions, but with gradually diminished intensity. With Fraction 7 no color was produced. These tests are of some importance as they show that the substance which produces the characteristic purplish color when the oil is treated with conc. formic acid is found among the lowest boiling constituents of the oil, but whether it is a terpene or not remains to be proved. We are not aware that this reaction has been reported for any terpene. With conc. nitric acid Fraction 4 gave a green color.

Although the data obtained are not sufficient to establish the identity of a low boiling compound, the physical constants of Fraction 1 may be considered proof of the presence of at least one terpene. It will also be seen that these constants are in better agreement with those of sabinene

¹ *Ann.*, 245, 251 (1888); 253, 251 (1889).

or sylvestrene than with those of α -pinene. The optical rotation of Fraction 2 shows that at least two compounds are present which have a lower boiling point than that of methyl chavicol. While the physical constants given for Fraction 2 may be considered as an indication of the presence of limonene, mixed with one or more other terpenes of lower optical rotation, there was nothing in the odor to suggest this.

Examination for Acids. Volatile Acids.—The aqueous alkaline liquid resulting from the saponification of the oil was concentrated on the water bath, filtered and acidified with dil. H_2SO_4 and then steam distilled. The distillation was continued until the distillate was only faintly acid. The distillate was collected in four fractions. Each fraction was made slightly alkaline with sodium hydroxide and concentrated on a water bath. Although there was an excess of alkali there was decomposition and loss of acid as indicated by the odor. The solutions were then treated with silver nitrate solution, drop by drop, until the sodium hydroxide was removed. The remaining precipitate was collected, dried and ignited. The percentage of metallic silver obtained was as follows: Fraction 1, 33.67%; Fraction 2, 39.8%; Fraction 3, 69.45%; Fraction 4, 73.9%. The silver salts were all quite dark in color. Whether the reduction was due to the presence of formic acid could not be satisfactorily established. From the data obtained it can not be stated what acids are present though there must be at least three volatile acids present.

Nonvolatile Acids.—The residue remaining in the flask after steam distillation was heated with barium carbonate and water, filtered and the filtrate treated with silver nitrate solution. A light yellowish precipitate was obtained, which, after drying and ignition, yielded 25.22% metallic silver.

Summary.

The oil of *Solidago rugosa* is composed mainly of terpenes, of which, at least, three are present. That α -pinene is one of these is highly probable. In addition there also appears to be present at least one ester and one free alcohol, 1.47% of ester calculated as bornyl acetate and 1.67% of alcohol calculated as borneol.

The oil of *Solidago odora* contains the following:

1. Terpenes, 10–15%.
2. Esters, about 3%, calculated as bornyl acetate.
3. Borneol and possibly another alcohol, the total percentage of free alcohol being about 3% calculated as borneol.
4. Methyl chavicol, forming about 75% of the oil.
5. A small amount of volatile fatty acids, at least three.
6. A small amount of nonvolatile acid.

ON THE COLLOIDAL SWELLING OF WHEAT GLUTEN.¹

BY FRED W. UPSON AND J. W. CALVIN.

Received March 1, 1915.

The colloidal swelling of wheat gluten is of interest in connection with the general problem of water absorption by animal and plant tissues as elaborately investigated by Fischer² and his coworkers, and in connection with the theory and practice of bread making. Wood³ and Wood and Hardy⁴ have shown that wheat gluten is an emulsoid colloid and that when in contact with a solution its properties depend upon the concentration of acid and salts in that solution.

Wood's experiments were carried out by immersing small bits of gluten suspended over glass rods in beakers containing solutions of varying concentration of different acids, both with and without the presence of salts, and noting the effect of the different solutions on "disintegration" and "loss of cohesiveness" of the gluten. As these changes in the properties of the gluten are best regarded in our more modern terms of colloid chemistry as expressions of a change in the degree of dispersion of the colloid, and as these changes while often associated with, have in reality nothing to do with the changes in the *hydration capacity* of the colloid, it seemed to us that our experiments dealing with this second problem were worthy of record, especially since the way in which they were carried out was an entirely different one from that adopted by Wood and Hardy. The experiments are also of interest in that they substantiate the important work of Fischer and others on the general problem of water absorption by proteins.

The colloidal swelling of animal proteins was first studied by F. Hofmeister.⁵ It has since been extensively worked upon by Pauli,⁶ Spiro,⁷ Ostwald,⁸ Fischer² and others. Gelatin swells more in the solution of any acid than it does in pure water. The amount of swelling in a given time for a given acid varies directly with the concentration of the acid

¹ This paper was originally accepted for publication in THIS JOURNAL for July, 1914. The papers by Wood and by Wood and Hardy came to our notice after we had returned our proof. We withdrew our paper and now present it with the revisions made necessary because of the previous work of these two authors. The experimental details of our work were sent Dr. Fischer early in May, 1914, and are quoted by him in his "Oedema and Nephritis," second edition, New York, 1915, recently issued.

up to a certain point. Thus Ostwald found that $N/38$ hydrochloric acid gave a maximum swelling of gelatin plates after twenty-four hours. With increasing concentrations of the acid beyond this point, the absorption of water became less.

While gelatin swells more in the solution of any acid than it does in pure water, the various acids do not bring about the same degree of swelling when equinormal solutions are compared. Ostwald found the order in which the different acids cause gelatin to swell to be: hydrochloric, nitric, acetic, sulfuric, boric.

The addition of any salt to the solution of an acid decreases the amount that gelatin will swell in that solution. Fischer¹ has shown that, for a given acid, the effect of the salt in decreasing the amount of swelling of gelatin increases with increasing concentration of the salt. If the concentration of salt is made high enough the effect of the acid may be almost or entirely suppressed.

Equimolar solutions of different salts do not produce the same effect in diminishing water absorption by gelatin. Thus Fischer found when different sodium salts are compared that the chloride and nitrate show the least effect, the phosphate and tartrate the greatest, the acetate and sulfate an intermediate one. Again when different salts of the same cation with different anions were compared (as a series of chlorides), he found that the ions like those of the monovalent alkalis show the least retarding effect, those of the trivalent metals like iron and aluminium the greatest, while the bivalent ones of calcium and magnesium fall between.

A further fact is to be noted. Nonelectrolytes, like sugar, alcohol and urea produce a much less marked antagonistic effect on the absorption of water by gelatin in acid and neutral solution than do neutral salts.²

Fischer finds that what holds for gelatin as regards water absorption holds also for fibrin³ and indeed for animal colloids⁴ in general, such as frog muscle, sheep eyes, catgut and the like.

Experimental Part.

The gluten for the following experiments was prepared by washing the starch from flour under a stream of distilled water. We found the character of the gluten to be quite different when tap-water, which contains salts, was used in place of distilled water, being tougher and more elastic and smaller in bulk, just as pointed out by Wood and Hardy.⁵ Since we wished to avoid the effect of any salts which might be absorbed by the gluten from the tap-water, all samples of gluten were prepared

with distilled water. The gluten ball was pressed out between glass plates to a fairly uniform thickness. After standing some time between the plates (during which time some fluid was usually squeezed off), discs could be cut from the gluten with a large cork borer, which were fairly uniform as to surface and weight. The discs were weighed to the nearest centigram and placed in the solution for exactly two hours, when they were removed, drained on a Buchner funnel and weighed again. The method is necessarily somewhat crude because the gluten is moist when weighed originally and because of the variation in the amount of water which mechanically adheres to the discs. Nevertheless, when the average of a number of determinations is taken the results are surprisingly uniform.

0.5 <i>N</i>	—0.19	—0.09	—0.14

The curves showing the amount of water absorption with increasing concentration of acid for Tables I, II, and III are shown in Fig. 1. The curves represent the average for four, three and two determinations, respectively, for lactic, acetic, and hydrochloric acids. The concentrations of acid are plotted along the horizontal, and the water absorption in grams per gram of moist gluten is plotted on the vertical axis. An inspection of these curves brings out some interesting facts. For hydrochloric acid the maximum absorption is obtained with a concentration of $0.005\ N$, while the concentration for maximum absorption with lactic acid lies between $0.01\ N$ and $0.02\ N$ and for acetic acid is $0.04\ N$. It is to be noted that for concentrations above the one for maximum absorption, the curves do not fall off at anything like the same rate for the three acids. The curve for hydrochloric falls much more rapidly than the curves for the other two. This agrees with the results as found by Fischer¹ for fibrin and by Ostwald for gelatin.² Fischer obtained maximum swelling of both fibrin and gelatin in approximately $0.025\ N$ hydrochloric acid and diminished swelling for concentration above this.

Of special interest is the fact that both lactic and acetic acids show concentrations of optimal swelling for gluten. Such an optimal swelling of a protein in a "weak" acid, has never before been observed. It does not occur in gelatin, fibrin and the other animal colloids thus far studied. The swelling of gluten also diminishes much more rapidly with increasing concentration of hydrochloric acid beyond the optimal point, than does the swelling of gelatin or fibrin. It is also of interest that moist gluten *loses* water in the higher concentrations of hydrochloric acid $0.2\ N$ and $0.5\ N$. We have established that gluten discs lose weight in these higher concentrations of acid because of loss of water and not because of "solution" of the gluten. Examination of the surrounding fluids in these higher concentrations of acid fails to reveal more than traces of dissolved protein, whereas in the lower concentrations where greatest swelling takes place considerably more protein is dissolved. When gluten swells in dilute acid the discs puff up and take on an appearance somewhat resembling cotton balls, finally becoming transparent, soft and gelatinous. In $0.2\ N$ and $0.5\ N$ hydrochloric acid the discs do not change in appearance or in physical properties except to become tougher and more elastic just as in salt solutions. Discs which have lost water in $0.5\ N$ hydrochloric acid gain water and become soft and gelatinous when placed in more dilute acid. Those which have absorbed water to more than double their weight in the more dilute acid, lose it if placed in $0.5\ N$ acid. The taking up and giving off of water is, in other words, largely reversible.

When any salt is added to an acid in which a gluten disc is swelling,

¹ Fischer, *Oedema and Nephritis*, Sec. Ed., N. Y. (1915), pp. 44, 48.

² *Loc. cit.*

Fig. 1.

the swelling is much reduced. This is shown in Table IV and Fig. 2 which is based upon the results shown in this table.

TABLE IV.—0.005 *M* SALT SOLUTIONS AND VARYING CONCENTRATIONS OF LACTIC ACID.

Conc. of acid solution.	Wt. of water absorbed in g. per g. of moist gluten.				
	0.005 <i>M</i> $K_2C_4H_4O_6$.	0.005 <i>M</i> K_2HPO_4 .	0.005 <i>M</i> KCl.	0.005 <i>M</i> . $CaCl_2$.	No salt.
No acid	—0.11	—0.14	—0.11	—0.11	—0.01

0.01 <i>N</i>	0.25	0.63	0.98	0.57	1.81
0.02 <i>N</i>	0.55	0.86	1.28	0.68	1.87
0.04 <i>N</i>	0.73	0.97	1.30	0.89	1.72
0.1 <i>N</i>	1.06	1.12	1.43	0.96	1.69

Fig.

In Table V are given the figures showing the effect of varying concentrations of four salts and also of glycocoll on the absorption of water by gluten in the presence of 0.01 *N* lactic acid. The results are shown graphically in Fig. 3.

In all cases there is a rapid decrease in water absorption with increase in the concentration of the salt. In the higher concentrations of phos-

phate and tartrate the gluten disc drops to a weight below that of the original moist disc.

TABLE V.—0.01 *N* LACTIC ACID AND VARYING CONCENTRATIONS OF SALTS AND OF GLYCOCOLL.

Conc. of salt solution.	Wt. of water absorbed in g. per g. of moist gluten. 0.01 <i>N</i> lactic acid and				
	KCl.	K ₂ HPO ₄ .	K ₂ C ₄ H ₄ O ₆ .	CaCl ₂ .	Glycocoll.
No salt	1.70	2.12	1.87	2.02	1.70
0.0001 <i>M</i>	1.23	1.17	1.18	1.50	..
0.002 <i>M</i>	1.09	0.85	0.85	1.21	1.57
0.005 <i>M</i>	0.74	0.49	0.26	0.85	1.65
0.01 <i>M</i>	0.46	0.06	—0.02	0.43	1.29
0.02 <i>M</i>	0.21	—0.18	—0.11	0.11	1.21
0.04 <i>M</i>	—0.03	—0.21	—0.14	0.00	1.14
0.1 <i>M</i>	0.71
0.2 <i>M</i>	0.53
0.4 <i>M</i>	0.50

At the concentration of 0.02 *M* the order of salts as regards their effect in diminishing absorption is the same as found by Fischer for gelatin and fibrin, namely: chloride, tartrate, phosphate. That the relative position of the curves for the four salts is not the same for all concentrations may or may not be significant. We do not think the matter due to experimental error. There is undoubtedly a very important relation between the exact concentration of the acid and the inhibiting effect at different concentrations, of the salts. Of special interest is the fact that glycocoll behaves like a salt in reducing the swelling of gluten in acid solution. The effect, however, is less marked than with the different salts studied.

A series of photographs will help to make evident the significant differences in the swelling of gluten under different conditions.

Plate I.

Plate I shows the lactic acid series (a) of Table I. Beaker 1 contains distilled water. Beakers 2 to 7 contain lactic acid in concentrations from 0.002 *N* to 0.1 *N* as shown in Table I. The difference in size of the discs in distilled water and in the different concentrations of acid is plainly evident.

Plate II shows a 0.005 *N* lactic acid series, to which has been added varying concentrations of K_2HPO_4 as in Table V. Beaker 1 contains

Plate II.

0.01 *N* lactic acid. Beakers 2 to 7 contain 0.01 *N* lactic acid with K_2HPO_4 varying in concentration from 0.01 *M* to 0.4 *M*. The increasing antagonistic effect of the salt with increasing concentration is very apparent.

TABLE VI.

A. Original wt. of discs.		B. Wt. of discs after 2 hrs. in acid.		Conc. of acid.	C. Wt. of discs after transference to 0.1 <i>N</i> K_2HPO_4 for 1 hr.	
a.	b.	a.	b.		a.	b.
1.39	1.23	1.41	1.20	No acid	1.14	0.95
1.30	.26	3.21	2.89	0.002 <i>N</i>	.18	.16
1.33	.22	3.43	3.54	0.005 <i>N</i>	.22	.10
1.39	.28	3.57	3.67	0.01 <i>N</i>	.27	.17
1.42	.24	3.92	3.67	0.02 <i>N</i>	.30	.14
1.29	.27	3.90	3.85	0.04 <i>N</i>	.17	.15
1.29	.29	3.95	3.69	0.1 <i>N</i>	.21	.24
1.31	.29	3.69	3.56	0.2 <i>N</i>	.28	.26
1.31	1.30	3.52	3.46	0.5 <i>N</i>	.35	.35

Table VI shows the reversible nature of water absorption by gluten. There are shown in Col. A the original weights of two series of gluten discs, and in Col. B their weights after remaining two hours in acetic acid solutions varying from 0.002 *N* to 0.5 *N*. In Col. C are given the weights of the same discs after remaining one hour in 0.1 *N* dipotassium phosphate solution. These experiments show how the discs, after taking up water in the acid solutions to twice their original weight or more, give up the water in the salt solution. Not only do they reassume their original weight, but their original appearance and physical properties as toughness and elasticity as well.

TABLE VII.—EFFECT OF TEMPERATURE ON WATER ABSORPTION.

Solution.	Wt. of water absorbed in g. per g. of moist gluten.	
	24°.	39°.
In water.....	0.06	0.09
In 0.01 <i>N</i> HCl.....	1.47	2.01
In 0.01 <i>N</i> lactic.....	1.65	2.66
In 0.01 <i>N</i> acetic.....	1.68	2.79

Table VII is introduced to show the effect of temperature on the absorption of water by gluten. It shows that gluten swells the more in acid solutions the higher the temperature.

TABLE VIII.—0.01 *N* LACTIC ACID WITH VARYING AMOUNTS OF FLOUR AND BRAN EXTRACTS.

0.01 <i>N</i> lactic acid cont. extract from flour.	Water abs. in g. per g. of moist gluten.	0.01 <i>N</i> lactic acid cont. extract from bran.	Water abs. in g. per g. of moist gluten.
No extract	2.23	No extract	1.48
0.625 g. per 100 cc.	2.16	0.625 g. per 100 cc.	1.12
1.25 g. per 100 cc.	1.81	1.25 g. per 100 cc.	1.02
2.50 g. per 100 cc.	1.47	1.87 g. per 100 cc.	0.91
5.00 g. per 100 cc.	1.25	2.50 g. per 100 cc.	0.82
		4.75 g. per 100 cc.	0.33

TABLE IX.—0.01 *N* LACTIC ACID WITH VARYING AMOUNTS OF CANE SUGAR.

Conc. of sugar solution.	Water abs. in g. per g. of moist gluten.
None	1.75
0.1 <i>M</i>	1.41
0.2 <i>M</i>	1.54
0.5 <i>M</i>	1.42
1.0 <i>M</i>	0.71
1.5 <i>M</i>	0.28

Table VIII shows that water extracts of flour and bran reduce the swelling of gluten in acid solutions. Their effect is similar to, though not as marked, as the effect of neutral salts.

Table IX shows that nonelectrolytes such as cane sugar are comparatively ineffective in reducing the swelling of gluten in acid solutions except in high concentrations. Fischer finds the same for gelatin and sugar solutions.

The experiments described in this paper show that the mixture of vegetable proteins which comprises wheat gluten behaves in a manner entirely analogous to the animal colloids as studied by Fischer and others. Moist gluten absorbs water from acid solutions and the amount of absorption varies with the kind and concentration of the acid. The presence of neutral salts retards water absorption by gluten, and in the higher concentrations of salt may even cause loss of water from moist gluten. Gluten which has taken up water in an acid solution loses water and regains its original physical properties when placed in a salt solution. The nonelectrolytes are much less effective than electrolytes in inhibiting the swelling of gluten in acid solutions. These experiments therefore contribute to the important problem of the mechanism of water absorption and secretion by living plants which in animals has been proved by Fischer to be essentially a colloid phenomenon.

The facts brought out in our experiments, coupled with those of Wood and Hardy, are also of importance in relation to certain theoretical and practical problems of milling and baking. This topic we propose to discuss in a forthcoming bulletin from the Nebraska Experiment Station.

We would here express to Dr. Martin H. Fischer of the University of Cincinnati our appreciation of his interest in this work.

STUDIES ON AMYLASES. X. COMPARISON OF CERTAIN PROPERTIES OF PANCREATIC AND MALT AMYLASE PREPARATIONS.

By H. C. SHERMAN AND M. D. SCHLESINGER.

Received February 23, 1915.

Notwithstanding the numerous investigations of recent years, no consensus of opinion has yet been reached as to how far the enzymes of similar activity, but different origin, are to be regarded as distinct substances.

The best amylase preparations obtained in this laboratory from the pancreas and from malt are found to be very similar in physical properties and in chemical nature, so far as shown by their qualitative reactions, the percentage of nitrogen which they contain, and the distribution of this nitrogen among the different types of amino-acid radicals. That they are nevertheless not identical appears to be established by certain differences in their behavior.

Activity.

Optimum Reaction.—Perhaps the most noticeable difference between these two enzymes is that malt amylase is most active in an acid, and pancreatic amylase in an alkaline solution.

Electrometric measurements recently made in this laboratory¹ have shown that the optimum acidity for malt amylase (saccharogenic action in 30 minutes at 40°) is P_H^+ 4.2 to 4.6, the optimum action being found at this point, whether the activating agent be a strong acid, a weak acid, or an acid phosphate. Solutions of this hydrogen ion concentration give a distinct (but not strong) red reaction with azolitmin, while methyl orange gives an orange color.

Exact measurements of the optimum alkalinity for pancreatic amylase have not yet been made, but the reaction which has seemed best in the regular testing of these preparations has been that obtained by the use of 7 cc. of 0.02 *M* disodium phosphate and 5 cc. of *M* sodium chloride in each 100 cc. of previously neutral 2% starch. Such a solution gives a distinct (but not strong) blue reaction with azolitmin and is colorless with phenolphthalein. According to Sørensen this indicates a P_H^+ of 8.0 to 8.5. We hope soon to confirm this by the electrometric method.

Diastatic Power.—When each is tested in the presence of its proper activating electrolyte but with time, temperature, and substrate the same, the diastatic powers of the best preparations thus far obtained are fully twice as high for the pancreatic as for the malt amylase. The most active preparations of pancreatic amylase show diastatic powers around

¹ Sherman and Thomas, *THIS JOURNAL*, 37, 623 (1915).

4000 (new scale) corresponding to Lintner figures of about 6000, which means that the enzyme preparation forms 10,000 times its weight of maltose in 30 minutes at 40°. The most active preparations of malt amylase yet obtained showed powers of 1570 (new scale) corresponding to a power of about 2350 on Lintner's scale, and forming about 4000 times its weight of maltose in 30 minutes at 40°.

The foregoing statements refer in all cases to the relative amounts of reducing sugar formed under the action of the enzyme (saccharogenic activity or saccharogenic power). That the amylolytic activity, as usually measured by determining the relative amount of starch *all* of which is digested under specified conditions into products giving no blue or violet color with iodine, runs approximately parallel with the saccharogenic power among amylase preparations from the pancreas and not among the corresponding preparations from malt, constitutes another interesting point of difference between the two amylases. This point was discussed recently¹ and therefore need not receive further attention here.

Proteolytic Activity.—Another pronounced difference between our amylase preparations from the two sources is that in those from pancreatin, proteolytic activity, as shown in the digestion both of casein² and of gelatin,³ was concentrated with the concentration of the diastatic power, whereas in our purified malt amylase preparations we have not yet succeeded in demonstrating any proteolytic activity.

Deterioration.—Our pancreatic and malt amylase preparations also differ strikingly in the rate at which their solutions lose diastatic power on standing.⁴ Under the conditions obtaining in our experiments, malt amylase is much the more stable in pure water solution, while pancreatic amylase is the more stable in 50% alcohol and remains active longer than the malt amylase when allowed to act upon starch.

The following are illustrative of numerous experimental data on which the foregoing statement is based:

Pancreatic and Malt Preparations in Solution at Ice-box Temperature.—The results of deterioration experiments with commercial pancreatin and malt extract, with purified amylases of high activity, and with intermediate products, are shown in Table I. (When a value is given in parenthesis with the designation of the preparation at the head of a column, it represents the original diastatic power of the preparation when first obtained.)

¹ THIS JOURNAL, 35, 1784-90 (1913).

² *Ibid.*, 34, 1109-10 (1912).

³ Wahl, *Orig. Com. 8th Intern. Congr. Appl. Chem.*, 14, 215 (1912).

⁴ The rate of deterioration when kept in the dry state varies too much with conditions to permit definite conclusions to be drawn from the data at hand. On the whole, the pancreatic preparations appear to have retained their diastatic power rather than those from malt, when kept dry at the same temperature.

TABLE I.—DETERIORATION OF PANCREATIC AND MALT AMYLASES IN WATER AT 5-10°.

It will be seen from the table that, whether crude or purified material be compared, the malt amylase is much the more stable in cold water solution (5° to 10°). The solution of commercial pancreatin lost one-third of its activity in 3 days, while the malt extract showed a smaller loss after 6 days, its activity when 3 days old being nearly equal to that when freshly prepared. The highly purified pancreatic amylase (No. 60) lost all of its activity within 24 hours, while the highly purified malt amylase preparation (No. 52) lost less than one-fifth of its activity under the same conditions. Pancreatic preparation No. 21 (having about three-fifths the activity of No. 60) lost half its diastatic power in 48 hours, while malt preparation No. 112 (having three-fifths the activity of No. 52) showed no appreciable loss in the same length of time.

In the case of the pancreatic amylase it is plain that the rapidity of deterioration is proportional to the purity of the preparation and, in general, a similar relationship appears among the malt preparations. The latter, however, show irregular results, possibly because they are less homogeneous products, and probably also because the malt amylase solutions retain their activity so long that (when no antiseptics are used) there is sometimes bacterial action even at the low temperature of these observations. More experiments upon the influence of antiseptics are contemplated.

Both the great stability of the malt amylase solutions as compared

* In this case only, the activity was studied beyond the 28th day. The last observation was taken on the 53d day and showed a diastatic power of 230, indicating that in this case there was little loss of activity in over seven weeks.

with those of pancreatic amylase, and the fact that the former may show increased activity after standing for some time may be due, in part at least, to the presence in the malt preparations of some malt albumin which retards hydrolysis of the enzyme when in solution, or possibly protects it from deterioration in some other way. This point was discussed in our last paper.

Effect of Heat upon Dry Enzyme.—It is well known that enzymes, when dry, are much more stable at high temperatures than are their solutions. In our experience, however, it has not been found possible to heat the dry enzyme preparations at 100° without considerable loss of diastatic power. Pancreatic amylase preparation 35, which originally had a power of 3450, showed after heating for one hour at 100° a power of 1020. Malt amylase preparation 111B, which originally had a power of 1150, showed after the same treatment a power of 510. Thus the heating destroyed about two-thirds of the activity of the pancreatic and about one-half the activity of the malt amylase.

Statements in the literature to the effect that dry enzymes can be heated at 100° "without loss of activity," are probably based (for the most part at least) upon qualitative experiments and should perhaps be construed to mean "without becoming inactive," *i. e.*, the loss of activity is only partial and in qualitative experiments would very likely not be apparent.

Effect of Temperature and of Activating Salts upon Deterioration of Pancreatic and Malt Amylase in Water Solution.—The effect of temperature upon the rate of deterioration of diastatic power in commercial and purified amylase preparations, and the relative stability of these preparations in pure water solution and in the presence of "activating" salts, are shown in Table II. It will be seen that in pure water solutions the deterioration is always more rapid the warmer the solution. For both pancreatic and malt amylase the deterioration is more rapid the purer the enzyme. Pancreatic amylase in water solution is to an important extent preserved from deterioration by the presence of the mixture of salts which is favorable to its action (sodium chloride and secondary sodium phosphate); on the other hand, purified malt amylase may deteriorate more rapidly in the presence of its "activating" salt (primary sodium phosphate) than in pure water, probably because the deterioration is due to an hydrolysis of the enzyme, which is accelerated by increasing the hydrogen ion concentration of the solution. As will be more fully explained beyond, the enzyme is, in these deterioration experiments, dissolved in the water or salt solution in larger quantity (concentration) than would be used in determinations of diastatic power or in long-digestion experiments, since portions of the deteriorating solution must be

withdrawn from time to time in order to determine the proportion of enzyme still remaining active.

TABLE II.—DETERIORATION AT DIFFERENT TEMPERATURES IN WATER WITH AND WITHOUT "ACTIVATING" SALTS.

Diastatic power found when solution had stood at temperature and for time given below.	From pancreas.								From malt.

3 hrs.	57	165	1520	535	1720	390	5.0	870	930	
18 hrs.	0	
24-27 hrs.	0	124	1440	0	1200	0	6.1	5.3	3.9	870	870	780	480	
2 days	1080	5.3	5.0	2.1	750	390	
3 days	5.0	...	0.6	750	360	
4 days	4.9	4.7	0.2	870	600	750	300	
5 days	4.9	4.3	0	830	490	730	290	
6 days	4.7	4.1	...	830	230	560	290	

In water solutions the deterioration is more strikingly accelerated by rise of temperature in the case of the pancreatic than of the malt amylase.

A further comparison of the rate of deterioration of pancreatic preparations of different degrees of purity, when kept in pure water at room temperature, may be summarized briefly as follows:

Initial diastatic power.....	3430	2000	1185	425	150
Percentage of initial power lost in 20 minutes....	45.5	32.5	25.8	19.0	11.3
Percentage of initial power lost in 3 hours.....	?	73.3	72.3	62.5	62.0

All of these solutions became entirely inactive within 24 hours. These data seem sufficiently suggestive to warrant fuller investigation at accurately controlled temperatures.

Behavior in the Presence of Substrate.—In marked contrast to their deterioration in water solutions (with and without activating salts), is the behavior of the two amylases in the presence of a sufficient amount of starch to test the duration of their activity, when allowed to come in contact with their substrate, and the maximum amount of reducing sugar calculated as maltose which the enzyme can form in relation to its own weight. In Table III are shown the data obtained when different amylase preparations were allowed to act upon many times their weight of soluble starch, the latter being usually in the form of a 1% solution. Toluene

was used as antiseptic in all these cases. At intervals of about 24 hours, portions of each solution were withdrawn for testing with iodine and for the determination of maltose. The colors obtained in the iodine test, and the number of times its weight of maltose which the enzyme had formed up to the time of the test, are given together in the table.

On the scale of diastatic power in use in this laboratory,¹ pancreatic amylase preparation 57 showed a power of 3700 (in the air-dry condition, corresponding to about 4000 for the dry substance) which is a higher activity than we had previously² observed. Pancreatic preparation 50 had a power of 3200, and preparation 34 a power of 3430 when freshly prepared, and of 2560 at the time of the experiment recorded in Table III. Malt amylase preparation 52 had a power of 1470 when freshly prepared, but at the time of the "long-digestion" experiments recorded in the table it had been kept in powder form for some months and its diastatic power had fallen to 980. This malt preparation, as originally tested, bears about the same relation in diastatic power to the best malt amylase yet obtained, which pancreas preparation 50 bears to 57; in relative activity at the time these tests were made it is similarly comparable to pancreas preparation 34. A comparison of malt preparation 52 with pancreas preparations 50 and 34, as regards duration of activity and relation between initial and total activity, seems therefore logical and brings out the following interesting difference:

Malt amylase preparation 52 produced 2450 times its weight of maltose in 30 minutes, in 48 hours it had produced 93,000 times its weight of maltose, and thereafter it showed no activity.

Pancreatic amylase preparation 50 formed 8000 times its weight of maltose in 30 minutes; 440,000 in 48 hours; 516,000 in 96 hours.

Pancreatic preparation 34 under similar conditions formed 6450 parts of maltose in 30 minutes; 305,000 in 48 hours; 408,000 in 72 hours; 470,000 in 96 hours.

Thus, while the malt amylase had expended its entire activity within 48 hours and produced in all about 38 times as much maltose as it formed in the first 30 minutes, the pancreatic amylases in the same circumstances (presence of large excess of substrate) continued active for 72 to 96 hours and formed, respectively, in the first 48 hours, 55 and 48 times, and in all, 65 and 73 times as much maltose as in the first 30 minutes.

Thus the influence of the substrate in protecting the enzyme from deterioration in aqueous solution was much greater in the case of the pancreatic than of the malt amylase.

Direct comparison of the data for the malt amylases, as given in Table II,

¹ Sherman, Kendall, and Clark, *THIS JOURNAL*, 32, 1082-85 (1910); Sherman "Methods of Organic Analysis," 2nd Edition, 117-118.

² *THIS JOURNAL*, 33, 1202 (1911).

with those in Table III might lead to the impression that this enzyme deteriorates faster in the presence of its substrate, but no such interpretation is justified, because the ratio of water to enzyme is about 1000 times as great in the latter experiments as in the former. It therefore seemed desirable, in the case of the malt amylase, to compare the rate of deterioration at the different dilutions, notwithstanding the fact that only approximate results can be obtained from deterioration experiments in which the ratio of water to enzyme is of such magnitude as obtains in the long-digestion experiments. The data of such a comparison are shown in Table IV.

TABLE IV.- INFLUENCE OF DILUTION UPON DETERIORATION OF MALT AMYLASE AT 40°.

Diastatic power found after solution had stood as indicated below.	Malt amylase preparation No. 139 (960).		
	10 mgs. in 100 cc. pure water (1:10,000) at 40°.	0.01 mg. in 100 cc. pure water (1:10,000,000) at 40°.	0.01 mg. in 100 cc. water containing the "optimum" concentra- tion of NaH_2PO_4 at 40°.
After 15 minutes.....	760	500	500
After 2 hours.....	760	200	200
After 24 hours.....	700	100	100
After 48 hours.....	630	0	0
After 4 days.....	600		
After 7 days.....	270		
After 10 days.....	100		

From these data it will be seen that the malt amylase deteriorated as much in one day at a dilution of 1:10,000,000 as in 10 days at a dilution of 1:10,000. Parallel experiments with pancreatic amylase are impracticable because of its much more rapid deterioration in water.

The significance of the different behavior of the two amylases in water solution, and of the influence of the substrate upon the rate at which the enzyme loses its diastatic power will be discussed further on in this paper after certain chemical and physical characteristics have been described.

Deterioration in Alcohol at Different Temperatures.—Whereas in pure water solutions the pancreatic amylase deteriorates much more rapidly than malt amylase, this is not the case when the preparations are dissolved in 50% alcohol, as will be seen from Table V.

From the data in Table V it is evident that the alcohol solutions of both the amylases are much more stable at low temperature (5° to 10°) than at the ordinary room temperature of about 23°.

While not enough observations have been made to permit detailed comparison, it appears that, as in the case of water solutions, the purer the enzyme the more rapid its deterioration.

Comparing the data of Tables I, II, and V it will be seen that, at similar temperatures, purified pancreatic amylase is more stable in 50% alcohol than in water, whereas purified malt amylase is more stable in water than in 50% alcohol.

Chemical Composition and Color Reactions.—Our preparations of both pancreatic and malt amylase are essentially proteins in that they show the typical color reactions,¹ contain 15 to 16% of nitrogen,² and on hydrolysis are resolved into amino acids. Determinations, by the Van Slyke method, of the distribution of the nitrogen among the different types of amino acid radicals show³ that these preparations contain the same forms of nitrogen in about the same proportions as found in such typical proteins as casein and edestin.

Amylase preparations from both sources react as ordinary proteins in the Millon, xanthoproteic, tryptophan, and biuret tests.

Physical Properties.—The amylases from malt and from pancreas are both soluble in water and in 50% alcohol; insoluble in strong alcohol or acetone. In general, our preparations from malt are less readily soluble in water or in diluted alcohol than are those from pancreas.

Solutions of preparations from both sources give similar colloidal appearance under the ultramicroscope, but some isolated observations upon one of our malt preparations suggest that a part at least of the colloidal appearance may be due to material other than the active enzyme, possibly inactive protein formed by deterioration of the enzyme during purification as explained later in this paper. We hope to make a more systematic series of ultramicroscopic observations in the near future.

In diffusion experiments both amylases are retained either by parchment paper or by collodion membrane. Occasionally the dialyzate shows some diastatic power, but this is so slight in comparison with that of the dialyzing solution, and so irregular in its occurrence, that it may readily be due to imperceptible defects in the membrane. (See also description of dialysis experiments beyond.)

¹ THIS JOURNAL, 33, 1203 (1911); 35, 1622 (1913).

² *Ibid.*, 34, 1106 (1914); 37, 643 (1915).

³ *Ibid.*, 35, 1792-4 (1913).

Coagulation.—One per cent. solution of either amylase when heated above 50° yields a precipitate of coagulated albumin. This coagulum gives in both cases a blue-violet biuret reaction. The filtrate from this coagulum gives a biuret reaction which is rose-red in the case of the pancreatic, and violet-red in the case of the malt preparation. Thus both of these amylase preparations resemble that of Osborne in yielding coagulable albumin and a proteose or peptone, the latter apparently representing a product of somewhat more advanced hydrolysis in the case of pancreatic than of malt amylase.

In order to study further the change which takes place on coagulation, 200 mg. of a malt amylase preparation¹ (equivalent to 0.1836 g. of dry ash-free substance) were dissolved in 20 cc. of water and heated gradually in a beaker with constant stirring. Between 50° and 55° , coagulation took place and the coagulated protein flocculated well, leaving a clear solution. The coagulum after washing and drying weighed 0.1136 g. (61.8% of the dry weight of the sample) and contained 16.1% of nitrogen. The filtrate, containing 0.0700 g. of the original (dry ash-free) substance yielded 0.00959 g. nitrogen, showing 13.7% of nitrogen in the noncoagulable fraction of the enzyme preparation.

In a parallel experiment with pancreatic amylase, 300 mg. of preparation 60, equivalent to 0.2640 g. dry, ash-free substance, was dissolved in 30 cc. of water and heated as above. Coagulation occurred between 50° and 55° . The coagulum after washing and drying weighed 0.0306 g. (11.6% of the original dry weight) and showed 16.9% of nitrogen. The uncoagulable ash-free material of the filtrate weighed 0.2334 g. and showed 14.9% of nitrogen.

Dialysis.—Under the heading of activity, we have described above the rapid deterioration of pancreatic amylase in water solution at room temperature, and the relative stability of malt amylase under the same conditions. In the preceding paper² we have shown that the most serious loss of diastatic power encountered in the purification of malt amylase is that due to its deterioration during dialysis, and have suggested that this deterioration may be due to the removal through the dialyzing membrane of a portion of the proteose (or peptone) fraction of the enzyme.

The following experiments were designed to test this view:

1. A solution of 20 mg. of a purified preparation of malt amylase (Preparation 117; power 1070, new scale) in 50 cc. water was dialyzed against 500 cc. water at a temperature of 5° to 10° for 24 hours, at the end of which time the activity of the solution corresponded to a power of 190 (new scale), *i. e.*, four-fifths of the power was lost. The dialyzate alone showed almost no activity, 50 cc. forming only enough maltose to

¹ Preparation 111B described in the preceding paper.

² THIS JOURNAL, 37, 643 (1915).

reduce 3 mg. of cuprous oxide; but 50 cc. of the same dialyzate, when added to 0.5 cc. of the dialyzed solution, increased the activity of the latter to the extent of producing enough additional maltose to reduce 15 mg. of cuprous oxide. This corresponds to a restoration of about one-thirtieth of the power which the enzyme had lost during the dialysis. As a difference of one-thirtieth of the total power is hardly larger than the experimental errors involved in such work we should not attach much importance to this apparent restoration of a part of the lost activity, except for the fact that a similar result was again observed in the subsequent trial in which the experimental conditions were quite different. At any rate, it is plain that only a small part of the lost power was restored to the dialyzed solution by the addition of the dialyzate, indicating that, when the two constituents of the enzyme are separated by dialysis, at least one of them undergoes some further change which prevents the regeneration of more than a small fraction of the enzyme when the two solutions are subsequently mixed.

2. A solution of 200 mg. of preparation 111B (power when freshly prepared 1470, new scale, at time of this experiment 1050, new scale) in 20 cc. water was dialyzed against 200 cc. water at a temperature of 5° to 10° for 48 hours, at the end of which time the activity of the solution corresponded to a power of 750 (new scale), *i. e.*, about 30% of the power was lost. That the loss here is less than in the preceding experiment is doubtless due to the much lower ratio of water to enzyme. In this case the dialyzate showed measurable activity, about 6% of the total initial power, and again the mixing of the dialyzate with the dialyzed solution resulted in a small but appreciable restoration of power, somewhat greater than in the preceding experiment, as would be expected in view of the lower ratio of water to enzyme.

The dialyzate was concentrated by evaporation and found to give a distinct biuret reaction which was notably pinker in color than that given by the original enzyme solution. The same amount of (boiled down) dialyzate which gave this biuret reaction failed to give any coloration with triketohydrindene hydrate (ninhydrin).

All of our observations upon the properties of the pancreatic and malt amylase preparations, including their behavior in solution in the presence and absence of substrate and in dialysis and coagulation, appear to be consistent with the following hypothesis as to their chemical nature, based on that suggested by Osborne in 1896:

Pancreatic and malt amylases, although not identical substances, may each be regarded as a complex protein consisting of an albumin fraction and a proteose (or peptone) fraction. In either case, when the enzyme is heated in water solution these parts are separated by hydrolysis and the

albumin fraction coagulated. Probably the same sort of hydrolysis takes place to some extent at room temperatures, or even in cooler solutions.

In the case of malt amylase this cleavage into albumin and proteose appears to be an easily reversible reaction, so that when simply standing in water solution the enzyme molecule is in equilibrium with its cleavage products and there is no rapid destruction of the enzyme by the water at ordinary temperature. If, however, such a water solution is placed in a dialyzer it deteriorates¹ much more rapidly, probably because of the removal of the dialyzable cleavage product. Since the diastatic power thus lost is only to a slight extent restored by subsequently mixing the dialyzate with the dialyzed solution, it appears probable that the dialyzable proteose fraction, when separated from the albumin fraction by the dialyzer membrane and exposed to the action of a relatively large amount of water, undergoes some further cleavage or other change which is evidently not readily reversible.

In the case of pancreatic amylase it would seem that a similar cleavage of the enzyme into an albumin and a proteose or peptone takes place, but that this action is much less readily reversible than in the case of malt amylase, so that on standing in water solution the pancreatic amylase deteriorates very much more rapidly. The fact that the boiled-down solution of the noncoagulable cleavage product gives a pinker color with the biuret reagent in the case of pancreatic than of malt amylase, suggests that the proteose fraction of the enzyme may more readily undergo further cleavage in the case of pancreatic amylase and that this may account for the fact that the enzyme is not (as in the case of malt amylase) protected from rapid deterioration by establishing equilibrium with its primary cleavage products.

Probably in both cases the amylolytic action involves first a combination of the amylase with the starch, and while in such combination the labile constituent of the enzyme is protected from destructive change. With pancreatic amylase this has the effect of greatly prolonging the "life" of the enzyme which would otherwise undergo rapid hydrolytic destruction as outlined in the preceding paragraph. On the other hand, with malt amylase the labile constituent is protected by the readily reversible character of the primary hydrolysis which results in the establishment of a condition of equilibrium in which most of the enzyme exists intact, so that there is only a very slow deterioration, even in the absence of the substrate, and the influence of the latter upon the duration of activity of the enzyme is therefore not readily demonstrable.

¹ Since in all of our work the activating salts are added to the optimum concentrate at the time of determining diastatic power, the deterioration cannot be attributed simply to the removal of electrolytes.

Summary.

The purified amylase preparations obtained from the pancreas and from malt are similar in many respects but are not identical substances.

Both are amorphous nitrogenous substances soluble in water or in 50% alcohol, but insoluble in concentrated alcohol or acetone.

Both show typical protein reactions in the Millon, xanthoproteic, tryptophane, and biuret tests.

Both contain 15 to 16% nitrogen and when examined by the Van Slyke method are shown to yield the eight forms of nitrogen distinguishable by this method (ammonia, melanine, arginine, lysine, cystine, histidine, and amino and nonamino nitrogen not precipitable by phosphotungstic acid) in proportions within the range of variation shown by such typical protein substances as casein, edestin, hair, and hemoglobin.

Both the pancreatic and the malt amylase preparations, when heated in solution, yield coagulated albumin and a proteose or peptone, the presence of the latter in the filtrate from the coagulum being shown by protein reactions and nitrogen content. The biuret reactions of these filtrates are pinker than those of the original enzyme solutions.

The malt amylase exerted its optimum diastatic (saccharogenic) power in a somewhat acid solution ($P_H^{+} 4.4 \pm 0.2$), whereas the optimum for the pancreatic amylase was slightly alkaline (P_H^{+} in the neighborhood of 8 to 8.5).

When each amylase is allowed to act upon soluble starch for thirty minutes at 40° under its optimum conditions of reaction and salt concentration, the pancreatic amylase shows a much higher activity than any yet obtained from malt. In such a test the pancreatic amylase forms about 10,000 times its weight of maltose, corresponding to a "new scale" diastatic power of 4,000 or a Lintner figure of about 6,000; the malt amylase forms about 4,000 times its weight of maltose giving a "new scale" diastatic power of 1570 or a Lintner figure of about 2350.

In long-digestion experiments at 40° the malt amylase has thus far been observed to form a total of 93,000 times its weight of maltose, whereas the pancreatic amylase has formed 1,200,000 times its weight of maltose.

The most highly purified preparations of pancreatic amylase show also a pronounced proteolytic action both upon casein and gelatin, while in the purified malt amylase preparations we have been unable to demonstrate any proteolytic activity.

In purified pancreatic amylase, the amylolytic and saccharogenic powers are concentrated in practically the same ratio; purified malt amylase of high saccharogenic activity does not show a correspondingly high amylolytic power, at least as measured by present methods.

In a solution of either amylase the activity deteriorates more rapidly the higher the temperature or the greater the dilution, but malt amylase

is always more stable than pancreatic amylase when simply standing in pure water solution.

On the other hand, pancreatic amylase is the more stable in 50% alcohol solution, and shows a more sustained activity in long-digestion experiments, in which there is present a relatively large amount of substrate together with such a concentration of "activating" electrolytes as had been found best adapted to each enzyme in the ordinary determination of diastatic power.

Both amylases deteriorate during dialysis, and much more rapidly at room temperature than at 5° to 10°. The increased deterioration in dialysis over simple standing in water at the same concentration is more readily demonstrable in the case of malt amylase.

The problem of the chemical nature of the enzymes is discussed in the light of the new observations on composition, coagulation, dialysis, activity, and deterioration.

We are greatly indebted to the Carnegie Institution of Washington for grants in aid of this investigation.

STUDIES ON THE ACTION OF EREPSIN.

By FRANK E. RICE.

Received February 4, 1915.

Since the discovery of erepsin by Cohnheim,¹ in 1901, it has been investigated principally from the point of view of the physiologist. The properties of erepsin and the nature of its action as an enzyme, independent of any function it may have in the animal organism, have been less studied.

Erepsin is known to readily attack peptones and polypeptids, resolving them into their constituent amino acids. Only a few proteins have been found to be digested to any great extent, casein being the most notable example.

Maximum ereptic activity is manifested in weakly alkaline media. Vernon,² in studying the action of erepsin on Witte peptone, found that, while small quantities of alkali accelerated the digestion by erepsin, in higher concentrations it injured the enzyme to some extent. He concluded, that "over a certain range of alkalinity these two opposite influences nearly neutralize each other."

For ereptic experimentation, pure intestinal juice, or, a solution of

¹ *Z. physiol. Chem.*, 33, 451-65 (1901); 35, 134-140 (1902); 49, 64-71 (1906); 51, 415-24 (1907).

² *J. physiol.*, 30, 330-70 (1903).

the enzyme prepared by extracting the macerated mucous coat of the small intestine with water or weakly alkaline solution, has been used. The latter preparations have been found to be more active.¹

No satisfactory method for standardizing the ereptic power of residues has ever been proposed. The activity of ereptic preparations has usually been only estimated by approximately determining the extent of digestion by them of polypeptids or peptones.

Experimental.

1. **Determination of Amino Nitrogen in Peptone Solutions.**—Witte peptone was found to be easily hydrolyzed by erepsin, and was used in all following experiments as substrate.

The hydrolysis of substances of peptone character is most accurately followed by determining the quantity of free amino nitrogen produced in the solution in the splitting up of the peptone molecules. Two methods for this determination have been principally used: the titration method proposed by Sørensen,² and the gasometric method of Van Slyke.³

The results obtained from these two methods have been compared by some investigators. White and Thomas⁴ preferred the Van Slyke method for their work. Abderhalden and Kramm,⁵ also Rogozinski,⁶ believed that the Sørensen method gave more reliable results.

Van Slyke pointed out that, among other things, the temperature of the reagents had an influence upon the apparent amount of nitrogen liberated in his apparatus. It seemed necessary to study the effect of temperature on the reaction in the apparatus, as well as the effect of time, which was shown by Abderhalden and Kramm to be considerable. The influence of the rate of shaking the apparatus was also determined.

The titration by the Sørensen method was carried out as suggested by the author. To 20 cc. of the peptone solution were added the neutralized formaldehyde-alcohol mixture and thymol phthalein; this was titrated with 0.2 *N* NaOH solution.

The Van Slyke apparatus was set up as described by the designer. It was connected with a motor, and during the reaction was shaken at the rate of about 250 vibrations per minute; the lower part of the mixing chamber passed through a distance of about three-fourths of an inch. Ten cc. portions of peptone were run each time, and 0.5 cc. amyl alcohol was added to prevent frothing.

³ *J. Biol. Chem.*, 9, 185-204 (1911); 12, 275-84 (1912).

⁴ *Ibid.*, 13, 111-16 (1912-13).

⁵ *Z. physiol. Chem.*, 77, 425-34 (1912).

⁶ *Ibid.*, 79, 398-414 (1912).

Experiment 1.—Witte peptone solution contained 3 g. per 120 cc. Result of the titration by the Sørensen method—4.28 mg. amino nitrogen per 10 cc.

Results obtained in the Van Slyke apparatus:

Temp. of reagents,	22.5	22.5	24	24	28	28°
Time of reaction,	6	8	6	8	6	8 minutes
Amino nitrogen per 10 cc.,	4.03	4.40	4.12	4.51	4.34	4.72 mg.

Experiment 2.—In this experiment a peptone solution was used that had been digested with erepsin for some time. Titration by the Sørensen method gave 19.26 mg. amino nitrogen per 10 cc.

Results obtained by the Van Slyke method:

Temp. of room and reagents,	15	15	15	23	23	27	27°
Time of reaction,	7	9	11	5	7	5	7 minutes
Amino nitrogen per 10 cc.,	19.12	19.77	19.77	19.84	20.52	20.28	21.27 mg.

Experiment 3.—To determine the effect of the rate of shaking the apparatus upon the quantity of gas evolved. The same peptone solution was used as in Experiment 2.

Rate per minute,	190	250	300
Time,	7	7	7 minutes
Temperature,	23	23	23
Amino nitrogen per 10 cc.,	14.41	20.52	21.20 mg.

From these experiments it must be concluded that the Van Slyke method for the determination of amino nitrogen gives unreliable results unless extreme precaution is taken to keep all the conditions constant. The accuracy of results obtained by the formol-titration method of Sørensen is in no way affected by the method of manipulation; furthermore, it has been found that a number of determinations of amino nitrogen may be made more rapidly by the titration method than by the use of the Van Slyke apparatus. For these reasons, the Sørensen method for the determination of amino nitrogen has been used in the following experiments.

2. Preparation of the Erepsin-containing Material.—For the most part the procedure suggested by Cohnheim was followed. The mucous coat of the small intestine was ground in a mortar with sand, 0.1% sodium carbonate solution, and a little toluol, and finally, allowed to stand at 38° for from one to ten days. This digest was made acid with acetic acid and filtered, whereby a clear, yellowish solution was obtained. To this was added saturated ammonium sulfate in the proportion of three parts to two of the enzyme solution. The residue, thus obtained, was removed by filtration and preserved in a desiccator over sulfuric acid.

In preparing a solution from this material, small quantities were shaken with 0.1% sodium carbonate solution, and dialyzed against flowing water for three to five days. (This length of time has always been found sufficient for the removal of ammonium salts.) This solution was used in digestion experiments with peptone. An aliquot portion was evaporated to dryness, and the loss on ignition of the solids determined. This weight has been taken as the quantity of enzyme present in the solution.

3. Action of Erepsin on Solutions Containing Varying Amounts of Peptone.—Peptone solutions of different concentrations were prepared, and allowed to be acted on by equal quantities of erepsin. In this, as well as in all succeeding erepsin digestion experiments, liberal use was made of toluol as preservative, and the digestion temperature was always 38° .

AMINO NITROGEN PER TEN CC.

At beginning,	3.08	4.07	5.14 mg.
End of ten hours,	5.47	6.61	7.81 mg.
Increase,	2.39	2.54	2.67 mg.

It is seen that the amount of amino nitrogen split off from the peptone molecule by erepsin varies considerably with the initial concentration of the peptone solution. Therefore, in all following experiments care was taken that the digesting solutions were of the same concentration with reference to peptone. This was brought about in the following way: A peptone solution was prepared by boiling four or five grams of Witte peptone per 100 cc. of water, cooling, and filtering. Amino nitrogen was determined in the filtrate. For digestion experiments this peptone solution was diluted so that it finally contained 3.5 mg. amino nitrogen per 10 cc. A determination of total nitrogen by the Kjeldahl method shows such a solution to contain 33.46 mg. nitrogen per 10 cc.

4. The Digestion of Peptone by Erepsin as Affected by the Degree of Alkalinity.—In the following experiments the quantity of peptone in solution, also the quantity of erepsin, remained constant; the quantity of sodium hydroxide was varied. Digestions were run for ten hours.

Experiment 1.—

CC. of 0.2 N NaOH per 60 cc.,	1	2	4	5	6
Increase in mg. amino nitrogen per 10 cc.,	2.34	2.66	2.66	2.17	1.44

Experiment 2.—

Cc. of 0.2 N NaOH per 60 cc.,	1.7	2.0	2.5	3.0	3.5
Increase in mg. amino nitrogen per 10 cc.,	1.85	1.85	1.83	1.85	1.80

There seems to be no definite point which would be considered optimum for ereptic action. The addition of 1.7 to 4 cc. of 0.2 N NaOH per 60 cc. of the digesting solution accelerates the digestive action to about the same extent; and, the activity is seen to be diminished where alkali is added in greater or less quantities.

In all succeeding experiments, digesting solutions contain 2 cc. 0.2 N NaOH per 60 cc.

5. Action of Alkali on Peptone.—Vernon found that sodium carbonate had a slight hydrolytic action on peptone as measured by the biuret method. In the following experiment a solution of peptone was prepared of the same strength used in the erepsin determinations; each 60 cc. contained 2 cc. of 0.2 N NaOH. The solution was preserved with toluol, and allowed to stand at 38° . At intervals, portions of the solution were

titrated by the formol-titration method and the amount of aminonitrogen calculated.

Time,	0	1	4	10	34 days.
Amino nitrogen per 10 cc.,	3.50	3.53	3.53	3.53	3.50 mg.

There is no hydrolysis of peptone by alkali of the strength used in erepsin digestions.

6. Course of the Digestive Action of Erepsin on Peptone with Regard to Time.—In this experiment the amounts of peptone and sodium hydroxide in the solutions are constant, and the amount of erepsin is varied: A, 3.81 mg.; B, 7.62 mg.; C, 13.33 mg. per 60 cc. of solution. Results are expressed in mg. amino nitrogen per 60 cc.

Time, 0	4	7	10	13	24	52	144	840 hrs.
A,	21.18	25.68	28.62	32.76	33.84	42.66	54.26	123.50
B,	21.18	28.92	34.02	40.80	43.50	56.34	75.26	113.40
C,	21.84	34.80	42.18	50.82	55.68	72.43	93.32	135.24

By plotting the quantity of amino nitrogen in solution with time (see Fig. 1), it is seen that the "curves" are nearly straight until after ten

FIG. 1.

hours, *i. e.*, the quantity of amino nitrogen split off by the enzyme is nearly proportional to the time, at the beginning of the reaction. After ten hours, however, there is less and less hydrolysis per unit of time and the curves approach one another (Fig. 2). This latter phenomenon was also pointed out by Bayliss in the action of trypsin on caseinogen.¹

Since hydrolysis seemed to proceed at a uniform rate during the first

¹ Bayliss, "The Nature of Enzyme Action."

ten hours, digestions were run for this length of time in the following experiments where comparative results were required.

FIG. 2*.

7. Digestion with Varying Amounts of Erepsin.—All solutions were prepared as follows: Enough strong peptone solution was measured out to contain 21 mg. of amino nitrogen. To this was added 2 cc. 0.2 *N* NaOH, the erepsin solution, enough water to make 60 cc., and about 8 drops of toluol. Digestions were allowed to proceed for ten hours at 38°. At the beginning and end of the ten hour period, 20 cc. portions were titrated, and the quantity of amino nitrogen calculated in mg. per 60 cc.

Mg. erepsin per 60 cc.,	1.25	2.50	5.00	7.50	10.00	15.00	20.00
Mg. amino nitrogen produced,	6.00	10.08	16.80	22.68	28.20	37.02	44.68

In the study of the action of erepsin on deuteroalbumose, Kutscher and Seeman¹ found the amount digested to be proportional to the square root of the concentration of the erepsin. This may be represented by the formula

$$N/E^{1/2} = \text{constant},$$

where *N* is the amount of hydrolysis produced by *E*, the amount of erepsin.

If, however, the amount of hydrolysis is proportional to the amount of active enzyme, as has been found in the case of some enzymes, the following formula should hold:

$$N/E = \text{constant}$$

In the following table the above figures have been applied to these

¹ *Z. physiol. Chem.*, 35, 432-58 (1902).

formulae: (N and E are taken in mg. amino nitrogen and erepsin per 60 cc., respectively).

E,	1.25	2.50	5.00	7.50	10.00	15.00	20.00
N,	6.00	10.08	16.80	22.68	28.20	37.02	44.88
N/E $\times 100$:	480	403	336	302	282	247	224
N/E ^{1/4} $\times 100$:	537	637	752	828	891	955	1003

This would indicate that neither the direct proportion nor the square root law hold; but the ratio which would most nearly yield a constant should be found between the two.

The ratio, which has been found to apply for nearly all erepsin preparations studied, is $-N/E^{1/4} = \text{constant}$. In the following table the above results are applied to this formula:

E,	1.25	2.50	5.00	7.50	10.00	15.00	20.00
N,	6.00	10.08	16.80	22.68	28.20	37.02	44.88
N/E ^{1/4} $\times 100$:	508	507	502	500	501	485	474

This rule is seen to hold quite well within the limits of experimental error, where the extent of hydrolysis is not too great. In the last two solutions the reaction proceeded so rapidly that the accumulating products have checked the action of the enzyme.

In a similar manner the results obtained on page 323 may be used:

E,	3.81	7.62	13.33
N,	11.58	19.62	28.98
N/E ^{1/4} $\times 100$:	425	428	416

Still another preparation gave similar results:

E,	5	10	15	20
N,	9.12	15.96	21.12	26.58
N/E ^{1/4} $\times 100$:	273	284	277	281

In all the above cases the erepsin was obtained from the dog. The following results were obtained on erepsin extracted from the horse intestine:

E,	9.8	14.7	19.6	29.4
N,	6.90	9.60	11.82	17.10
N/E ^{1/4} $\times 100$:	125	128	127	135

In the following table numbers I and II show the rule to apply to the action of erepsin obtained from the rabbit, erepsin from the cat (III) shows similar results. The figures under IV were obtained for a solution of erepsin from a dog, which had stood at about 12° for one year.

					III. Cat.		IV. Dog.	
E.....	9.8	9.96	11.8	23.6	4.5	9.0	4.2	8.4
N.....	19.6	16.68	9.42	15.48	4.13	6.47	7.14	12.24
N/E ^{1/4} $\times 100$	180.0	179.0	148.0	145.0	133.0	125.0	243.0	248.0

It is not claimed that erepsin will act according to this law on all substrates and under all conditions, but under the peculiar conditions of these

experiments the law has been found to hold well within the limits of experimental error.

8. A Method for Comparing Ereptic Power of Extracts.—As has already been pointed out, if a solution of Witte peptone of such strength that there is present 21 mg. amino nitrogen per 60 cc., containing also 2 cc. 0.2 *N* NaOH, be acted upon by erepsin for ten hours, the amino nitrogen liberated will be proportional to the weight of erepsin raised to the three-fourths power, provided, further, that there is not greater enzyme activity than which would liberate more than 30 mg. of amino nitrogen per 60 cc. In other words, $N/E^{3/4}$ is constant under the conditions stated, where *N* = the amount of amino nitrogen produced, and *E* = weight of erepsin extract.

In the following experiments where activity of erepsin preparations was to be compared, the constant— $N/E^{3/4} \times 100$ —was determined for each; quantities *N* and *E* were taken in milligrams. This value was designated as *ereptic power*.

9. Purification of Enzyme Extracts.—Very few attempts have been made to prepare erepsin in any state of purity. Cohnheim tried several methods of purification but was unable to get a preparation free from protein. Euler¹ and Raubitschek² used special methods for preparing erepsin solutions from the mucous coat, but have not compared the power of these preparations with those obtained by the simpler methods first suggested by Cohnheim.

Cohnheim used an alkaline physiological salt solution for extracting the enzyme from the mucous coat. Erepsin-containing residues were precipitated from these solutions by the addition of saturated ammonium sulfate in the proportion of three parts to two of the enzyme solutions. Some experiments were made to determine the effect of carrying out these details upon the ereptic power of the preparations finally obtained.

Experiment 1.—Equal portions of the mucous coat were digested with equal quantities of the following: A, 0.1% sodium carbonate solution; B, water; C, 0.1% acetic acid solution. Erepsin extracts were obtained from these with ereptic power as follows:—A 144, B 144, C 88.

The use of 0.1% sodium carbonate solution containing 0.9% sodium chloride, and of a solution of 0.1% sodium carbonate alone, was tested similarly. The former solution yielded an extract with ereptic power, 215, and the latter, 248.

It seems that there is no advantage in digesting the mucous coat with alkaline solution, nor in using an alkaline solution containing sodium chloride, over digesting with pure water. Digestion with weak acid seems to injure the enzyme slightly.

Experiment 2.—In this experiment three extracts were prepared: A.—After the digestion of the mucous coat with 0.1% sodium carbonate solution, the mixture was

¹ *Z. physiol. Chem.*, 51, 213-25 (1907).

² *Z. exp. Path. Ther.*, 4, 674-80 (1907).

acidified and filtered, and a portion was dialyzed for ten days. (This length of time was found necessary for the removal of substances titratable by the formol-titration method.) B.—To a portion of the filtrate obtained in A, ammonium sulfate was added to one-third saturation. This was filtered, the residue discarded, and to the filtrate ammonium sulfate added to two-thirds saturation. Upon again filtering the residue was suspended in 0.1% sodium carbonate, dialyzed, and filtered. C.—To a portion of the filtrate obtained in A, ammonium sulfate was added to two-thirds saturation at once, and the residue treated as in B. The ereptic power of the enzyme in solution A was found to be 153, solution B 180, solution C 180.

These results indicate that there is no advantage in fractional precipitation with ammonium sulfate, and that only slightly more active residues may be obtained by the use of ammonium sulfate at all. In another experiment the erepsin in the original solution after dialysing was even more active than that obtained by precipitating with ammonium sulfate.

Other conditions being identical, it has been found that the longer the time of contact of the macerated mucous coat with the solvent, the more powerful the erepsin preparations obtained. Mucous coat from a cat was divided into two portions and each digested with 0.1% sodium carbonate solution: (1) for five days, (2) for ten days. The ereptic power of the preparation finally obtained from (1) was found to be 175, and that from (2), 240. It has usually been found that very little is gained by extracting the mucous coat more than ten days.

Sörensen¹ obtained erepsin solutions by pressing the juice from the mucous coat by means of the Büchner press.

In two cases, pressed juice was obtained from portions of the mucous coat by means of the Büchner method.² These solutions were precipitated by saturated ammonium sulfate solution. Residues thus obtained exhibited much less ereptic power than those obtained by the solution method. Furthermore, by extracting the cake remaining behind in the press, with 0.1% sodium carbonate, it was found that the greatest part of the erepsin had been adsorbed, and that this portion was more active than that which was pressed out.

Other methods that were tried for preparing more active erepsins, *i. e.*, preparations with less admixture of impurities, included the Jacoby uranyl phosphate method,³ precipitation of the enzyme or its impurities along with cholesterol,⁴ precipitation with alcohol, and extracting the erepsin-containing precipitates with organic solvents. In none of these instances was there obtained a preparation of greater ereptic activity than that resulting from the direct solution of the mucous coat and dialyzing.

¹ *Biochem. Z.*, 7, 45-101 (1908).

² Abderhalden, *Handbuch der chemischen Arbeitsmethoden*, 3, 394.

³ *Z. physiol. Chem.*, 30, 135-48 (1900).

⁴ Schrumph, *Beitr. chem. Physiol. u. Path.*, 6, 396-97 (1905).

Adsorbents were found useful by Michaelis¹ in separating invertin from its protein admixture. The following experiment exhibits the behavior of erepsin in contact with kaolin and hydrated aluminum oxide.

To each of three equal quantities of erepsin solution was added 1 g. of kaolin. One (A) was made slightly acid with hydrochloric acid; a second (B) was made alkaline with sodium hydroxide; the third (C) remained neutral. All were made up to the same volume, shaken five minutes, and filtered. Ereptic activity of the filtrates was determined with the following results:

E	(A), 5.7	(B) 17.3	(C) 10.2
N,	0	14.03	10.07
Ereptic power,	0	165	176

The original solution had an ereptic power of 160. Kaolin in neutral or alkaline solution seems to remove more impurity than enzyme, however, the increase in ereptic activity produced by this treatment is not of such magnitude that it may be considered very important in preparing more powerful residues.

A suspension of hydrated aluminum oxide was prepared by adding ammonium hydroxide to a solution of aluminum acetate, and washing the precipitate by decantation several times. In a manner similar to that described above, the action of this on erepsin in acid, alkaline, and neutral solution was tested. It was found in all three cases that the enzyme was completely adsorbed from its solution by the hydrated aluminum oxide.

The results obtained in this experiment are of interest principally in the consideration of erepsin as a colloid.

10. Action of Erepsin on Blood Fibrin.—Certain investigators have found blood fibrin to be slightly digested by erepsin, others have concluded that there was no action. Cohnheim believed that fibrin was not attacked. Kutscher and Seeman found slight action. Vernon believed that erepsin had little or no action. Weinland² found that fibrin was slightly digested by extracts made from the intestinal mucous coats of the pig, however, he believed this to be due to the presence of trypsin which he was unable to wash from the intestines with which he worked.

In the following experiment the action of erepsin on dried blood fibrin was tested. Portions were added to erepsin solutions, some sodium hydroxide solution added, and the whole made up to 50 cc. In all cases toluol was added as preservative. Digestion was allowed to proceed at 38°. At the end of the digestion periods, the solutions were filtered, brought to the neutral point using neutral red as indicator, and the amino nitrogen in solution determined by the titration method of Sørensen.

¹ *Biochem. Z.*, 7, 488-92 (1908).

² *Z. Biol.*, 45, 292-97 (1903).

Experiment 1. Effect of varying the degree alkalinity.—In each case there was present 1 g. of fibrin, and 33 mg. of erepsin per 50 cc. To A was added 0.25 cc. 0.2 *N* NaOH, to B 1.5 cc. In the blank (C) was used 1.5 cc. 0.2 *N* NaOH, but no enzyme. The digestion ran three days. Upon determining the quantities of amino nitrogen in the filtrates, the following results were obtained: A 2.8 mg. per 10 cc., B 0.42 mg., C 0.28 mg.

It is seen that in a very weakly alkaline solution, erepsin attacked commercial fibrin quite vigorously, however, where 1.5 cc. 0.2 *N* NaOH was added, the quantity of amino nitrogen split off was very little greater than that in the blank. It has been found that the action of trypsin upon fibrin is very little hindered by the presence of NaOH in the higher concentration. Equal quantities of trypsin acting upon one gram of fibrin for three days produced 4.62 mg. of amino nitrogen per 10 cc. of filtrate when 0.25 cc. 0.2 *N* NaOH was present in 50 cc., and 4.20 mg. when 1.5 cc. was present. These facts can be made use of in testing erepsin preparations for presence of trypsin. In the following case this is illustrated:

A solution containing 23 mg. of erepsin (from horse), and 1.5 cc. 0.2 *N* NaOH was made up to 50 cc., and 1 g. fibrin added (A). Another solution (B) was prepared similarly, 5 mg. trypsin being added instead of erepsin. A third preparation (C) contained 23 mg. of the same erepsin, 5 mg. trypsin, and the same quantity of sodium hydroxide. The blank (D) contained only sodium hydroxide and fibrin. Digestion was run three days. Filtrate from A was found to contain 0.63 mg. amino nitrogen per 10 cc.; B, 1.74, C, 2.17 mg.; D, 0.56 mg.

Experiment 2. Action of Erepsin on Fresh Blood Fibrin.—A quantity of fibrin was obtained by whipping fresh horse blood. This was washed, first in flowing water to remove the main part of the blood, then, ground in a mortar to break up the large clumps, and again washed many times by decantation with hot water and 10% sodium chloride solution—finally with hot water to remove all sodium chloride. The action of erepsin and trypsin on this material was tested in a way similar to that described above. In all tests there were approximately equal amounts of fibrin.

(A) contained erepsin and 0.25 cc. 0.2 *N* NaOH. (B) contained an equal quantity of erepsin and 1.5 cc. 0.2 *N* NaOH. In (C) and (D) were equal quantities of trypsin, also 0.25 cc. and 1.5 cc. 0.2 *N* NaOH, respectively. (E) was run as a blank—1.5 cc. 0.2 *N* NaOH, but no enzyme. All solutions were made up to 50 cc. Digestions were run for three days. In the filtrate from (A) was found 1.4 mg. amino nitrogen per 10 cc.; (B), 0.21; (C), 2.17; (D), 2.31; (E), 0.

This shows that erepsin has considerable action of fresh blood fibrin, also; and it is seen again that the higher concentration of alkali almost completely checks the action of erepsin but does not hinder the digestive action of trypsin on fibrin.

11. Action of Erepsin on Gelatin.—Hamburger and Hekma,¹ using the intestinal juice of man, found no action on gelatine.

A solution of gelatin was prepared by dissolving five grams in 200 cc. of hot water, and adding 8 cc. of 0.2 *N* NaOH. Digestions were made as follows:

¹ *J. physiol. Path. gén.*, 4, 805-19 (1902).

(1) To 60 cc. of gelatin solution were added 15 cc. (containing 17 mg.) of erepsin; (2) to 60 cc. of gelatin solution were added 15 cc. (containing 15 mg.) of trypsin; (3) was run as blank—60 cc. gelatin solution plus 15 cc. water. Amino nitrogen, as determined by the formol-titration method, was per 10 cc.

	(1).	(2).	(3).
At beginning.....	0.74	1.09	0.67
End of twenty hours.....	3.29	2.94	0.67
End of two days.....	4.86	3.18	0.65

The erepsin used in the above experiment was obtained from a rabbit, and it was found by testing its action on fibrin to be free from trypsin. The experiment shows the action on gelatin to be very great, certainly no less than that produced by an equivalent amount of trypsin.

12. Erepsin as an Autolytic Enzyme.—Kutscher and Seeman found that if the mucous coat of the small intestine be allowed to stand under toluol or chloroform, autodigestion takes place.

Some observations were made to determine whether or not autodigestion of the mucous coat of the small intestine was in any way related to the presence of erepsin. The ground mucous coat was allowed to stand under water, or weak solutions of acid, or alkali, with toluol as preservative. All solutions were made acid and filtered. Portions of the filtrates were neutralized, using neutral red as indicator, and the amino nitrogen determined by the formol-titration method. The quantity of amino nitrogen was taken as a measure of the extent of autolysis.

In this experiment the intestinal mucous coat of the cat was divided into three portions, and digested for five days at 38° with the following solutions: (1) 0.1% sodium carbonate, (2) water, (3) 0.1% acetic acid. Determination of amino nitrogen in the filtrates gave the following results: (1) 11.2 mg. amino nitrogen per 10 cc., (2) 9.5 mg., (3) 6.8 mg.

If autolysis can be measured by the amount of amino nitrogen produced, these results show that in this case it takes place to the greatest extent in alkaline solution, whereas, in most tissues this process has been found to be most active in acid media.

It has been found that in cases where autolysis of the tissue had been most active, more powerful erepsin preparations could be obtained. The following example illustrates this:

The intestinal mucous coats of two dogs were extracted with approximately equivalent quantities of 0.1% sodium carbonate solution. Filtrate from (A) was found to contain 10.8 mg. amino nitrogen per 10 cc., from (B) 35.9 mg. Ereptic power of the preparation obtained from solution (A) was 200, from solution (B) 440.

These results, together with the fact already mentioned—that somewhat more powerful preparations could be obtained by allowing the initial extraction of the mucous coat to continue for a longer period of time, would lead to the conclusion that autolysis of the mucous coat tissue is related to the activity of the erepsin.

In the following experiment the intestinal mucous coat of a cat was

divided into two portions. From one part, erepsin was prepared in the usual way. This preparation was believed to be free from other enzymes. The fibrin test for trypsin was negative; also, the constant, $N/E^{1/4}$ was found to hold when testing its action on peptone. The remainder of the mucous coat was heated to destroy enzymes present. This was thrown on cheese cloth and carefully washed with water. Only the larger portions of the tissue were then used:

(1) To a part of the mucous coat was added the erepsin, 0.5 cc. 0.2 *N* NaOH and water to make 30 cc.; (2) this was run as blank and contained 0.5 cc. 0.2 *N* NaOH and water only. These preparations were digested ten days at 38°, then filtered. Filtrate from (1) was found to contain 3.4 mg. amino nitrogen per 10 cc., (2) 0.4 mg.

While these results seem to show that erepsin may be the cause of autolysis in the tissue of the mucous coat of the small intestine, it is not proved, however, that, in addition, other autolytic enzymes are not present in the fresh tissue.

13. Permanence of the Enzyme.—The ereptic preparations have generally been preserved in one of two ways: (1) the residue obtained from the precipitation of ammonium sulfate, kept in a desiccator over sulfuric acid; (2) a solution in water that has been dialysed and is neutral, and kept at a temperature of 10° to 15°.

A preparation obtained from the horse, and preserved according to the former method, had an ereptic power at the beginning of 109; at the end of eleven days, 105; thirty-five days, 102; sixty days, 97. Dog erepsin residues gave the following results: ereptic power of the fresh residue, 278; the same, fifty days old, 232. Another preparation from the dog showed an ereptic power of 119 when fresh, but after ten months it had fallen to 58.

Some results on the loss in activity of the dialysed aqueous solution are as follows: A solution containing dog erepsin had, when fresh, ereptic power of 277, at the end of ten days, 262. Fresh solution containing horse erepsin exhibited a power of 100; at the end of ten days, 86.

The following results on two dog erepsin preparations show the change on standing in aqueous solutions for longer periods: Fresh solution, ereptic power, 338 and 425; 8 months old, 248 and 254; 12 months old, 222 and 245.

Vernon recommended dilute alcohol as a preservative for erepsin. However, Cohnheim believed that treatment with alcohol weakened the enzyme. In this experiment a solution of dog erepsin with ereptic power of 320 was divided into two portions and treated as follows: to (1) was added one-half volume of alcohol, and to (2) was added the same quantity of water. At the end of six months the ereptic power of (1) was 196, and of (2) 220. These results show that weak alcohol does have an injurious action on erepsin, and that it is better to preserve the enzyme in water.

14. Effect of Bacterial Growth in Erepsin-containing Solutions.—

In a number of cases where the preservative was allowed to disappear from erepsin preparations, or, where the preservative was added in insufficient amounts, very marked bacterial decomposition took place. This was accompanied by the appearance of a tryptic enzyme in the solutions. Accordingly, such solutions became useless for ereptic experimentation; they exhibited strong action on fibrin and the three-fourths law was found to no longer hold.

A portion of a solution which had become contaminated, acting on 1 g. of fibrin for two days, produced 7 mg. soluble amino nitrogen per 10 cc., when there was present 1.5 cc. 0.2 *N* NaOH. The same solution gave the following results when tested on peptone:

E,	20	30	40	50
N,	11.10	14.10	16.38	18.30
$N/E^{3/4} \times 100$:	117	110	103	97

Some of the ammonium sulfate residues became decomposed, and showed similar results. Likewise, in some cases where the intestine was not used for a number of days after the death of the animal, enzyme preparations obtained, gave results of a similar order. It is therefore necessary to guard against bacterial growth in the preparation of enzyme solution by the liberal use of toluol. Many times thymol may be added to advantage in addition to toluol.

Summary and Conclusions.

Witte peptone is quite readily hydrolyzed by erepsin. The extent of hydrolysis may be measured by determining the quantity of free amino nitrogen split off from the peptone molecules. The Sørensen formol-titration method was found more satisfactory than the Van Slyke method for the determination of free amino nitrogen in peptone solutions.

The quantity of amino nitrogen split off by the action of erepsin on peptone varies with the amount of peptone in solution.

The extent of hydrolysis of peptone produced by moderate amounts of erepsin during the first ten hours is directly proportional to the time.

The quantity of amino nitrogen split off during the first ten hours is proportional to the weight of erepsin raised to the three-fourths power. This was found true for preparations obtained from the dog, cat, rabbit, and horse.

Most active erepsin preparations may be obtained as follows: The small intestine, obtained as soon as possible after the death of the animal, is split open, and washed well with running water. The mucous coat is scraped away with a piece of glass. This is ground with sand and a little water in a mortar, transferred to a 0.1% sodium carbonate solution, and allowed to stand with frequent shaking at 38° for ten days. A preservative must be present. The suspension is then filtered through cheese

cloth, and the filtrate made slightly acid with acetic acid. Upon allowing to stand in a warm place for a short time the suspended matter flocculates, and may be rapidly filtered off, using an ordinary filter. The filtrate is dialysed against flowing water for ten days. A nearly colorless solution is thus obtained, which responds to the biuret test very weakly; it contains only a trace of amino nitrogen. It exhibits ereptic action quite strongly.

Erepsin is completely adsorbed from acid, alkaline, and neutral solutions by aluminum hydroxide; it is also adsorbed by kaolin in acid solution. It is not in the least adsorbed by kaolin from neutral or alkaline solution.

Erepsin attacks fibrin in very weakly alkaline solution. Upon slightly increasing the amount of alkali in solution (1.5 cc. 0.2 *N* NaOH per 50 cc.) there is practically no action. While ereptic action on fibrin is held in check by this strength of alkali, tryptic digestion is scarcely hindered. This fact may be made use of in testing erepsin preparations for the presence of trypsin.

Erepsin hydrolyses gelatin very rapidly.

Experiments indicate that erepsin attacks the tissue of the mucous coat of the small intestine, from which it may be concluded that it is the enzyme, or one of the enzymes, inducing autolysis of that tissue. Autolysis in this case is greatest in alkaline solution.

The residues obtained by precipitation with ammonium sulfate and preserved dry, seem to lose in ereptic power somewhat more rapidly after the first few days than neutral aqueous solutions. Dilute alcohol is a less satisfactory medium for preserving erepsin than water.

Bacterial growth should be prevented in all stages of the preparation of erepsin, since it may be accompanied by the production of proteolytic enzymes.

The writer wishes to express his thanks to Professor Andrew Hunter at whose suggestion this work was begun, and who took an active interest in its progress. Professor M. Dresbach and Mr. A. E. Livingston of the Cornell Medical College kindly provided most of the animal intestines used.

ITHACA, N. Y.

ON THE PHYSIOLOGICAL ACTIVITY OF COMBINED HYDROCHLORIC ACID.¹

By J. H. LONG.

Received March 26, 1915.

The question of the efficiency of hydrochloric acid, when combined with different compounds in the digestion of proteins by pepsin, has

¹ This investigation has been made with the assistance of a grant from the Committee on Therapeutic Research, Council on Pharmacy and Chemistry, American Medical Association.

received much attention in earlier years but has been settled only in a very general way. The acid combined with inorganic bases is of course inactive in this direction, but as to the behavior of proteins or protein derivatives in combination there was, and there is yet, some dispute.

The early discussions of the question we find between 1880 and 1890; when, by the introduction of new indicators, the conception of acid held by protein could be more easily followed. Slightly earlier than this Hoppe-Seyler had made the observation that hydrochloric acid gradually combines with the products of peptic digestion and that the rapidity of digestion diminishes because of this combination.¹ Danilewski, in 1880,² discusses the nature of this acid combination and refers the property to the gradual formation, or liberation, of bodies of amine character. With the progress of digestion the amounts of these would increase. To follow the changes in the amount of free acid or free alkali after treatment of protein with an excess of either, he recommends the use of tropaeolin oo and ooo. His observations were somewhat inexact, however.

The use of phloroglucin and vanillin mixture as an indicator for "free" acid was introduced by Guenzburg in 1887,³ and the sugar and resorcinol mixture by Boas a little later.⁴ Congo red seems to have been recommended for physiological investigations somewhat earlier. Through the aid of these indicators it became possible to study much more conveniently the behavior of hydrochloric acid in artificial digestion processes, as well as in the stomach. The distinction between the behavior of phenolphthalein and methyl orange in the titration of digestion mixtures was gradually cleared up.

It was shown by v. Pfungen⁵ and others that the hydrochloric acid which combines with protein is so loosely held that it may be dissociated more or less readily by dilution with water, although there is no separation by dialysis. For this reason the proposed method for the recognition of free hydrochloric acid by the addition of cinchonine and extraction with chloroform must be of no value in the separation of actually free hydrochloric acid in excess over the protein. However, the differences in behavior between the more complex proteins and their derivatives or digestion products was not at this time recognized.

An important addition to the methods for the identification of actually "free" acid was made by F. A. Hoffmann⁶ when he proposed to employ the speed of the inversion of cane sugar as a measure of acidity present

in such cases where protein is concerned. The method had been used successfully in other mixtures. In these papers the notion of mass action in the combination of acid and protein is brought out sharply, as well as the disturbance through dissociation by water. Substances like peptone hydrochloride and betain hydrochloride dissociate in water and permit the acid to act as physiologically free. But substances like quinine hydrochloride, on the other hand, hold the acid in such combination that it is not available for peptic digestion. The distinction is brought out by E. Salkowski and M. Kumagawa,¹ who were able to show that hydrochloric acid combined with leucine or other amino acid so as to form a chemically neutral salt is still physiologically active, since in aqueous solution the acid leaves the leucine and promotes peptic digestion.

In a later publication, following criticism of this point of view by Rosenheim² and Hoffmann,³ Salkowski⁴ goes more fully into the subject and shows the conditions under which the hydrochloric acid may become inactive. This follows when a very large amount of egg albumin or fibrin is digested with a limited amount of the leucine hydrochloride or similar substance. It might have been pointed out that digestion with ordinary free acid would be very slow, or might even fail, under the same conditions. This last view is a contradiction of the one advanced by Schiele,⁵ according to which the only active acid is that which is already in combination with protein. The so-called free acid would be useful only in combining with the digestion products formed beyond the albumose stage. As these products of hydrolysis are formed, more and more acid will be taken up. Any excess of acid beyond this may be harmful, or at any rate unnecessary.

The rather numerous investigations which have appeared on the question of the behavior of combined hydrochloric acid leave a number of points still undecided. The real activity of the acid in presence of an excess of protein calls for a fuller study, and especially by aid of the electrometric methods which permit a determination of true acidity without the introduction of anything to disturb existing conditions of equilibrium. In the work to be described below, the digestive activity of hydrochloric acid combined with certain amino acids, on the one hand, and with complex proteins, on the other, is compared. As the experiments in this investigation are practically all comparative, digestion is measured by the simple means of filtration and Kjeldahl determinations of the soluble nitrogen. For the purpose this affords a satisfactory measure of what may be called "digestion."

1. The Behavior of Betain Hydrochloride.

This substance was chosen to illustrate the behavior of an amino acid-like body, because of its comparatively simple structure, and the ease with which it may be obtained in pure condition. It may be secured from chemical dealers and at the present time is obtainable, also, in nearly pure form under the name of *acidol* from one of the large German chemical companies. The original source is the residue from beet-sugar manufacture. The free hydrate has been given the formula $(\text{CH}_3)_3 \equiv \text{N} \cdot \text{OH} - \text{CH}_2\text{COOH}$, while the hydrochloride is $\text{Cl}(\text{CH}_3)_3 \equiv \text{N} - \text{CH}_2\text{COOH}$. For the experiments below the commercial product was crystallized from hot alcohol. The purified salt, on titration with 0.1 *N* alkali and phenolphthalein, gave a sharp result for the halogen acid present. The end point in the titration with methyl orange is nearly as sharp, but the volume of alkali added is slightly less. In other words, the basic behavior comes slightly in evidence here. The titration with alkali and phenolphthalein is complete. What is the actual $[\text{H}]$ ion concentration in solutions of this salt? To determine this a series of solutions were made to contain definite amounts of HCl . These solutions were used in digestion experiments to be given. The hydrochloride used, as crystallized above, had a purity of 98.2%, shown by silver and alkali titrations.

In preliminary experiments on the rapidity of digestion by aid of pepsin I used in one instance 5 g. of fibrin with 4.42% of nitrogen, 50 mg. of pepsin, 500 mg. of the hydrochloride and 50 cc. of water. The mixture was digested at 40°. In two hours the reaction was far advanced, with most of the fibrin in solution, but it was continued fourteen hours longer, sixteen hours in all. The mixture was boiled and filtered, the residue being well washed. In the filtrate the soluble nitrogen was found to be 231.7 mg., as the mean of two experiments. This is greater than the total nitrogen of the fibrin, but must be diminished by the nitrogen of the betain hydrochloride and the pepsin, 45.5 mg. $231.7 - 45.5 = 186.2$. As the total fibrin nitrogen was 221 mg. the result shows a digestion value of 84.2%.

In a similar experiment with eggs I employed the coagulum from 1.2 g. of egg albumin powder containing 70% of dry protein. In the mean of two experiments the nitrogen found was 131.6 mg. This must be diminished by the nitrogen of a blank experiment in which killed pepsin was used. At the end of each digestion the mixtures were exactly neutralized with sodium hydroxide, boiled and filtered. In this way the neutralization precipitate was excluded. $131.6 - 44.1 = 87.5$ mg. of nitrogen from the more advanced digestion, which was practically completed in two hours, but which was continued over night as above.

These experiments indicate an advanced degree of digestion, and

nearly as much as would have been obtained by the use of the equivalent amount of free hydrochloric acid.

For most of the experiments detailed below a solution was used which contained 10.69 g. of the betain hydrochloride dissolved in water to make 500 cc. This corresponds to 2.5 g. of actual HCl in the water volume, or 25 mg. HCl to 5 cc. of solution.

Experiments were now made with a constant volume of liquid, weight of pepsin, weight of egg, but variable acid product, the digestions being carried uniformly through four hours. In each test the weights were as follows:

Coagulum from 1.5 g. egg albumin = 1.06 g. protein.

Pepsin 15 mg. in 30 cc. solution.

Liquid volume made always to 60 cc.

At the end of the digestion, conducted at 40°, the mixtures were boiled and filtered. The slight residues were well washed and the total filtrates used for nitrogen determinations. The volumes of betain hydrochloride solution taken contained the equivalents of 25, 50, 75, 100, 125 and 150 mg. of actual HCl and would furnish, therefore, a considerable amount of nitrogen to the filtrate. The volume in test A was 5 cc., containing 106.9 mg. of the hydrochloride and, therefore, 9.6 mg. of N. This weight is subtracted from the result of the Kjeldahl, and corresponding amounts in the other tests. The pepsin N is too small to be noted here.

The results of the Kjeldahl determinations are given below, and the values are corrected for the betain hydrochloride N. It is assumed that all the nitrogen from this source came through in the filtrate, which is probably correct for a test carried out in this manner. When neutralization is effected before filtering, however, some of the betain may be separated and precipitated with the neutralization product.

E	125	0.1526	0.9538
F	150	0.1618	1.0112

A parallel set of experiments was carried out, using free hydrochloric acid in place of the betain hydrochloride of Table I. The conditions of the tests were otherwise the same. It was observed that the digestions began somewhat earlier and for a time appeared to be more marked than with the betain salt. At the end of the period of four hours the extent of the digestion in the two cases was nearly the same, with the advantage slightly in favor of the free acid, as shown in Table II.

As showing, further, the rapid digestive action of the betain hydrochloride experiments were made with fibrin, as with the egg. In each test 3.9 g. of fibrin, equivalent to 1.06 g. of protein, were used. The total liquid volume was 60 cc., containing varying amounts of the betain salt and 15 mg. of pepsin. The digestion time was three hours at 40°. At the end of the time the mixtures were boiled, diluted and filtered for the Kjeldahl determinations. The results of the tests are given in Table III.

TABLE III.

	Cc. betain HCl sol.	Total N.	Betain N.	Net N.	Protein.
A.....	5	0.0462	0.0096	0.0366	0.2287
B.....	10	0.1496	0.0192	0.1304	0.8150
C.....	15	0.1824	0.0288	0.1536	0.9600
D.....	20	0.1869	0.0384	0.1485	0.9281
E.....	25	0.1995	0.0480	0.1515	0.9468
F.....	30	0.2160	0.0575	0.1585	0.9906

The digestions progressed very rapidly and it is evident that the salt dissociates largely and in amount sufficient to produce a change in the protein almost comparable with that of the free acid. That some of this separated acid goes at once into combination with the protein is suggested by the following experiment:

The coagulum from 1.5 g. of egg powder, representing about 1 g. of true protein, was mixed with 30 cc. of the betain HCl solution containing 150 mg. of the acid. The mixture was shaken through two hours to effect complete combination. (Data to be given in another paper will show something about the rapidity of combination of weak acid with protein.) At the end of the shaking, the mixture was filtered and the solid residue washed with about 30 cc. of water. The filtrate, titrated by aid of methyl orange, required 22.6 cc. of 0.1 *N* NaOH, while 30 cc. of the original required 40.8 cc. Therefore, 40.8 — 22.6 = 18.2 measures the acid held, about 66.4 mg., for the gram of protein. This is essentially the amount which would have been taken up from a weak solution of free hydrochloric acid.

In two similar experiments portions of coagulum from 1.5 g. of egg were mixed with 20 cc. of the betain hydrochloride solution and 50 cc. of water and shaken through one hour, but not as actively as before. The mixtures were filtered, the residues being washed as before. In one filtrate the HCl required 19.6 cc. of 0.1 *N* silver nitrate equal to 71.5 mg. of the acid, while in the other filtrate 19.5 cc. of 0.1 *N* NaOH were needed to neutralize the acid. The results agree in showing that 28.5 mg. of HCl had been taken by the protein in this case, where the original concentration of the acid was much stronger than in the first test.

It is desirable to know the actual concentration of the active hydrochloric acid in these solutions used for the digestion experiments, that is, the [H] concentration. Attempts were made to determine this in two ways: First, by the use of a series of indicators as suggested by Frieden-thal, Salm and others, and perfected by Soerensen and second, by the measurement of the electric potential in concentration cells. This method seems to give much better results than could be secured by the indicator titrations and was finally followed for all the tests. Cells of the Ham-

burger type were used for a time, but were later given up in favor of the Hasselbalch cell and the 0.1 *N* calomel electrode, as recommended by Soerensen.¹ The much easier correction for the diffusion potential is a point of great practical importance here, and for this purpose observations were made with 3.5 *N* and 1.75 *N* KCl, as a connecting bridge between the concentration cell and the calomel electrode.

For the sake of comparison and to test the general accuracy of the method I made a series of determinations of π_0 , the potential of a true normal solution, at 18°, following the Soerensen procedure. This I found to be = 0.3381 at 18°, and about 0.3379 at 20°, which is a trifle higher than the Soerensen value, viz., 0.3377. I kept the temperature as nearly as possible at 20° during the tests, and therefore took

$$P_H = (\pi - 0.3379)/0.0582$$

as the formula for reduction generally employed. For higher temperatures the denominator is a little larger and is practically 0.0002 more for each degree. (The whole denominator is 0.0001987 T , where T is the absolute temperature.) As the P_H is the common logarithm of the reciprocal value of the [H] concentrations of the solutions, the latter is easily calculated.

Determinations made on the solutions of the same strength as were employed in the digestion experiments gave these results. The figures given under "theory" show the [H] concentrations on the assumption that the HCl is fully separated from the salt and completely dissociated.

TABLE IV.

	Cc. betain HCl sol.	H ₂ O.	P_H .	C_H .	Theory C_H .
A.....	5	55	2.067	0.0085	0.0114
B.....	10	50	1.868	0.0135	0.0228
C.....	15	45	1.753	0.0176	0.0343
D.....	20	40	1.656	0.0220	0.0456
E.....	25	35	1.592	0.0256	0.0571
F.....	30	30	1.534	0.0292	0.0686

The experimental results are very interesting. The weakest solution is slightly more than 0.01 *N*, while the strongest is less than 0.1 *N*. It must be remembered that the betain hydrochloride is dissolved so as to make in 5 cc. the equivalent of 25 mg. of HCl, and each solution was diluted to 60 cc. with pure water before each test. As the dissociation in the 0.01 *N* HCl is not far from 95%, it will be seen that in the weakest solution the [H] of the mixture is about 85% of the theoretical. In the strongest solution, the [H] concentration is about 46% of the theoretical.

Several determinations were made of the concentration of the [H] in the acid liquid standing over egg coagulum at the outset of digestion, or before pepsin is added. Two tests are sufficient to illustrate this con-

¹ *Biochem. Z.*, 21, 131 (1909); *Ergeb. der Phys.*, 12, 393 (1912).

dition. In the first, 10 cc. of the above betain hydrochloride solution (= 50 mg. HCl) were mixed with 50 cc. water and the coagulum from 1.5 g. of egg. In the second case 30 cc. of the same acid solution were mixed with 30 cc. of water and the 1.5 g. of egg. The mixtures stood two hours with frequent shaking and were then filtered. The potential tests were made on the filtrates, with these results:

Cc.	P _H .	C _H .
10	2.259	0.0055
30	1.745	0.0179

In the first case the concentration of the acid left is about what comes from the dissociation of a protein hydrochloride in excess of water. In the second case the hydrogen ion concentration is reduced to that of an original solution of 15 cc. of the betain hydrochloride. The gram of protein has taken up approximately 7% of acid and the supernatant liquid exhibits clearly the excess.

In ordinary digestion experiments in which a protein-like egg albumin is dissolved by pepsin and hydrochloric acid, the concentration as well as the total amount of the latter come into play. We speak of a 0.2% acid as being a good concentration, and this is true, provided the total amount of acid is more than enough to combine with all the protein. In the usual test to measure the activity of pepsin, as given in the U. S. Pharmacopeia, for example, we have a mixture containing about 1.25 g. of real protein with one-tenth its weight of actual HCl in 40 cc. of liquid. The original concentration of the acid is therefore about 0.3%, but approximately one-half of this is taken up by the protein, leaving a residual concentration of 0.15%, which is probably more than is required for maximum activity. From the experiments above with betain hydrochloride, as well as with free HCl, it is seen that digestion is rapid in a far lower concentration.

II. The Behavior of Glutaminic Acid Hydrochloride.

For the experiments here, I used a pure preparation made in the laboratory by the hydrolysis of casein and which, by titration of the chlorine and by a nitrogen determination, was known to be practically pure glutaminic acid hydrochloride, $\text{COOH} \cdot \text{CH}_2\text{CH}_2 \cdot \text{CHNH}_2 \cdot \text{COOH} \cdot \text{HCl}$. The salt is readily soluble in water and 500 mg. required 54.5 cc. 0.1 *N* NaOH for titration with phenolphthalein. This measures the hydrochloric acid and one carboxyl group.

Preliminary experiments showed that solutions of this hydrochloride in presence of pepsin digested egg and fibrin rather rapidly. In the following four trials the coagulum from 1.2 g. of egg was used in A and B, and 5 g. of prepared fibrin in C and D. In each case 50 mg. of pepsin, 600 mg. of glutaminic acid hydrochloride and 50 cc. of water were used. The mixtures were digested at 40° over night. At the end of two hours the

disintegration was far advanced, and apparently complete over night. Blank experiments were made by using killed pepsin to correspond to each case. The mixtures were boiled, filtered, the filters washed and the filtrates used for nitrogen tests.

TABLE V.

	Total N.	Blank N.	Net N.	Protein.
A.....	0.1568	0.0358	0.1230	0.7687
B.....	0.1638	0.0338	0.1300	0.8125
C.....	0.2471	0.0357	0.2114	1.3212
D.....	0.2541	0.0357	0.2184	1.3650

The whole of the nitrogen of the pepsin and of the hydrochloride should appear in the blank and should be nearly 50 mg. But it is evident that, with the capture of some of the hydrochloric acid by the protein, the glutaminic acid becomes less soluble and possibly precipitates to some extent. However, the total digestion seems to be from 75 to 80% of what might be theoretically expected, indicating a behavior much like that of the betain hydrochloride.

A number of digestion experiments were then made exactly as with the betain salt. A solution of glutaminic acid hydrochloride was made containing 6.285 g. to 250 cc. Five cc. of this contains 125.69 mg., or 25 mg. of HCl in combination. The N content of 5 cc. is 9.6 mg.

As in the former experiments the coagulum from 1.5 g. of egg albumin was always taken, corresponding to about 1 g. of protein. The digesting volume was always 60 cc., of which 30 cc. were made up of a pepsin solution containing 15 mg. of pepsin. The digestions were carried on through four hours at 40°, and at the end of this time the mixtures were boiled, diluted, and filtered for the nitrogen tests. The actual digestions began somewhat more slowly than with the betain hydrochloride, and evidently do not go as far. This is probably due to the fact that the hydrogen ion concentrations are lower, as will appear below. Table VI gives the result of the determinations for soluble nitrogen.

TABLE VI.

	Cc. glut. HCl sol.	Total N.	Glut. N.	Net N.	Protein.
A.....	5	0.0196	0.0096	0.0100	0.0625
B.....	10	0.0711	0.0192	0.0519	0.3244
C.....	15	0.1211	0.0288	0.0923	0.5769
D.....	20	lost	0.0384
E.....	25	0.1765	0.0480	0.1285	0.8051
F.....	30	0.1894	0.0575	0.1319	0.8244

It is seen that these digestion values are not as high as were found in the case of the other hydrochloride and the table to be given below will afford a possible explanation of this. Some of the same solution was employed for determination of the hydrogen concentration at 20°, as de-

scribed for the experiments with the betain hydrochloride. Table VII below gives the numerical values.

TABLE VII.

	Cc. glut. ac. HCl sol.	H ₂ O.	P _H .	C _H .	Theory C _H .
A.....	5	55	2.216	0.0060	0.0114
B.....	10	50	2.010	0.0097	0.0228
C.....	15	45	1.908	0.0123	0.0343
D.....	20	40	1.852	0.0140	0.0456
E.....	25	35	1.811	0.0154	0.0571
F.....	30	30	1.785	0.0164	0.0686

It is plain that we have, in all the dilutions, a lower hydrogen concentration than was the case with the betain salt. In the last mixture, equivalent to 150 mg. of hydrochloric acid in the 60 cc., the concentration is but little over half that of the corresponding betain hydrochloride. This difference undoubtedly accounts for the lower digesting activity observed in the experiment.

The [H] concentrations observed here are practically all due to the dissociation of the inorganic acid, as the dissociation of the glutaminic acid is very low. The residual concentrations of similar solutions, standing over egg albumin, were found to be very trifling in a number of experiments similar to those carried out for free hydrochloric acid to be referred to below.

III. The Behavior of Protein Hydrochloride.

In the foregoing we have seen the behavior of hydrochloric acid combined with small groups comparable to the component structures of the protein molecule itself. The acid unites readily with the complex protein, as it does with the amino acid derivatives, and the question of its physiological action here now comes up. In the therapeutic use of hydrochloric acid it is usually administered in the form of diluted solutions of the free acid, and the only important objection to this is the strongly acid taste. To overcome this objection such bodies as the betain hydrochloride have found favor and it has been shown above that a marked digestive activity is actually present with them. Combinations of proteins and hydrochloric acid have also come into use in recent years, and for these claims of acid strength are made. The experiments to be given below are intended to throw light on this point.

In the investigations I used a form of acid albumin obtained by adding hydrochloric acid to egg albumin and evaporating to dryness at a low temperature. The dry substance was powdered and mixed with enough more albumin powder to bring the HCl content to exactly 5%. The product has a strong acid taste and is only partly soluble in water. The nitrogen content was found to be 12.25%, but when the product is shaken up in water the amount of nitrogen dissolved is not large. Two experi-

ments illustrate this: Two portions of 2 g. were shaken up with 100 cc. of water and incubated at 40° through six hours. To one of these portions 50 mg. of killed pepsin had been added. At the end of the time the liquids were filtered and on the filtrates nitrogen determinations were made.

	Total N.	Sol. N.	Pepsin N.	Net N.
A.....	0.245	0.0196	..	0.0196
B.....	0.245	0.0209	0.0008	0.0201

While not a large proportion of the protein is soluble, an appreciable amount of the acid dissociates and may be obtained in the clear filtrate. This is best shown by starting with a larger weight of the powder. 10 g. were shaken up with 250 cc. of water and allowed to settle over night. Part of the supernatant liquid was filtered off and portions of 10 cc. were titrated with 0.1 N NaOH.

10 cc. with methyl orange require 1.1 cc. = 100 mg. HCl for whole.

10 cc. with phenolphthalein require 1.7 cc. = 155 mg. HCl for whole.

This result shows that while some of the acid comes through combined with protein, some must be considered as existing in the form of free acid. This amounts to about 20% of the whole acid in the substance shaken up with water.

In the presence of pepsin the mixture undergoes rather a slow digestion, and the amount of hydrochloric acid now found in the filtrate is increased, but not greatly as the digestion is incomplete. This is shown by Table VIII where the effect of adding more protein is also brought out. In these experiments 2 g. of the powder and 50 mg. of pepsin were added to 100 cc. of water and digested through six hours at 40°. In some of the cases the coagulum from egg powder with 70% of real protein, and fibrin with 29% of real protein, was added. The results were as follows:

TABLE VIII.

	Prot. HCl. G.	Added pepsin. Mg.	Added Protein.		Sol. N.	Protein.
			G.			
A.....	2	0.0196	0.1226
B.....	2	50	0.1472	0.9200
C.....	2	50	1	egg	0.1117	0.6981
D.....	2	50	2	egg	0.0790	0.4936
E.....	2	50	2	fibrin	0.1260	0.7875
F.....	2	50	3	fibrin	0.1142	0.6937
G.....	2	50	5	fibrin	0.0825	0.5156

The protein in the 2 g. of the powder used above amounts to about 1.53 g. Slightly over 60% of this digests when no more protein is present, but the addition of either egg or fibrin brings the digested amount down to a much lower figure. With increasing amounts of added protein the digested fraction progressively diminishes. This is undoubtedly because of the binding of the hydrochloric acid. In similar experiments with

other amounts of protein added, no greater weight of protein was digested. It appears, therefore, that acid held in this way is not capable of insuring an active digestion, even of its own protein.

The concentration of the dissociated hydrochloric acid is very low in the mixture of the powder with water. This was observed with the mixture made by adding 10 g. of the powder to water enough to make 250 cc. of solution. The mixture was well shaken through an hour and allowed to stand over night. The acid strength was determined in a cell of the Hamburger type against 0.1 N HCl. The result was found, $C_H = 0.00726$. The insoluble residue was again shaken with water and allowed to stand. The supernatant liquid gave a lower acid value than before. This operation was repeated twice. The results of the four trials were as follows, showing for the H concentrations:

1st water, 0.00726; 2nd water, 0.00517; 3rd water, 0.00483; 4th water, 0.00352.

Assuming the hydrochloric acid to be all split off in the first water treatment the concentration should be 0.0548, or with 95% dissociated 0.05296. The amount of free acid available for activation of pepsin is, therefore, but a fraction of that split off from the betain hydrochloride. A preparation of this character is sold under the name of *oxyntin* as a hydrochloric acid substitute.

This holding of the HCl by protein is shown easily in another way, using moist, freshly coagulated egg albumin as a substratum. I made a series of experiments in which different amounts of coagulated egg were mixed with 150 cc. of N/15 HCl and either digested through a certain time or allowed to stand some hours before testing. In all cases the character of the liquid standing over any remaining albumin was determined. The volume of this liquid which could be filtered off was found. The results of experiments are given in Table IX.

TABLE IX.

	A.	B.	C.	D.	E.	F.	G.
Coag. from	5	6	8	10	5	10	15 g. egg
Treatment	Digested	Digested	Digested	Digested	Not digest.	Not digest.	Digested
Vol. filt.	149 cc.	146 cc.	138 cc.	135 cc.	100 cc.

In A, B, C, D, and G the digestions were carried through 4 hours at 50°, with the addition of 50 mg. of pepsin. In A and B practically all of the protein went into solution before the end of the period. In C some was left which held a little of the digesting liquid and in D the amount was still greater. In G the portion digested was apparently very slight and the volume of liquid which ran through the filter was much less. The weights of actual protein, and acid added, expressed in percentages of the protein weight, are as follows:

TABLE X.

	A.	B.	C.	D.	E.	F.	G.
Weight of protein, g....	3.5	4.2	5.6	7.0	3.5	7.0	10.5
Per cent. HCl.....	10.43	8.69	6.52	5.21	10.43	5.21	3.48

The potential tests in six of the undiluted filtrates, representing the real acid concentration of the supernatant liquids, gave these results:

TABLE XI.

	A.	C.	D.	E.	F.	G.
PH.....	1.696	2.352	2.636	1.403	1.763	2.957
CH.....	0.0201	0.0044	0.0023	0.0396	0.0173	0.0011

In A an appreciable amount of free acid is found in the liquid after digestion, while in E, of the same original strength but not digested, the free acid concentration is nearly twice as great. In C there is scarcely enough acid for proper digestion, while in D there was an appreciable amount of albumin left. In G the acid concentration was far too low for digestion, as most of the egg remained undissolved. What passed through the filter was merely acid albumin. In E and F there was, of course, no digestion and very little solution. The amounts of free acid were consequently higher here.

After making the potential tests some of the liquids were returned to the original filtrates and mixed with wash water sufficient to bring all the volumes up to 250 cc. In this way practically everything soluble was washed out of the filters. 25 cc. portions of the filtrates were titrated with 0.1 N alkali and with 0.1 N silver nitrate, after separation of albumin, with the following results:

TABLE XII.

	NaOH with methyl orange.	NaOH with phenol phthalein.	NaOH formal ti- tration.	AgNO ₃ ti- tration.	Per cent. of HCl recovered.
A.....	Ca 6 cc.	12.2	14.0	9.7	97
B.....	Ca 3 cc.	13.0	15.4	9.2	92
C.....	Trace	12.8	15.5	8.6	86
D.....	0	13.0	15.4	8.6	86
G.....	0	5.4	6.5	3.5	35

The results with the methyl orange titration were far from sharp, as is always the case in presence of partly digested protein, and merely give an indication of the practical absence of free hydrochloric acid in three of the cases. Figures showing the results of the formaldehyde titration are also added, but they show no marked increase of protein products in the digestion filtrates. No great importance can be attached to them for the further reason that the weak acid concentrations were probably not sufficient to prevent a slight bacterial action between the time of digestion and the titration. But the results of the silver nitrate determinations are interesting. If all the hydrochloric acid had passed

into the filtrates the amount of silver nitrate required would have been exactly 10 cc. in each case. But there was always a loss depending on the amount of acid held by the undigested protein. By *prolonged washing all of this acid could have been dissociated and washed out*. Such acid cannot be considered as mechanically retained, but is doubtless chemically combined. In Sample G two-thirds of the acid is so held, and here the protein residue is very large.

For the actual digestion of protein by pepsin and acid it is not necessary that the amount of free acid should be large, but there *must be some excess, if the digestion is to be at all rapid*. This slight excess may probably come in some cases as a result of dissociation. In Sample C we have about the limit of digestive action, but with the same amount of acid and double the protein there is practically no digestion in G.

These experiments are sufficient to show that combinations of protein and HCl, with not more than 5 or 6% of the latter present, can have no value as digestive agents. This amount of acid is scarcely sufficient to permit the digestion of the protein itself, to say nothing of the digestion of added protein. In this respect the protein-acid combinations are not comparable with the combinations with amino acids. In Experiment A, where the digestion is rather rapid and is practically completed in two hours, the [H] concentration was found to be $P_H = 1.696$. It is interesting to note that this value is between the limits found by Soerensen¹ for the optimum digestion of egg albumin, as measured by a quite distinct process, *viz.*, the determination of the amount of nitrogen in the digestion filtrate which may not be precipitated by stannous chloride. His optimum is given at $P_H = 1.63$. It is evident, however, that any marked increase of albumin in A would lead to a decided decrease in the digestive activity.

In these experiments I have received valuable assistance from Miss Mary Hull to whom my thanks are due.

Resume.

It has been shown in this paper that the hydrochlorides of betain and glutaminic acid dissociate in aqueous solution to sufficient extent to permit the acid to aid pepsin in the rapid digestion of egg albumin or fibrin. This behavior is probably typical of amino acid combinations in general. In the case of the betain salt the action is almost equal to that of dilute hydrochloric acid of the same gross concentration. With glutaminic acid hydrochloride the action is somewhat slower, but still marked. In either case, in the mixture of coagulated protein and the hydrochloride, a part of the HCl will leave the latter and become attached to the protein.

Mixtures made by combining hydrochloric acid with protein, in a sense

¹ *Biochem. Z.*, 21, 297 (1909).

analogous to the hydrochlorides of amino acids, are physiologically much less active. Such mixtures hold scarcely enough acid to digest themselves perfectly. If further amounts of protein are added, with pepsin, digestion becomes very slow. When the protein and hydrochloric acid are so related as to bring the $[H]$ concentration down to $P_H = 2.96$ the rate of digestion is slow. This is the case when the weight of the acid is about 3.5% of the weight of the egg albumin, and 150 cc. of $N/15$ acid is the liquid volume.

On the other hand, when the weight of the acid in 150 cc. of $N/15$ HCl is about 10% of the weight of the albumin, and the hydrogen concentration of the supernatant liquid is about $P_H = 1.69$, we have very rapid digestion. This appears to be near the maximum of activity. We find all degrees of digestive activity between these limits. Dry preparations of protein and hydrochloric acid about midway between these limits cease to be physiologically active.

GASTRO-INTESTINAL STUDIES. VII. THE UTILIZATION OF INGESTED PROTEIN AS INFLUENCED BY UNDERMASTICATION (BOLTING) AND OVERMASTICATION (FLETCHERIZING).

BY L. F. FOSTER AND P. B. HAWK.

Received July 18, 1914.

I. Introduction.

Within the last few years attention has been frequently called to the importance of the proper mastication of food. Campbell¹ in 1903 made the following statements:

"The primary object of mastication is to break up the food so as (1) to facilitate the swallowing of it and (2) to insure its admixture with the digestive juices, both of the mouth and whole digestive canal. Mastication has other far-reaching effects. It promotes the flow of saliva, secures proper insalivation of food, increases the quantity of alkaline saliva passing into the stomach, stimulates the heart and circulation, and, finally, influences the nutrition of the jaws and their appendages by stimulating blood and lymph circulation. Proper mastication tends to diminish the amount of food consumed, by reducing the quantity needful to constitute a sufficiency, for the more perfectly a food is chewed the more perfectly is it digested and the more economically is it disposed of in the system. Insufficient mastication is the cause, direct or indirect, of many evils. It may cause local irritation resulting in acute gastritis; appendicitis is believed by Sir Frederick Treves to be due directly to food bolting, gastric intestinal catarrh may be induced through the action of certain toxins; gastric secretion may be checked through paralysis of stomach nerves, while the teeth and jaw structures are underdeveloped and disposed to disease."

¹ *Lancet*, July 11, 1903.

Chittenden¹ has stated that thorough mastication of food is a material aid to digestion which is to take place in the stomach and intestine. Metchnikoff,² on the other hand, argued that it is harmful to chew food too long and to swallow it only after it has been kept in the mouth a considerable time. A disease known in America as "Bradyphagia" has arisen from the habit of eating too slowly. Einhorn³ found that the disease is rapidly cured when the patients make up their minds to eat more quickly. According to Brown⁴ the importance of chewing with reference to protein foods at least, has been grossly overestimated. He has emphasized that all high-protein feeding animals bolt their food.

In recent years the advantages of eating slowly and chewing thoroughly have been suggested by Horace Fletcher⁵ and his associates. As a result the term, fletcherism, has crept into our language. Experimental work undertaken by Chittenden, Fletcher and others has shown that by practicing thorough mastication man can, for a time at least, maintain his life processes normally on a supply of protein food less than one-half as large as that prescribed by the so-called standard dietaries.

2. Description.

Purpose and Plan.—The purpose of this investigation was to study the utilization of a typical protein as influenced by different degrees of mastication. The experiment was conducted upon two young men and consisted of four seven-day periods as follows: (1) Preliminary normal, during which the food was masticated normally; (2) bolting, in which the meat was swallowed with no attempt at mastication; (3) fletcherizing, when the food was chewed until carried down the oesophagus by the "swallowing impulse;" (4) final normal, in which ordinary mastication was practiced. The preliminary normal period of nine days was subdivided into a six-day and a three-day period. This is explained by the fact that the diet was increased at the beginning of the latter sub-period.

Subjects.—The subjects of this experiment were two laboratory assistants, F and J. F was a man of medium size, 22 years old and 58.3 kg. in weight. Previous to the experiment he had been on a comparatively simple protein diet. J was of larger build, 24 years of age, and weighed 63 kg. Previously, he had been ingesting a rather high protein diet at one of the local boarding clubs.

Diet.—A uniform diet of the following composition was fed throughout the experiment:

¹ Chittenden, "Nutrition of Man," New York, 1907, p. 23.

² Metchnikoff, "Prolongation of Life," New York, 1908, p. 159.

³ Einhorn, *Z. diät. u. physik. Ther.*, 8, 622 (1905).

⁴ Brown, "Parcimony in Nutrition."

⁵ H. Fletcher, "New Glutton or Epicure," New York, 1906.

TABLE I.

Food.	Subject F.		Subject J.	
	Amount. G. or cc.	Nitrogen. G.	Amount. G. or cc.	Nitrogen. G.
Beef.....	185	11.207	215	13.025
Graham crackers.....	150	1.932	150	1.932
Milk.....	650	3.309	800	4.072
Butter.....	150	0.155	150	0.155
Water.....	1800	..	2100	..
Salt.....	16	..	2.0	..
Agar-agar.....	10	..	15	..
Total.....	..	16.603	..	19.184

It is to be noted that meat contributed the major portion of the protein of the diet. The meat, which consisted of the best round steak procurable, was freed from all visible fat and connective tissue and was cut into 15 mm. cubes. It was cooked by being allowed to simmer for two and one-half hours in boiling water. After thorough mixture it was sampled for analysis, placed in pint mason jars, and autoclaved at 115° by the discontinuous method. The jars were stored in a refrigerator. Distilled water was drunk throughout the experiment. Agar-agar was added to the diet to facilitate defecation.

Methods.—Carmine was used to separate the feces of the several periods, satisfactory differentiations resulting in every instance. The carmine was taken in a gelatine capsule with the initial meal of each period. Total nitrogen was determined in foods, feces, and urine. The Kjeldahl method was employed, copper sulfate being used in the digestion. Analysis of feces was made on each individual stool, except when two or three small stools were passed within a short time, in which cases they were combined. Determinations were made in duplicate upon the fresh stools without previous drying. After defecation each stool was weighed, thoroughly mixed until uniform throughout, and transferred to a weighing bottle. As soon after as possible, samples were weighed for analysis. During the bolting period the macroscopic meat residues present in the feces were carefully removed and their nitrogen content determined separately. Urine was collected in 24 hr. periods, two-liter acid bottles being used as containers and powdered thymol added as a preservative.

Daily Routine.—The daily periods began and ended at 7.15 A.M. The daily program was as follows: 7.15 A.M., urination and defecation; 7.20, body weights without clothing; 7.45, breakfast; 12.00, luncheon; 5.00, exercise; 6.00, dinner; 10.30, bed. Defecation did not always occur before breakfast.

The daily ration was divided approximately into three equal portions, one for each meal. Subject F took 300 cc. of water with each meal. Two or three hours after each meal 300 cc. were drunk, making a total of 1800

cc. for the 24 hours. Subject J also ingested 300 cc. with each meal but took 400 cc. after meals, making a total 24-hour intake of 2100 cc. Exercise was taken at 5.00 each afternoon. This consisted either of a brisk two and a half mile walk or a twenty-minute swim. Both subjects were working especially hard on research problems throughout the experiment.

3. Experimental.

Discussion of Data.—The protein utilization was calculated by the ordinary method:

$$\frac{(\text{Nitrogen in Food} - \text{Nitrogen in Feces}) \times 100}{\text{Nitrogen in Food}} = \text{Percentage Utilization}$$

1. Subject F—Table II.—In the ordinary preliminary normal period the average daily output of fecal nitrogen was 0.759 g. This value was increased to 0.948 g. in the bolting period. The protein utilization fell from 95.43% to 94.29%. As a result of fletcherizing the food, the daily output of fecal nitrogen was lowered to 0.726 g. This was a slight decrease from the value obtained in the preliminary normal period. A correspondingly higher utilization, 95.63% was sustained during this period. In the final normal period the daily nitrogen output increased slightly to 0.765 g., a value differing but little from that of the preliminary normal period.

The results obtained are not surprising. The fine comminution of the food brought about by fletcherizing would induce its more complete utilization, thus reducing the nitrogen output in the feces. On the other hand the fact that every stool passed during the bolting period contained macroscopic meat residues seemingly indicates that the food was less efficiently utilized during this period. However, if the mean nitrogen excretion of the two normal periods is compared with that of the fletcherizing period, a slight difference of 0.036 g. of nitrogen per day is noted. Comparing in the same way the protein utilization we note that the increase is but 0.22% in favor of fletcherism. It may be concluded that even though meat residues of macroscopic size were found in the feces passed during undermastication, the total amount of meat residues was but slightly in excess of that in the normal feces.

Passing to the urinary data, the average daily nitrogen excretion of 16.369 g., during the preliminary period fell to 16.229 g., in the bolting period. This value rose to 16.697 g., in the fletcherizing period and fell to 16.639 g. in the final normal period.

The decreased urinary nitrogen excretion during food bolting might be explained by the fact that less of the ingested protein was hydrolytically split by the digestive juices. The increased output of fecal nitrogen coupled with the appearance of macroscopic meat residues in all stools from this period, lends support to this explanation. The fine division

of the meat by fletcherism, on the other hand, probably induced the splitting of a larger quantity of protein by the digestive juices, and this in turn resulted in the appearance of an increased amount of exogenous nitrogen in the urine. As the daily nitrogen excretion was slightly higher during the final than in the preliminary normal period, it may be concluded that the effect of fletcherizing the food extended into the subsequent period.

2. Subject J—Table III.—During the preliminary normal period protein was not so well utilized as in the subsequent periods. The average

daily nitrogen output in feces was 1.306 g., the utilization being 93.19%. In the bolting period the daily nitrogen output was 1.266 g., with a utilization value of 93.41%. In the fletcherizing period the fecal nitrogen decreased, the average output being 0.906 g. per day. An accompanying increased utilization value of 95.32% was manifest. An average output of 0.919 g. was sustained during the final normal period of the experiment. The utilization was only slightly decreased, the value here being 95.21%.

The incomplete utilization of protein during the preliminary period was undoubtedly due to the extremely nervous condition of J. His diary for one of the last days of the period reports, "Much gas in my stomach, a constant taste of the meat eaten, and a general feeling of lassitude." J was constipated during the last days of the period, the final feces not appearing until the fourth day of the subsequent period. It seems reasonable to infer that under these conditions digestion was somewhat sluggish and a consequent inefficient utilization of protein resulted.

The discrepancy in protein utilization between the preliminary and final normal periods is perhaps susceptible of another interpretation. The effects of over mastication may have extended into the final period, in other words, a specific adaptation of the protein digestive juices may have been induced by the fine division of the protein through complete mastication. Neilson and Terry¹ have reported adaptations in the salivary glands of dogs. These investigators found that the saliva of dogs fed on bread exhibited stronger amylolytic power than that of meat-fed dogs. Neilson and Lewis² found evidence of adaptation in human saliva, while Simon³ reported a greater amylolytic activity in human saliva on carbohydrate diet than on either a mixed or protein diet. Mendel, Chapman and Blood,⁴ Carlson, and Chittenden,⁵ Garry,⁶ and Wohlgemuth,⁷ have failed to detect any evidence of adaptation of human saliva to diet, even as a result of years of feeding a particular diet. Walther⁸ holds that adaptation of the digestive juices may occur if a particular diet be maintained some time, while Labosov⁹ has noted lasting alterations in the gastric glands as the result of altered dietetic conditions. London and Krym¹⁰ failed to determine any specific adaptation in the intestinal secretion of dogs. London and Lukin¹¹ as well as London and Dobrowolskaja¹² failed to detect any adaptation of digestive juices as a result of feeding a particular food. A review of the literature on the subject of adaptation seems to justify the following conclusions of Mendel, Chapman and Blood:¹³

"It is difficult to conceive of a sudden adaptation resulting from several days' feeding of a certain diet as advocated by the Pawlow school. The assumption of an entirely new role by a secretion or gland as the result of a few days' feeding is scarcely a biological probability."

It seems probable that in the case of J the output of fecal nitrogen and consequent protein utilization during the final period of the experiment, should be considered more nearly normal values. The slightly abnormal condition of J during the preliminary period would seem to explain his lowered utilization.

More pronounced difference in the amounts of urinary nitrogen excreted in the several periods were noted in the case of J than was true with F. The daily average of 18.827 g. in the preliminary fell to 17.990 g. in the bolting period and rose to 20.118 g. in the fletcherizing period. As in the experiment on F, a higher value in the final normal than in the preliminary normal period was noted, this output in case of J being 19.703 g. The lowered nitrogen excretion during bolting, and its marked increase during fletcherizing, possibly indicates that the degree of comminution of protein food determines, to a certain extent at least, the amount of hydrolytic cleavage by the digestive juices.

Composition of the Feces. 1. Metabolic Products.—It was formerly believed that all, or nearly all, of the nitrogen of the feces was due to undigested food, Voit¹ first showed that this was not necessarily true but that digestive juices and epithelium might leave residues Voit reached this conclusion when he found that fasting dogs eliminated a dark colored feces. The mucous membrane of the intestine by its secretion and by the abundant quantity of detached epithelium contributes essentially to the formation of feces. This follows from the finding of L. Hermann² that a clean, isolated loop of intestine collects material similar to feces.

In studies on food utilization it is important to know what part of the fecal nitrogen is metabolic in origin and what portion is due to undigested food. At present no sharp method of separation is known. Tsuboi³ has shown that on a flesh diet animals eliminate a feces consisting largely of metabolic products, the composition of which is widely different from that of the ingested meat. There was no proportionality between the amounts of nitrogen fed and the metabolic nitrogen excreted; neither did moderate amounts of nitrogen-free food appreciably alter the character of the feces. This investigator concluded that the greater part of the fecal dry matter is metabolic in origin. Rieder⁴ found more nitrogen in feces on a nitrogen-free diet than in fasting feces. Later, this same investigator, using men and dogs as subjects found an increase in the fecal nitrogen

⁴ Rieder, cited by Tsuboi, *Loc. cit.*

excretion with the amount of nitrogen-free food fed. Tsuboi reported a similar finding. Rubner¹ found as much nitrogen in feces from a fluor-sugar-starch diet as the average from a meat diet. Using diets varying widely in composition, he obtained feces that differed but slightly in nitrogen content. The percentage of nitrogen in the feces was greater than in the food, except in cases of slightly utilized vegetable foods. Prausnitz² held that the composition of human feces never resembles that of ingested food, but on account of residual intestinal juices nearly always has a higher nitrogen content. This investigator also believed that human feces consist largely of residues not of ingested food but of intestinal secretions. Prausnitz reported meat residues in quantities varying from 1-3% of the moist feces, or 0.2%-1% of the ingested meat. The amount of feces, he holds, is dependent upon the character of the food, as some varieties require larger amounts of intestinal juices for digestion than others. H. Fletcher³ reports a feces of very small volume, pillular in form and almost odorless, as the result of proper mastication of food with its consequent reduction in the amount ingested.

Regarding utilization, Tsuboi⁴ maintained that previous work gave values that were too low, and concluded that, as nitrogen is continually being lost in the feces, to preserve body equilibrium it is necessary to replace this as well as the nitrogen excreted in the urine. Mendel and Fine⁵ believe that upon the ingestion of a meat diet, whose utilization as usually calculated is about 95%, the resulting feces are for the most part metabolic in origin. From the accumulated evidence it is reasonable to assume that a mixed diet gives fecal nitrogen the major quantity of which is metabolic in origin.

2. Bacteria in Feces.—It has been stated that one-third of the dry matter of human feces consists of bacteria, and at least one-half of the total nitrogen content is of bacterial origin.⁶ It is a well-known fact that the bacteria of the large intestine depend to a large extent for their nutrition upon the residues, not only of unabsorbed intestinal juices, but also of undigested protein food. Consequently, a quantitative determination of the bacterial nitrogen in feces gives no absolute value, but one that necessarily includes a portion of the nitrogen due to undigested food residues. For this reason fecal bacteria cannot, with absolute accuracy, be included as metabolic products. However, as may readily be recognized, it is impossible experimentally to make a quantitative separation of the metabolic from the non-metabolic products of feces.

3. **Estimation of Metabolic Nitrogen in Feces.**—It has been suggested that for every gram of total nitrogen in feces, 0.92 g. arise from residues of digestive juices, while the remaining 0.08 g. are due to unutilized protein food. Though this correction was not based upon any experimental data, it has been used to some extent in calculating utilization values.

To determine experimentally as nearly as possible the portion of total fecal nitrogen due to metabolic products, the method of Mendel and Fine¹ was employed. At the close of the final period of the experiment, the average daily output of feces by each subject during the four periods was calculated. A nitrogen-free diet of equal calorific value to that previously ingested was chosen. To supplement this diet an attempt was made to add agar-agar in amounts sufficient to bring the daily output of feces up to approximately the average daily output during the experiment.

Agar-agar is especially valuable in cases like the present. It gives bulk and softness to the feces and facilitates their elimination. Further,² being resistant to bacterial action it causes neither gas formation nor the production of harmful decomposition products. Though in certain of the herbivora common agar may be utilized up to 50%, Lohrlich³ found that in man it is digestible to but a very small extent. The minute quantities digested are probably hydrolyzed to galactose. The indigestibility of agar is recognized and therefore it is given in cases of constipation. Schmidt⁴ believes it to be the best form of cellulose for the correction of constipation, as it is high in hygroscopic properties, non-irritant and absolutely insoluble and unabsorbable.

The feces obtained from the nitrogen-free diet were analyzed for total nitrogen, and daily averages calculated as in the experiment proper. Corrections were applied for the nitrogen of the unutilized butter, carmine and gelatine capsule. This resultant value was subtracted from the average daily nitrogen output of each period. The difference was assumed to be the N due to unabsorbed residues of meat, and the protein utilization was calculated on this basis.

The following nitrogen-free diet was selected for determining the metabolic-nitrogen of the feces:

TABLE IV.

	F.		J.	
	Amount.	Grams N.	Amount.	Grams N.
Butter.....	300	0.31	320	0.33
Sugar.....	128	..	128	..
Agar-agar.....	20	..	25	..
Water.....	2900	..	3100	..
Salt.....	1.6	..	2	..

¹ *J. Biol. Chem.*, 11, 5 (1912).

² Swartz, *Transactions of the Connecticut Academy of Arts and Sciences*, 16, 247 (1911).

³ Lohrlich, cited by Swartz, *Loc. cit.*

⁴ Schmidt, *Münch. Med. Wochschr.*, 41 (1905).

Assuming that the butter was 90% utilized, 10% of the butter nitrogen should appear in the feces. Correction was made for this nitrogen. The actual water ingestion was greater than during the experiment, when the subjects had been receiving milk which contained approximately 87% water. The water represented in the daily milk intake was calculated and the amount added to the original intake. The diet was ingested throughout a four-day period, during which time the usual routine of the experiment was followed as previously described.

a. **Subject F.**—The daily output of feces was 166.5 g., a much greater average than during the experiment. The average nitrogen content of the output was 0.5 g. No doubt this value is too high, inasmuch as the volume of feces during this period was nearly twice that obtained during the ingestion of the experimental diet and we would be justified in expecting an increase in metabolic nitrogen with an increase in bulk of the material in the intestine. The actual relationship could only be determined by a separate experiment. In Table V are found corrections for fecal nitrogen. It should be noted that after applying this high value as a correction the excretion of nitrogen in form of food residues is still approximately a quarter of a gram per day during normal mastication. The utilization percentages calculated on the basis of the above correction are of course somewhat higher than those in Table II, but undoubtedly they are more nearly correct values.

By calculating the metabolic nitrogen from a bulk of feces equal to that excreted during the experiment, proper, a smaller correction was obtained. The metabolic nitrogen was calculated by a direct proportion as follows: Daily output of feces from experimental diet: Daily output of feces from nitrogen-free diet:: Daily output of metabolic nitrogen during experiment: Daily output of nitrogen from nitrogen-free diet, or

$$89.1 : 166.5 :: M : 0.500 \quad M = 0.268 \text{ g. per day.}$$

The corrected fecal nitrogen output and the corresponding utilization values are found in Table VI. In using the correction obtained by calculation, tacit assumption is made that the content of metabolic nitrogen is proportional to the volume of feces excreted. Although there are no experimental data covering this point, it is hardly reasonable to expect that such would be the case. It is quite probable that 0.268 g. of metabolic nitrogen per day is a low value. The original value of 0.5 g. per day probably is more nearly normal, although the actual output undoubtedly lies between this and the 0.268 g. obtained by calculation.

b. **Subject J.**—The daily output of feces, from the nitrogen-free diet, was 124.3 g., in the case of J. As the average daily excretion during the experiment was 97.3 g., the discrepancy here was less than that manifested in the case of F. The metabolic nitrogen output and the corrected utilization percentages (Table VI) should be considered more nearly accurate

than were the corresponding values in the case of F. The calculation for metabolic nitrogen was made as previously described:

$$97.3 : 124.3 :: M : 0.552 \quad M = 0.432 \text{ g. per day.}$$

In Table VI may be found the values obtained by using this correction.

¹ Corrected for the nitrogen contained in capsule and in carmine.

4. General Discussion.

In establishing the digestibility of a food Best¹ has suggested that we must respect its influence on secretion; its absorption and sojourn in the stomach and intestine. It is a well-known fact that meat remains a relatively long time in the stomach. Tabler² has shown that the stomach acts as a reservoir for protein and that considerable absorption takes place there. Chittenden³ has taken this same view, although he believes that absorption is slow. Fermi⁴ found that finely hacked or well chewed meat was more easily digested by dogs than either coarsely cut or poorly chewed material. Cohnheim⁵ fed two fistulated dogs with meat, the first receiving it in finely hashed condition, the second in the form of cubes of 1-3 centimeters diameter. In the case of the first dog the material left the stomach 1 hour and 35 minutes after ingestion, 59% being digested. The meat cubes remained in the stomach of the second dog 2 hours and 31 minutes, 92% being digested. It was evident that although the cubes remained longer in the stomach, peptonization was markedly higher. Cohnheim concluded that the ingestion of finely chopped meat places more work on the intestine than on the stomach, whereas the reverse is true in case of ingestion of cubes. In one case trypsin brought into solution 0.13 g. of nitrogen; in the other 0.8 g. London and Polovzova⁶ found that with few exceptions, proteins are not absorbed in the stomach, but that most proteins are made soluble in the stomach to the extent of about 78%. 92% of this soluble material consists of proteoses and peptones, which is quickly attacked by the intestinal juices. It has been shown by Zunz⁷ that enzymes of the stomach have the ability to hydrolyze protein to peptones, proteoses, and amino acids, yet the length of time required is far in excess of that during which protein remains in the stomach.

It seems reasonable to suppose in the case of man that bolted meat would remain longer in the stomach than material which had been reduced to a state of fine division through fletcherism. Abderhalden and Meyer⁸ have demonstrated that the activity of pepsin is not necessarily confined to the stomach, but that it may be continued in the intestine. The proteins undigested in the stomach adsorb the enzyme and carry it into the intestine. Following the digestion of these proteins by the contained enzyme, this released pepsin is free to digest other proteins as well, since the reaction of the intestinal canal is often acid. It would seem from these

findings that in food bolting, peptic digestion in the intestinal canal may have an important bearing.

Despite the claim that fletcherism¹ and the use of smaller quantities of food decrease the number of intestinal bacteria, Metchnikoff² does not agree that putrefaction is prevented. It is logical to infer that for the optimum utilization of starchy foods, habits of thorough mastication, should be encouraged with the purpose of increasing the digestion of the material at the beginning of the alimentary tract.

Concerning the utilization of meat protein, it may be concluded that the results of this investigation fail to demonstrate the advantages of fletcherism or the harmfulness of food-bolting.

5. Summary.

1. The question of the influence of mastication on the utilization of protein food was made the subject of this investigation. So far as could be determined, no work has been done on this problem; the statements of Fletcher and his associates are mainly theoretical assumptions.

2. Normal men were fed a fairly high nitrogen diet, the principal protein constituent of which was cooked beef in the form of 15 millimeter cubes. The experiment was divided into four periods: (1) Preliminary normal; (2) bolting; (3) fletcherizing; (4) final normal. Feces and urine were analyzed for total nitrogen.

3. The output of fecal nitrogen was highest during the food bolting; that during fletcherism was lowest. Protein utilization was most complete as the result of fletcherism, and least complete when bolting was practiced. The discrepancies, however, averaged only 1.6%. Utilization during fletcherism averaged 0.17% higher than during normal mastication.

4. During food bolting macroscopic meat residues appeared in every stool. In a single stool the amount was 16.5 g.

5. The fineness of the protein may determine the amount of its hydrolytic cleavage. This fact was shown by the higher nitrogen content of the urine in the fletcherizing period and the lowered output during bolting.

6. A nitrogen-free diet was fed through a four-day period at the close of the experiment proper. Total nitrogen was determined in the feces. The purpose of this was to determine as nearly as possible the average daily output of fecal metabolic nitrogen. This value was applied as a correction, and more accurate utilization data were thus obtained.

7. The fact that pepsin may be adsorbed in the stomach by particles of undigested food and carried into the small intestine to aid further in protein hydrolysis may have an important bearing on the question of the digestion of bolted meat.

¹ H. Fletcher, "The A, B, Z of our Nutrition," New York, 1904, p. 41.

² Metchnikoff, "Prolongation of Life," New York, 1908, p. 159.

8. Fletcherism of starchy foods should be encouraged so as to insure the salivary digestion of a large quantity of material.

9. The results of the present experiment so far as protein utilization is concerned do not support the claims of Horace Fletcher and his followers for the efficiency of excessive mastication of food, nor do they demonstrate the harmfulness of food-bolting to the organism.

PHILADELPHIA, PA.

NOTES.

A Convenient Apparatus for Chlorination with Phosphorus Pentachloride.—The common methods employed in chlorinating solid organic compounds, such as the sulfonic acids or their metallic salts are: (1) Shake material and PCl_5 together in a flask with or without reflux condenser, some authors advocating the use of a one-hole stopper and tube for the delivery of the HCl gas just above the surface of water in a bottle or flask. (2) Grinding material and PCl_5 together in a mortar or evaporating dish.

In method (1) it is difficult to thoroughly mix the materials, and the reaction is often slow in starting. In (1) and especially in (2) the large amounts of HCl gas evolved make the use of a hood necessary and the operation unpleasant at best. In this laboratory it has been customary to perform (2) out of doors.

The authors while working on sulfonic acid derivatives devised the following simple apparatus:

The material is placed in a heavy-walled, side-neck filter flask attached to a Richards or similar filter pump. Suction is applied and the PCl_5 added. The materials are ground together with a pestle made from heavy glass rod or large tubing. No HCl fumes escape into the air, making the use of a hood unnecessary.

If but small amounts of material are available a thick-walled, side-neck test tube may be used.

The method is, of course, not applicable if the product of chlorination is volatile.

LABORATORY OF ORGANIC CHEMISTRY,
MASSACHUSETTS AGRICULTURAL COLLEGE,
March 1, 1915.

The Condensation of Vanillin and Piperonal with Certain Aromatic Amines.—In a private communication J. R. Furlong calls my attention to the fact that some of the condensation products described under the above title (*THIS JOURNAL*, 35, 976 (1913)) were previously described by Manchot and Furlong (*Ber.*, 42, 4387). The compounds referred to are products of condensation of vanillin with *p*-aminobenzoic acid and with its ethyl ester and of piperonal with *p*-aminobenzoic acid.

There are a number of points, however, in which our observations and conclusions are at variance and I take this opportunity to mention them.

Manchot and Furlong condensed vanillin and *p*-aminobenzoic acid in boiling alcohol, obtaining a product which was "not crystalline" and "could not be crystallized in any way." They further state that if toluene is used as solvent in the preparation that "no reaction takes place." These statements are in striking contrast to my observations, in view of the fact that I use toluene as a solvent, with or without 5% of alcohol, and obtain a very beautiful crystalline product, melting at 211–2° instead of 209°, as given by Manchot and Furlong. The crystals, if formed slowly, are compact and brilliant; if formed quickly, are thin plates with sharply bevelled ends. Single crystals under the microscope appear colorless but in the mass are bright yellow. The reaction in toluene is indeed slow and the results obtained after boiling a few minutes might lead one astray. The reaction has begun, however, and is complete after boiling ten hours. Again Manchot and Furlong state that when heated with toluene, alcohol or benzene the compound breaks up, and yet I depend upon toluene for its preparation and its purification. In a special test on this point a small amount of the pure substance was dissolved in boiling toluene and cooled down. The crystals which separated had the same melting point as before. The filtrate was evaporated to dryness and only a trace of material was left. The toluene had been dried with calcium chloride. Alcohol, which Manchot and Furlong used, converts much of the compound into a varnish, even when allowed to evaporate spontaneously.

The red compound obtained by boiling the above compound in water is also in dispute. Manchot and Furlong state that it loses color at 75–7° and melts at 190–200°. I stated that it melts at 104–6° and might have added that it loses color as it re-solidifies with rising temperature and melts again at 190–200°. The behavior of the product when heated is, in fact, very irregular. Melting points from 84° to 106° may be obtained, depending upon the rate of heating or upon the temperature of the bath when the substance is placed in it. It is also an incomplete statement to say that it loses color at 75–7° because it loses color over a wide range of temperature, even as low as 65°. The formation of the red

compound is very rapid, the same product being obtained whether the anil is boiled 5 minutes with water or one hour.

Manchot and Furlong state that in the formation of the red compound the anil has taken up water as H and OH at the double bond, thus:

I had concluded that it was water of crystallization, but Furlong objects to this explanation, saying that I offer no evidence in support of it. I reply that it seemed the natural explanation. One thinks at once of such compounds as oxalic acid which melt in their water of crystallization, lose their water and then melt again at a much higher temperature. Other compounds like copper sulfate lose their color when the water is driven off. In the case of the red products, single crystals are reddish yellow but upon losing water they are quite colorless under the microscope. Manchot and Furlong's explanation, as they say, is that assumed by Hantzsch and Schwab (*Ber.*, 34, 829), who state that benzylidene-*p*-chloraniline hydrochloride takes up a molecule of water. This is however under the influence of a soda solution cooled below 0°. And further it is to be noted the benzylidene compound has already taken up a molecule of hydrochloric acid at the nitrogen atom. The case then is not analogous. Further, according to this explanation, an unsaturated compound becomes saturated and assumes its unsaturated character just as easily. The formation of the red compound undoubtedly begins at 70°, for Manchot and Furlong obtained a red oil in water at that temperature. I find that the water can be driven out of the compound at the same or even at a lower temperature. If the modern theory is true that unsaturated compounds are in a state of strain, involving a greater difficulty in producing unsaturated compounds than in producing saturated, this reversibility should not occur.

Furlong also refers to the lower melting point, 233-4°, which I gave to the condensation product of piperonal and *p*-aminobenzoic acid, whereas he found 242°. In view of the secondary product, melting at 171-3°, obtained when toluene is the solvent, whereas the use of alcohol seems to yield no such product, the figure may be too low, although the analysis does not indicate so great a difference.

Furlong finally refers to my hope of finding isomeric compounds in this field and states that Manchot and Furlong found that the condensation product of ethyl *p*-aminobenzoate and salicylic aldehyde occurs in two forms. At a later date Manchot and Palmberg (*Ann.*, 388, 103) regarded this as a case of keto-enol isomerism but were unable to obtain any ketone derivatives such as oximes to establish their conclusion. This view was based solely on the observation that ferric chloride acts more quickly

on one form than on the other at temperatures obtained by a mixture of carbon dioxide and acetone. This leaves much to be desired in the way of characterizing the keto form.

NEW BOOKS.

The Chemistry of the Radio-Elements. Part II. By FREDERICK SODDY. Longmans, Green & Company. 44 pp. Price, \$1.75.

The second part of Soddy's well-known book deals with the radio-elements and the periodic law. In the first chapter he brings the several theories discussed in Part I, up to date, and then goes into a somewhat detailed discussion of the work of A. S. Russell, K. Fajans and A. Fleck on isotopes or the chemically nonseparable elements. It is shown that when an α -particle is expelled it carries with it two atomic charges of positive electricity, and the expulsion of these two positive charges from the atom affects the valency of the product exactly as in ordinary electrochemical changes of valency. In the case of β -particle, which is a negative electron, the loss of this single atomic charge of negative electricity increases the positive valency of the product by one. In other words, the expulsion of an α -particle causes the element to shift its position in the periodic table by two places in the direction of diminishing mass so that the product is in the family next but one; the loss of a β -particle, however, causes the element to shift its position in the periodic table by one place in the opposite direction to that for an α -ray change. A loss of one α - and two β -particles, therefore, brings the product back into the same family as the parent. These elements are found to be nonseparable chemically, and are called *isotopes*. In general terms, "whenever two or more radio-elements fall into the same place in the periodic table, then independently of all considerations as to the atomic mass, the nature of the parent element and the sequence of changes in which they result, the elements in question are chemically nonseparable and identical." It is shown that this identity probably extends to the spectrum reactions and all physical properties with the exception of mass.

The final products of the disintegration of the thorium and uranium series fall in Group IV, Family B, and have atomic weights very close to that of lead. These elements are, therefore isotopes and are chemically nonseparable. In addition, they are isotopic with Radium B, Thorium B, Actinium B and Radium D. The possibility, therefore, of lead being a mixture of two or more chemically nonseparable elements is a pertinent one. T. W. Richards and Max Lambert have recently determined the atomic weight of lead obtained from radioactive minerals, and find the atomic weight to vary from 206.40 to 206.86, a very considerable variation from the atomic weight of ordinary lead, *vis.*, 207.15. Soddy, working

independently with lead from Ceylon thorite, obtained on three determinations the figures 208.5, 208.4, 208.3. These definite confirmations of the theory are intensely interesting.

The work is well written, and should be read by every chemist.

R. B. MOORE.

Oedema and Nephritis. A Critical, Experimental and Clinical Study of the Physiology and Pathology of Water Absorption in the Living Organism. By MARTIN H. FISCHER, Eichberg Professor of Physiology in the University of Cincinnati. Second and Enlarged Edition. Pages x + 695. John Wiley and Sons, Inc. Price, \$5.00.

Although Fischer states that edema and nephritis are problems of colloid chemistry, this book from the chemical standpoint is of interest only to those who are closely associated with biological work.

The first edition received so much adverse criticism that the author advises the interested reader to examine the evidence away from the noise of the pleading attorneys. With this advice in mind, it is yet hard for the reader to dismiss the feeling that the evidence in favor of his theory is presented in attorney-like fashion and that both sides are perhaps not equally well presented.

The retention of water in the tissues in cases of edema and nephritis, he states, is due to an abnormal production or accumulation of acids in the tissues. This increases the hydration capacity of the colloids and this is the explanation of edema. Nephritis is an edema of the kidney, glaucoma an edema of the eye, uremia an edema of the nervous tissues. He is aware that other substances than acids may be a cause of water retention, but in life he thinks these are of minor importance. Among such bodies are pyridine, certain amines, urea, and alkalies. In addition to edema and nephritis Fischer would explain absorption and excretion largely by a changing acid content of the tissues.

The evidence presented in favor of his theory is both experimental and clinical. Many test-tube experiments are cited to show the influence of alkalies and especially acids on the swelling of gelatin and fibrin and the influence of salts in diminishing this hydration. This forms the basis of the treatment which he recommends in certain cases of water retention in the body. At the same time he assures some of his critics that "These long suffering and mutilated materials" are not identical with, and are far less sensitive to the action of acids than the body proteins. The reasons for his treatment are discussed at length and his test-tube experiments are amply supported by work on animals and by clinical observations.

Much of the work upon which the theory rests has been severely criticised. The test-tube experiments speak equally well in favor of either alkalies or acids; but Fischer considers the conditions of life such that an increase in alkalinity of the body must be a rare occurrence, while acidosis is rather frequent. If Fischer's explanation of the facts is accepted, his

theory rests on a firm foundation. A successful explanation of facts, however, is not proof of the validity of an hypothesis, for we know that certain facts can be explained equally well by conflicting hypotheses. Some of the criticisms directed against his work bear out this statement.

His explanation of the edema in frog experiments (pp. 175, *et seq.*) is not accepted by McClendon (*Z. physik-chem. Biologie*, Bd. I., s. 169). McClendon gives experiments to prove that a living frog will absorb more water than a dead one and that the effect of the stoppage of circulation is to decrease rather than increase the absorption of water. Only after the tissues have long been dead will acidosis increase absorption. Finally, osmotic pressure will explain the whole water absorption. All this is contrary to Fischer's teaching, and to one who has not worked on either side of the question, the explanation is adequate.

Numerous other objections have been raised. Many of these Fischer has answered either in the book or in papers to which he gives references. The most important of these have been brought forth by Moore, and by Henderson and his collaborators. Henderson states that the acid concentration required to satisfy Fischer's theory can never be reached in the living body. From the clinical side the sharpest criticism is presented by the reviewer of the first edition of the book in the "Archives of Internal Medicine," Vol. 9, page 637.

His replies to these criticisms cannot be considered as on a par with his original presentation and betray an irritability and a use of sarcasm undesirable in a scientific discussion.

The results of the application of Fischer's treatment of edema and nephritis have been severely criticised and as warmly praised. Some believe it productive of human suffering and injury; others have found it almost a panacea. In this dilemma Fischer advises the physician to treat his nephritic cases by the old approved methods. If in spite of this he thinks death imminent, Fischer's treatment, which consists of alkali, salt and glucose, may be tried. If the patient dies, the expected will have happened; if he lives, it proves nothing but may encourage a repetition of the experiment. This he thinks is all that is necessary.

The book as a whole is extremely interesting and the presentation clear. The theory advocated is simple and explains many things for which we have no other explanation. Whether or not the theory deserves the wide application Fischer gives requires corroboration. It emphasizes the great importance of the colloids in physiology and pathology and will stimulate work in this field. The work yet necessary for the acceptance or rejection of the theory will be directly responsible for a better knowledge of edema and related problems. It is worthy of the attention of all interested in biological or medical work.

THE CHANGES OF MASS AND WEIGHT INVOLVED IN THE
FORMATION OF COMPLEX ATOMS.

[FIRST PAPER ON ATOMIC STRUCTURE.]

BY WILLIAM D. HARKINS AND ERNEST D. WILSON.¹

Received April 12, 1915.

In the study of the important question of the structure and composition of the elements, it might seem that a consideration of the relations existing between the atomic weights should give results of the greatest value. Unfortunately, however, the first suggestions presented to explain the relations which probably exist were given in such a form, and were based upon such extremely inaccurate values for the atomic weights that a very considerable prejudice has been developed against similar hypotheses.

The first important hypothesis in regard to atomic weight relations appeared in two anonymous papers in the *Annals of Philosophy* for 1815 and 1816, just one hundred years ago. These papers were known to have been written by Prout, whose ideas as they were presented received the vigorous support of Thomson, considered in England as the leading chemical authority of his day; and many years later, from 1840 to 1860, they were very strongly advocated by Dumas, who made a

¹ This first paper and the second and third papers which follow form the basis for a part of a dissertation presented to the University of Chicago by Ernest D. Wilson in part fulfilment of the requirements for the Ph.D. degree.

large number of atomic weight determinations during this period. Very many other chemists, among them Gmelin, Erdmann, and Marchand, were also numbered among Prout's supporters. On the other hand, Stas, who in the beginning tried to aid Dumas in the revival of Prout's hypothesis, afterward designated it as a pure fiction, and Berzelius at all times adhered to the view that the exact atomic weights could not be determined except by experiment.

The prejudice which existed a few years ago against Prout's idea is well shown by a quotation from von Meyer's *History of Chemistry*, printed in 1906.

"During the period in which Davy and Gay-Lussac were carrying on their brilliant work, and before the star of Berzelius had attained to its full luster, a literary chemical event occurred which made a profound impression upon nearly all the chemists of that day, *viz.*, the advancement of Prout's hypothesis. This was one of the factors which materially depreciated the atomic doctrine in the eyes of many eminent investigators. On account of its influence upon the further development of the atomic theory this hypothesis must be discussed here, although it but seldom happens that an idea from which important theoretical conceptions sprang, originated in so faulty a manner as it did."

Prout's work was not, as the above quotation infers, entirely "literary," for he made a large number of experimental determinations for use in his calculations of the specific gravity of the various elements, which he assumed to exist in the gaseous form. His experiments were, according to his own statements, somewhat crude; but he also made use of the more accurate data obtained by Gay-Lussac, and his work was based upon the volume relations of gases as discovered by the French investigator.

Exactly the form in which the numerical part of Prout's hypothesis should be expressed in terms of modern atomic weights, it is difficult to say, but the principal point is that his atomic weights, which, however, are not comparable with those now used, were expressed in whole numbers, as given below in two columns taken from his table:

TABLE I.—PROUT'S TABLE OF THE MORE ACCURATELY DETERMINED ATOMIC WEIGHTS.

Element.	Sp. gr.	Atomic weight, 2 vols. of hydrogen being 1.
H.....	1	1
C.....	6	6
N.....	14	14
P.....	14	14
O.....	16	8
S.....	16	16
Ca.....	20	20
Na.....	24	24
Fe.....	28	28
Zn.....	32	32
Cl.....	36	36
K.....	40	40
Ba.....	70	70
I.....	124	124

The atomic weights thus given by Prout are within a few units of the modern values in the case of the univalent atoms and for nitrogen; but the values given for the atoms of higher valence, with the exception of nitrogen, are approximately half the present values. This would mean that according to Prout's system, since the atomic weights he gives are whole numbers, the atomic weights of the present system should be divisible by two for the atoms of higher valence, which is equivalent to the use of the hydrogen molecule instead of the atom as a unit. In this connection it may be noticed that his atomic weights are taken on the basis of "2 volumes of hydrogen being 1."

Thus, from a numerical standpoint, Prout's hypothesis does not seem to mean what is usually supposed. Expressed in terms of the composition of what he considered to be complex atoms, it is given below in his own words:

"If the views we have endeavored to advance be correct, we may also consider the $\pi\rho\acute{o}\tau\eta\ \acute{\upsilon}\lambda\eta$ of the ancients to be realized in hydrogen, an opinion by the way, **not**, altogether new. If we actually consider this to be the case, and further consider the specific gravities of bodies in their gaseous state to represent the number of volumes condensed into one; or, in other words, the number of the absolute weight of a single volume of the first matter which they contain, which is extremely probable, multiples in weight must also indicate multiples in volume, and *vice versa*; and the specific gravities, or absolute weights of all bodies in the gaseous state, must be multiples of the specific gravity or absolute weight of the first matter, because all bodies in a gaseous state which unite with one another, unite with reference to their volume."

While it is true that Prout had at the time when he presented it, no real foundation for his ideas, more accurate work, while it proved his system to be invalid from a purely numerical standpoint, at the same time established the fact that the atomic weights of the lighter elements, on the hydrogen basis, are much closer to whole numbers than would be likely to result from any entirely accidental method of distribution. Thus the deviations of the lighter elements are small, as will be seen by the following table:

Element.	At. wt. H = 1.	Deviation from a whole number.
He.....	3.97	0.03
Li.....	6.89	0.11
Be.....	9.03	0.03
B.....	10.91	0.09
C.....	11.91	0.09
N.....	13.90	0.10
O.....	15.88	0.12
F.....	18.85	0.15

The average of these deviations is 0.09 unit, while the theoretical deviation on the basis that the values for the atomic weights are entirely accidental, is 0.25 unit. If the first seventeen elements are used in the calculation, the average deviation is found to be 0.15 unit, while the re-

Per cent. variation of 21 elements (omitting Be, Mg, Si, Cl), or the packing effect = 0.77%

Average deviation of the atomic weights, H = 1, from whole numbers = 0.21

Theoretical deviation of atomic weights from whole numbers on the basis that the deviations are entirely accidental = 0.25

Average deviation of the atomic weights, H = 1, for the eight elements from helium to sodium = 0.11

Average deviation of the atomic weights, O = 16, when Mg, Si, and Cl are omitted = 0.05

Average deviation of the atomic weights, O = 16, for the eight elements from helium to sodium = 0.02

¹ W. A. Noyes ("A Text-book of Chemistry," p. 72) states that the atomic weight used for hydrogen, 1.0078, is probably not in error by so much as 1 part in 5000.

² Heuse (*Verh. deut. physik. Ges.*, 15, 518 (1913)) obtained the value 4.002 as the result of 7 experiments.

³ Leduc (*Compt. rend.*, 158, 864 (1914)) gives the atomic weight of neon as 20.15 when hydrogen is taken as 1.0075. Leduc's value is not used, on account of the discovery of the complexity of neon as described in the text of the paper.

⁴ Richards and Hoover (*THIS JOURNAL*, 37, 95 (1915)) determined the atomic weights of carbon as 12.005, and of sodium as 22.995, and in Vol. 37, p. 108, they give the atomic weight of sulfur as 32.06.

⁵ The atomic weight for phosphorus is taken as 31.02 from recent determinations made by Baxter (*THIS JOURNAL*, 33, 1657 (1912)).

sult obtained for twenty-five elements is 0.21. The more complete table, designated as Table II, gives these deviations, which are seen to be negative in almost every case, the exceptions being magnesium, silicon, and chlorine. The exclusion of beryllium from consideration in this connection is due to the fact that its atomic weight is not known with sufficient accuracy, and neon is not taken into account, since its positive variation may be explained by the discovery by Thomson and by Aston that neon is a mixture of two isotopes of atomic weights twenty and twenty-two.

Not only is the variation from a whole number a negative number, but in addition its numerical value is nearly constant, the average value for the 21 elements being 0.77%, while the six elements from boron to sodium show values of 0.77, 0.77, 0.70, 0.77, 0.77, and 0.77%. The deviation is therefore not a periodic, but a constant one. If, then, a modification of Prout's hypothesis that the elements are built up of hydrogen atoms as units is to be taken as a working basis, it becomes important to find a cause for the decrease in weight which would result from the formation of a complex atom from a number of hydrogen atoms. The regularity in the effect suggests that, in general, this decrease in weight is probably due to some common cause, though the exceptional cases of magnesium, silicon, and chlorine, show that there is certainly some other complicating factor. The discovery of the reason for the deviation of the same kind in the case of neon, where it is due to its admixture with an isotope of higher atomic weight, suggests that it may not be impossible to find explanations for these three other exceptions. In order to have a term for the percentage decrease in weight, it may be well to call this the packing effect, or the percentage variation from the commonly assumed law of summation, that the mass of the atom is equal to the sum of the masses of its parts.

It has formerly seemed difficult to explain why the atomic weights referred to that of oxygen as 16 are so much closer to whole numbers than those referred to that of hydrogen as one, but, the explanation is a very simple one when the facts of the case are considered. The closeness of the atomic weights on the oxygen basis to whole numbers, is indeed extremely remarkable. Thus for the eight elements from helium to sodium the average deviation is only 0.02 unit, which is less than the average probable error in the atomic weight determinations. When twenty-one elements are taken from the table, omitting the exceptional cases of magnesium, silicon, and chlorine, the deviation averages only 0.05 unit, while if these are included, this is increased only to 0.09 unit. These results have been calculated without taking the sign into account. If the sign is considered the average deviation is reduced to 0.01 unit for the twenty-one elements. The probability that such values

could be obtained by accident, is so slight as to be unworthy of consideration. If an oxygen atom is a structure built up from 16 hydrogen atoms, then the weight according to the law of summation should be 16 times 1.0078 or 16.125. The difference between 16.125 and 16.00 is the value of the packing effect, and if this effect were the same for all of the elements, except hydrogen, then the choice of a whole number at the atomic weight of any one of them, would, of necessity, cause all of the other atomic weights to be whole numbers. Though this is not quite true, it is seen that the packing effect for oxygen is 0.77%, which is the average of the packing effects for the other 21 elements considered. Therefore, those elements which have packing effects equal to that of oxygen will have whole numbers for their atomic weights, and since the other elements show nearly the same percentage effect, their atomic weights must also lie close to whole numbers.

According to this view, Prout's hypothesis from the purely numerical standpoint, is entirely invalid, but there still remains the problem of finding an explanation for three facts: First, that the atomic weights of the lighter elements on the hydrogen basis approximate whole numbers; second, that the deviations from whole numbers are negative; and third, that the deviations are practically constant in magnitude. Before considering any explanation of these facts it is of interest to consider the following extremely interesting comments upon this subject, as written by Marignac in 1860:

"We are then able to say of Prout's hypothesis that which we can say of the laws of Mariotte and Gay-Lussac relative to the variations of the volumes of gases. These laws long considered as absolute, have been found to be inexact when subjected to experiments of so precise a nature as those of M. Regnault, M. Magnus, etc. Nevertheless they will be always considered as expressing natural laws, either from the practical point of view, for they allow the change of volume of gases to be calculated in the majority of cases, with a sufficiently close approximation, or even from the theoretical point of view, for they most probably give the normal law of changes of volume, when allowance has been made for some perturbing influences which may be discovered later, and for which it may also be possible to calculate the effects. We may believe that the same is true with respect to Prout's law; if it is not strictly confirmed by experiment, it appears nevertheless to express the relation between simple bodies with sufficient accuracy for the practical calculations of the chemist, and perhaps also the normal relationship which ought to exist among these weights, when allowance is made for some perturbing causes, the research for which should exercise the capacity and imagination of chemists. Should we not, for example, quite in keeping with the fundamental principle of this law, that is to say, in admitting the hypothesis of the unity of matter, be able to make the following supposition, to which I attach no further importance than that of showing that we may be able to explain the discordance which exists between the experimental results and the direct consequences of this principle? May we not be able to suppose that the unknown cause (probably differing from the physical and chemical agents known to us), which has determined certain groupings of primordial matter so as to give birth to our simple chemical atoms, and to impress upon each of these groups a special character and peculiar properties, has been able at

the same time to exercise an influence upon the manner in which these groups of atoms obey the law of universal attraction, so that the weight of each of them is not exactly the sum of the weights of the primordial atoms which constitute it?"

It has usually been assumed, and without any really logical basis for the assumption, that if a complex atom is made up by the union of simple atoms, the mass of the complex atom must be exactly equal to the masses of the simple atoms entering into its structure. Rutherford, from data on the scattering of α -rays in passing through gold leaf, has calculated an *upper* limit for the radius of the nucleus of a gold atom as 3.4×10^{-12} cm. The mass of this relatively heavy atom is, according to this calculation, practically all concentrated in this extremely small space, which is so small that it could no longer be expected that the mass of such a nucleus, if complex, would be equal to the sum of the masses of its component parts. In fact, since the electromagnetic fields of the electrons would be so extremely closely intermingled in the nucleus, it would seem more reasonable to suppose that the mass of the whole would not be equal to the sum of the masses of its parts. The deviation from the law of summation cannot be calculated on a theoretical basis, but it can easily be determined from the atomic weights, if the assumption is made that the heavier atoms are condensation products of the lightest of the ordinary elements, that is of hydrogen. This deviation expressed in terms of the percentage change, is what has already been determined, and designated as the packing effect.

Since this packing effect represents a decrease in weight, the first problem which represents itself for determination is the *sign* of the effect which would result from the formation of the positively charged nucleus of an atom by the combining of positive and negative electrons into some form of structure. Richardson¹ suggests that the positive nucleus of an atom might be built up of positive electrons alone and still be stable if the law of force between them were

$$+ a/r^2 - b/r^{p_1} + c/r^{p_2}, \text{ where } p_2 > p_1 > 2.$$

Here the first term gives the usual law of force, the second causes the electrons when close together to attract each other, and the third expresses the repulsion which keeps them from joining together. It would, however, seem more simple to assume, what seems much more probable, that the nucleus is held together by the attraction of positive and negative electrons, both of which are assumed to be present in any complex nucleus.

Since, even when the mass is assumed to be entirely electromagnetic, there still remain two possibilities even for the simple case of hydrogen, first, that the hydrogen nucleus is the positive electron, and second, that it may be complex, it has seemed best to choose for the purpose of cal-

¹ "The Electron Theory of Matter," p. 582.

culatation the simplest system, which consists of one positive and one negative electron. The problem thus presented for solution is the determination of the sign and the magnitude of the change of mass which results when a positive and a negative electron are brought extremely close together.

Lorentz¹ speaks of this problem, but does not solve it either with respect to the sign or the magnitude of the effect. He does state, however, that if the electrons were to be brought into immediate contact, the total energy could not be found by addition, which may be considered as equivalent to the statement that the mass of a system made up in this way would not be the same as the sum of the masses of its parts. The fundamental equations used here as the basis of the calculation which follows, have been taken from the work of Lorentz.

The value of e , the charge on the electron, may be defined as

$$e = \iiint \rho d\tau,$$

where ρ is the volume density of the electricity, and $d\tau$ is an element of volume. For the purposes of the first part of the calculation, the electron may be considered as a point charge, but the values of the electromagnetic mass used later are given for the Lorentz form of electron, which takes the form of an oblate spheroid when in motion.

The space surrounding an electron must be considered as different from a space not adjacent to an electrical charge. If a charged particle is brought into this space it is acted upon by a force which varies from point to point, and has at every point in space a definite value and direction. This force is designated by \mathbf{E} , and is a vector point function. If the electron is in motion it acts as an electric current equal to $e\mathbf{u}$, where \mathbf{u} represents its velocity. The magnetic force due to this motion is easily seen to be a function of the current equivalent of the moving electron, and is also a vector, designated by \mathbf{H} . Then

$$\mathbf{H} = f(\mathbf{E}, \mathbf{u}, \phi)$$

¹ H. A. Lorentz, "The Theory of Electrons," 1909, pp. 47 and 48.

where ϕ is the angle between \mathbf{E} and the direction of motion. The direction of \mathbf{H} is perpendicular to the direction of u and is at the same time circular.

It is evident that the total energy of the system is a function of both the electric and the magnetic intensities. For the purposes of this calculation the mass of a system is considered as electromagnetic, and hence as a function of the energy of the system. Therefore it is necessary to use some function of both \mathbf{E} and \mathbf{H} . This function is designated by \mathbf{G} and is called the electromagnetic momentum. The derivation of the equations for \mathbf{G} has been given by Lorentz, so here it will be sufficient to define it as

$$\mathbf{G} = [\mathbf{E} \mathbf{H}]/c$$

where $[\mathbf{E} \mathbf{H}]$ means the vector product of \mathbf{E} and \mathbf{H} , and c is the velocity of light. From the expressions obtained for \mathbf{G} it is easy to obtain those which represent the mass.

In the treatment which follows, only the longitudinal electromagnetic mass is considered, and terms containing u to a higher power than the first are disregarded, as they appear to be unimportant. The following general treatment, in which Heaviside units are used, gives an outline of the method:

For the field due to a system of charges

$$\frac{[\mathbf{E} \mathbf{H}]}{c} = \frac{[(\sum_i \mathbf{E}_i)(\sum_j \mathbf{H}_j)]}{c} = \frac{\sum_i [\mathbf{E}_i \mathbf{H}_i]}{c} + \frac{\sum_{(ij)} [\mathbf{E}_i \mathbf{H}_j]}{c}$$

where the summation $\sum_{(ij)}$ is the vector product of each i with each j . The first summation gives the electromagnetic momentum which would be due to the particles if their fields did not overlap, and the second term, which is the important one here, gives the effect of the overlapping of the fields. This may be called the "mutual electromagnetic momentum" and designated by $\bar{\mathbf{G}}$.

For point charges

$$\mathbf{E}_1 = \frac{(1 - u^2)e_1}{4\pi r^2(1 - u^2 \sin^2 \theta_1)^{3/2}}$$

at the point P_x, y, z . Let

$$(1 - u^2 \sin^2 \theta_1) = \beta_1^2$$

and

$$(1 - u^2) = k^2.$$

The transverse component of \mathbf{E} due to the two particles 1 and 2 is

$$\mathbf{E}_t = \frac{k^2 e}{4\pi} \left\{ \frac{\sin \theta_2}{\gamma_1^2 \beta_1^3} \pm \frac{\sin \theta_1}{\gamma_2^2 \beta_2^3} \right\}$$

where the sign is *positive* if the charges have the same sign, and *negative* if they are of opposite sign. As only the longitudinal component of the vector \mathbf{G} is desired, only the transverse component of \mathbf{E} is needed.

$$\mathbf{H} = u/c \mathbf{E} \sin \phi$$

where ϕ = the angle between \mathbf{E} and the direction of u . If \mathbf{E}_1 is used, $\phi = 90^\circ$. Therefore

$$\mathbf{H} = u/c (\mathbf{E}_1 \sin \theta_1 \pm \mathbf{E}_2 \sin \theta_2)$$

$$\mathbf{G}_L = \frac{[\mathbf{E}, \mathbf{H}]}{c} = \frac{u}{c^2} (\mathbf{E}_1 \sin \theta_1 \pm \mathbf{E}_2 \sin \theta_2)(\mathbf{E}_1 \sin \theta_1 \pm \mathbf{E}_2 \sin \theta_2).$$

And

$$\begin{aligned} \bar{\mathbf{G}} &= \pm \frac{2u}{c^2} \int \mathbf{E}_1 \mathbf{E}_2 \sin \theta_1 \sin \theta_2 d\tau \\ &= \pm \frac{2u}{c^2} \frac{k^4 e^2}{(4\pi)^2} \int \frac{\sin \theta_1 \sin \theta_2}{\gamma_1^2 \gamma_2^2 \beta_1^3 \beta_2^3} d\tau. \end{aligned}$$

Now

$$\gamma^2 \beta^2 = \gamma^2 - u^2 (\gamma^2 \sin^2 \theta) \quad \text{and} \quad (\gamma^2 \sin^2 \theta) = y^2.$$

Neglect all of the terms in u^2 .

$$d\tau = 2\pi y dy dx.$$

Then

$$\bar{\mathbf{G}} = \frac{uk^4 e^2}{8c^2 \pi^2} \cdot 2(2\pi) \int_0^\infty \int_0^\infty \frac{y^3 dy dx}{\sqrt{\{(x-a)^2 + y^2\}[(x+a)^2 + y^2]\}^3}$$

which is obtained by making use of the symmetry of the equation. Or

$$\begin{aligned} \bar{\mathbf{G}} &= \left(\frac{uk^4 e^2}{8c^2 \pi^2} \cdot 4\pi \right) \frac{1}{a} \int_0^\infty \int_0^\infty \frac{y^3 dx dy}{\sqrt{\{(x-1)^2 + y^2\}[(x+1)^2 + y^2]\}^3} \\ &= \frac{uk^4 e^2}{2\pi c^2 a} J \end{aligned}$$

where

$$\begin{aligned} J &= \int_0^\infty \int_0^\infty \frac{y^3 dx dy}{\sqrt{\{(x-1)^2 + y^2\}[(x+1)^2 + y^2]\}^3} \\ J &= \frac{1}{2} \int_0^\infty dx \int_0^\infty \frac{u du}{[(\alpha+u)(\beta+u)]^{3/2}}, \end{aligned}$$

where $u = y^2$.

$$\alpha = (x-1)^2; \quad \beta = (x+1)^2; \quad \alpha - \beta = (-4x).$$

$$\begin{aligned} J &= \frac{1}{2} \int_0^\infty dx \left[\frac{2[(\alpha+\beta)u + 2\alpha\beta]}{(\alpha-\beta)^3[(\alpha+u)(\beta+u)]^{1/2}} \right]^\infty_0 \\ &\quad \int_0^\infty \left[\frac{(\alpha+\beta)}{(\alpha-\beta)^2} - \frac{2\alpha\beta}{(\alpha-\beta)^2 \sqrt{\alpha\beta}} \right] dx \\ &= \int_0^\infty \frac{1}{16x^3} [\alpha + \beta - 2\sqrt{\alpha\beta}] dx \\ &= \int_0^\infty \frac{[\sqrt{\alpha} - \sqrt{\beta}]^2}{16x^3} dx \\ &= \int_0^\infty \frac{[(x-1) - (x+1)]^2}{16x^3} dx \end{aligned}$$

$$\begin{aligned}
&= \int_0^1 \frac{(-2x)^2}{16x^2} dx + \int_0^\infty \frac{(-2)^2}{16x^2} dx \\
&\quad \frac{1}{4} + \frac{1}{4} \\
&\quad \frac{1}{2}
\end{aligned}$$

$$G = \frac{uk^4}{4\pi ac^2}$$

The mass represented by this value of \bar{G} is

$$\Delta m = \pm e^2/4\pi c^2 a.$$

Now the longitudinal mass, m_1 is

$$m_1 = e^2/6\pi c^2 R,$$

where R is the radius of the electron. By division

$$\Delta m/m_1 = 3R/2a,$$

where a is equal to one-half the distance apart of the electrons.

In the application of this last equation, R must be taken as the radius of the positive electron, since it is assumed that it is the seat of practically all of the mass of the atom. For a decrease of mass of 1% in this simple case the distance apart of the positive and negative electrons would be, according to the equation, 300 times the radius of the positive electron. In order to produce a decrease of mass equal¹ to the average decrease of weight found for the 21 elements given in Table II, or 0.77%, the distance apart of the two electrons as calculated, would be 400 times the radius of the positive electron. This, however, does not give the result for any actual case which is known, and in general the nucleus of an atom must be more complex than this. In a more complex nucleus it is possible that the positive and negative electrons need not come so close together in order to give the same decrease of mass. It is evident that the calculation cannot be applied to any special atom until the mass of the positive electron is determined. If, as Rutherford seems to think probable, the positive nucleus of the hydrogen atom is the positive electron, then the most probable composition of the helium nucleus would be four positive electrons to two which are negative, and it would not seem improbable that in such a system the effect upon the mass of the positive electrons might be greater than in the simpler case used for the calculation, which would mean simply that the positive and negative electrons need not be so close together to produce the same effect on the mass. Whether this is true or not could not be determined without a knowledge of the structure of the helium nucleus. If, as Nicholson assumes, the

¹ From the electromagnetic theory the velocity of high speed electrons also exerts a perceptible influence upon the mass, but the magnitude of this effect has not as yet been determined for the case of the electrons in an atom.

hydrogen nucleus is complex, the decrease of mass in the formation of one helium atom from four of hydrogen, would be due to the closer packing of the positive and negative electrons in the helium nucleus.

Earlier in the paper it has been shown that the fact that the atomic weights on the oxygen basis are much closer to whole numbers than those on the hydrogen basis, is explained by what has been called the packing effect, or the change of mass involved in the formation of heavier atoms from hydrogen. The average of the packing effects for the elements considered, is 0.77%. This is also the value of this effect for oxygen, which happens to have been chosen as the fundamental element in the determination of atomic weights. If the number representing atomic weight of hydrogen, 1.0078, is decreased by this percentage amount, it becomes 1.0000, which is the fundamental unit in atomic weight determinations. The atomic weights of the twenty-five fundamental elements listed in Table II, are found, on the whole, to be very nearly products of this unit by a whole number. While the numerical unit of measurement does not change, the actual unit of mass, the mass of the hydrogen nucleus, varies slightly from atom to atom, and this variation causes the slight deviation of the atomic weights from whole numbers.

The opposite of the system here proposed would be, to suppose that the values of the atomic weights are wholly the result of accident. On this basis the probability that the atomic weights fall as close to whole numbers as they do, may be calculated. In such calculations oxygen is omitted, since its atomic weight is fixed as a whole number, and hydrogen is not used, since its atom contains only one hydrogen nucleus.

The first calculation made was that of the probability that *each* of the atomic weights should be as close as it is to a whole number. The data used are those of Table II. The chance that the atomic weight of nitrogen should entirely, by accident, deviate from a whole number by only 0.01 of a unit was determined by dividing the unit into the 200 divisions corresponding to the assumed accuracy (Landolt-Börnstein-Meyerhoffer, Tabellen) of 0.005. The greatest possible deviation would then be 100 divisions, while the actual deviation of 0.01 unit corresponds to 2 divisions. The probability is then one-fiftieth. The chance that any number of independent events should all happen is the product of the separate probabilities of their each happening. The probability calculated in this way is 2×10^{-22} , or

$$\frac{2}{10,000 \text{ billion billion}},$$

which indicates that there is practically no chance that the atomic weights are entirely the result of accident.

Another probability, which seems to be of more value in connection with the present problem, is that the *sum* of the deviations shall not ex-

ceed the sum actually found. This is of the form known as De Moivre's problem, and the method was used by Laplace¹ in calculating the probability that the sum of the inclinations of the orbits of the ten planets to the ecliptic is not greater than the value found at that time, 0.914187 of a right angle. The result obtained was 1.1×10^{-7} . The problem is stated in the following way: An urn contains $n + 1$ balls marked, respectively, 0, 1, 2, 3, n ; a ball is drawn and replaced: required the probability that after i drawings the sum of the numbers drawn will be s . This probability is the coefficient of x^s in the expansion of

$$\frac{1}{(n+1)^i} (1-x^{n+1})^i (1-x)^{-i},$$

or the probability P is

$$P = \frac{1}{(n+1)^i} \left\{ \frac{i+s-1}{i-1} \frac{1}{s} - \frac{i}{1} \frac{i-1+s-n-1}{i-1} \frac{1}{s-n-1} + \frac{i(i-1)}{1.2} \frac{i-1+s-2n-2}{i-1} \frac{1}{s-2n-2} \dots \right\}.$$

In the case of the atomic weights P gives the probability that the sum of the deviations from whole numbers shall equal s , which is not what is desired. The result wanted is the probability that the sum of the errors shall be equal to or less than s , or the summation of the P s from 0 to s .

Now

$$\sum_{s=0}^{s=s} \frac{i+s-1}{i-1} \frac{1}{s} = \frac{i+s}{i} \frac{1}{s}$$

So the desired probability, P' is:

$$P' = \sum_{s=0}^{s=s} \frac{1}{(n+1)^i} \left\{ \frac{i+s}{i} \frac{1}{s} - \frac{i}{1} \frac{i+s-n-1}{i-1} \frac{1}{s-n-1} + \frac{i(i-1)}{1.2} \frac{i+s-2n-2}{i-1} \frac{1}{s-2n-2} - \frac{i(i-1)(i-2)}{1.2.3} \frac{i+s-3n-3}{i-1} \frac{1}{s-2n-3} \dots \right\}.$$

In solving this problem all of the first twenty-seven elements have been used with the exception of hydrogen and oxygen, and these *should* be omitted for the reasons given above. The errors in the determined values have been taken as they are given in Table II. The atomic weights used in the calculation are as follows:

He.....	4.002	Mg.....	24.32	Ca.....	40.07

¹ Laplace, "Oeuvres VII, Theorie Analytique des Probabilites," pp. 257-62.

The average probable error as determined from Table I is 0.043 unit, which is equivalent to about 24 divisions for one unit, or 12 divisions for half a unit, which is the maximum possible deviation from a whole number. Since n is 12, $n + 1$ is taken as 13. The sum of the deviations from whole numbers is 2.342, which is equal to 56 of the divisions determined above, or $s = 56$. The number of elements, i , is 26. The probability calculated on this basis is 6.56×10^{-8} , or approximately

15,000,000

It has been assumed in this paper that the cause of the deviations of neon, magnesium, silicon, and chlorine, which are exceptional in giving positive deviations from the atomic weights on the hydrogen basis, must be different from that which gives the deviations of the other elements. The cause of the deviation of neon has been explained, but for the others it is unknown. In the calculations of the probabilities given above these elements have been included. It may be of interest to note that if these elements had been excluded the probability for the 21 remaining elements would have been found to be about

7 billion

It is an interesting coincidence that the probability above found for the 27 lighter elements is about 1×10^{-7} , while the probability determined by Laplace that the sum of the inclinations of the ten planets then known, to the ecliptic, should not be greater than the sum of the measured values, is almost the same, or 1.123×10^{-7} . In the second paper of this series it will be shown that the atomic weights not only approximate whole numbers, but that these whole numbers are in addition *certain* numbers which are determined by a special system, and which may be given accurately by an equation of the form

$$W = 2(n + n') + \frac{1}{2} + [(-1)^{n-1} \times \frac{1}{2}].$$

The probability that the atomic weights should come so close to these *special* whole numbers is much less than that calculated above, so that the words of Laplace may be applied to the system presented here, as well as to the one he himself gives. That the atoms are built up of units of weight very close to one, and that therefore this modified form of Prout's hypothesis holds, "est indiquée avec une probabilité bien supérieure à celle du plus grand nombre des faits historiques sur lesquels on ne se permet aucun doute."

The accepted atomic weights on the oxygen basis as now used are closer to whole numbers than those given by Ostwald in 1890.¹ Ostwald's numbers are all larger than the corresponding whole numbers, so the

¹ *Allgemeine Chemie*, I, p. 126 (1890).

deviations were all positive. On the other hand, the present values show both positive and negative deviations. The fact that the small change of 0.77% from the oxygen to the hydrogen basis eliminates practically all of the tendency of the atomic weights to be near whole numbers, when as many as 27 elements are considered as in Table II, shows that the atomic weight of oxygen cannot be taken as very different from 16.00 without obscuring this relationship. Thus it has been shown that the probability that the atomic weights on the oxygen basis would come entirely by accident as close to whole numbers as they do, is 6.56×10^{-8} , or about

$$\frac{1}{15,000,000}.$$

A change of only 0.77% from the oxygen basis causes an enormous increase in the probability that the atomic weights obtained in this way could be as close to whole numbers as they are, entirely by accident. Thus the chance that the sum of the deviations should come out as equal to, or less than, the sum actually found, is 0.105, or

$$\frac{1}{10}.$$

As has been seen, there are 27 atomic weights distributed over 59 units of atomic weight. The greatest common divisor of the whole numbers corresponding to the atomic weights is one. The atomic weights are therefore such that numerically they seem to be built up from a unit of a mass of one, and the probability results seem to show that this unit of mass must be very close to 1.000, expressed to three decimal places. On the other hand, this unit of mass must be somewhat variable to give the atomic weights as they are, even although a part of the variation, in some cases, may be due to the inaccuracy with which the atomic weights are known. This leads either to the supposition (1) that the atoms are built up of some unknown elementary substance, of an atomic weight which is slightly variable, but is on the average extremely close to 1.000, and which does not in any case deviate very far from this value, or to the idea (2) which is presented in this paper, that the *nucleus* of a known element is the unit of structure. The atom of this known element has a mass which is close to that of the required unit, and it has been proved that the decrease of mass involved in the formation of a complex atom from hydrogen units is in accord with the electromagnetic theory. The adoption of the first hypothesis would involve much more complicated relations. It would necessitate the existence of another elementary substance with an atomic weight close to that of hydrogen, it would involve a cause for the increase of weight in the formation of some atoms, and a decrease in other cases, and it would also involve the existence of another unit to give the hydrogen atom.

In the second paper, which follows, still more evidence in favor of the theory that the other atoms are complex atoms built up from hydrogen units will be presented, and it will be shown that there is also an important secondary unit of structure.

The writers wish to thank Professor A. C. Lunn, of the Department of Mathematics, for outlining for them the mathematical analysis of the determination of the packing effect.

Summary.

1. The atomic weights of the first 27 elements, beginning with helium, are not multiples of the atomic weight of hydrogen by a whole number, as they would be if Prout's original hypothesis in its numerical form were true. This may be expressed by the statement that the atomic weights on the hydrogen basis are not whole numbers. However, when these atomic weights are examined critically it is found that they differ from the corresponding whole numbers by a nearly constant percentage difference, and that the deviation is negative in sign, with an average value of -0.77% .

2. This percentage difference has been called the packing effect, and it represents the decrease of weight, and presumably the decrease of mass, which must take place if the other atoms are complexes built up from hydrogen atoms. The regularity in this effect is very striking, the values for a number of the lighter atoms being as follows: He, -0.77 ; B, -0.77 ; C, -0.77 ; N, -0.70 ; O, -0.77 ; F, -0.77 ; and Na, -0.77% , while the average value for the first 27 elements is -0.77% .

3. The regularity of the packing effect gives an explanation of the well-known fact that the atomic weights on the oxygen basis are very close to whole numbers, while this is not true of the atomic weights on the hydrogen basis except in the case of the lightest elements from helium to oxygen. The atomic weight of hydrogen on the oxygen basis is 1.0078. If this were decreased by the value of the packing effect of 0.77% , it would become a whole number, 1.000. Then, if the other elements are built up from hydrogen atoms as units, all of the atoms which are formed with a packing effect of -0.77% , must have whole numbers for their atomic weights; thus the atomic weights of the elements listed in Section 2, above, must be whole numbers in six of the seven cases listed, He, B, C, O, F, and Na. The fixing of any one of these six atomic weights as whole numbers causes the other five to be whole numbers also. Thus the atomic weights referred to carbon as 12.00 would be the same as those referred to oxygen as 16.00. A variation of the atomic weight of an element on the oxygen basis from a whole number indicates that the packing effect for that element does not have the average value.

4. Recent work has shown that the nucleus of an atom must be extremely minute. Thus Rutherford gives the *upper* limit for the radius

of the relatively large and complex gold atom as 3.4×10^{-12} cm., while Crehore, who proposes another theory of the structure of the atom, considers that none of the electrons have orbits of a greater radius than 10^{-12} cm. The high velocity with which the β -particles are shot out in radioactive transformations has been considered as evidence that these electrons must come from much closer to the center of the atom than the assumed radius of the atom. It therefore seems practically certain that the electrons and positively charged particles which make up the nucleus of a complex atom, are packed exceedingly closely together. As a result of this close packing, the electromagnetic fields of the charged particles must overlap to a considerable extent, which would mean that the mass of the atom ought not to be equal to the sum of the masses of the individual particles from which it is built.

5. The closeness to which a positive and a negative electron would have to approach to give a decrease of mass equal to 0.77%, or the average value of the packing effect, is found by calculation to be to a distance of 400 times the radius of the positive electron. This case does not correspond to any element actually known, for the simplest of the atoms considered, helium, may be supposed to have a nucleus built up from four hydrogen nuclei and two negative electrons. However, the magnitude of the effect seems to be of the order which would be expected.

6. The probability for the first 27 elements, that the sum of the deviations of the atomic weights (on the oxygen basis from whole numbers) should by accident be as small as it is, is found to be one chance in fifteen million. On the other hand, a change of only 0.77% from the oxygen basis to that of hydrogen gives one chance in ten that the atomic weights should be as close to whole numbers as they are.

The second paper on atomic structure, which follows this one, gives still more evidence that the complex atoms are built up from hydrogen atoms as units of structure.

THE STRUCTURE OF COMPLEX ATOMS. THE HYDROGEN-HELIUM SYSTEM.

[SECOND PAPER ON ATOMIC STRUCTURE.]

BY WILLIAM D. HARKINS AND ERNEST D. WILSON.

Received April 12, 1915.

In the preceding paper it has been shown that the atomic weight relations of the elements are such as to make it extremely probable that the atoms are complex structures built up from hydrogen atoms. It therefore becomes important to determine in what way the hydrogen atoms unite

together to make up the complex. Rutherford proved that the α -particles which are shot out in the disintegration of the radioactive elements, have a mass of four units,¹ and that they give ordinary helium gas when they escape through the walls of a thin glass capillary tube in which the emanation is stored.² Fajans,³ Soddy,⁴ Russell,⁵ von Hevesy,⁶ and Fleck,⁷ have found that, when a radioactive substance ejects an α -particle, the new substance has different properties, and a different valence from those of the parent material. The change is such that the new element lies two places to the left in the periodic table, and therefore has an atomic number which is two less than before the alpha disintegration. It has been found that uranium, for example, can lose eight α -particles in eight steps, and change into a form of lead. From this it is seen that the radioactive elements, which have high atomic weights, must, at least in part, be built up of α -particles, and therefore of helium atoms, with this difference, that while the α -particle is probably present as a whole in the complex atom, the nonnuclear electrons of the helium atom, undoubtedly rearrange themselves in the complex atom, so that the helium atoms as a *whole* do not preserve their identity.

Now that it has been proved that the atoms of high atomic weight are built up, in part at least, of helium atoms, the question arises as to whether the same relations hold for the lighter atoms which have not been found to give an appreciable alpha disintegration. If they do, then a change of two places to the right in the periodic table, which is more accurately expressed as an increase of two in the atomic number, should increase the atomic weight by the weight of one helium atom, or by the number four. Since a change of two in the atomic number should increase the atomic weight by four, according to this theory, the average increase in the atomic weight per atomic number should be two. From this it might be expected that the tenth element would have an atomic weight equal to 20, and the twentieth element, an atomic weight of 40. That this is actually the case is seen, for neon, the tenth element has an atomic weight of 20, and calcium, the twentieth element, has a weight of 40. In order to investigate the question more in detail, a start may be made with helium, of an atomic number 2 and a weight of 4. The element of

⁷ Fleck, *Trans. Chem. Soc.*, 103, 381 and 1052 (1913).

an atomic number four, should be heavier by the weight 4, or its atomic weight should be equal to eight. Above this the elements, if built up according to this helium system would have the weights:

Atomic number.	Atomic weight.	Group number.
6	12	4
8	16	6
10	20	0
12	24	2
14	28	4
16	32	6

where each step is made by adding the weight of one helium atom. The equation which represents the idea that the atomic weights of the lighter elements, belonging to even numbered groups, change in the same way as the elements in a radioactive series (namely, by an amount equal to four for a change of two groups in the periodic table), is

$$W = 2n,$$

where W is the atomic weight and n is the atomic number.

If a similar system is supposed to hold for the odd numbered elements, then beginning with lithium of an atomic weight seven, and an atomic number three, the atomic weights according to the simple helium system would be:

Atomic number.	Atomic weight.	Group.
3	7	1
5	11	3
7	15	5
9	19	7
11	23	1
13	27	3
15	31	5
17	35	7
19	39	1

It is thus seen that for the odd groups as well as the even, the increase in the atomic weight is just that predicted for the addition of one helium atom for each step of two atomic numbers. The even and odd numbered elements are thus seen to belong to two different series. A single equation for both of these series may be easily written by introducing a term which disappears when n is even, and is effective when n is odd. If W is the atomic weight,¹

¹ Although it was not known to the writers at the time when this paper was written, it was found on looking up the subject that Rydberg, in an extremely important paper published in 1896 (*Z. anorg. Chem.*, 14, 80) found from a study of atomic weight relations that the elements belong to two series corresponding to the two formulas $4n$ and $4n-1$, where n is a whole number. Thus from an empirical basis he derived the same relationships as are developed in this paper from an entirely different standpoint; that is by the application of the relations found between the elements in a single radioactive series to the elements of small atomic weight.

$$W = 2n + \{1/2 + [(-1)^{n-1} \times 1/2]\}.$$

In Table I the atomic weights calculated according to this equation are given for the elements up to and including cobalt.

TABLE I.—A COMPARISON OF THE CALCULATED AND THE DETERMINED VALUES OF THE ATOMIC WEIGHTS.¹

Element.	n.	Calculated.	Detd.	Dif.	Probable error in detn.

It is interesting to note that of the 28 elements in this table, 13, or very nearly half, have atomic weights which are divisible by 4, and that of all of the possible multiples of 4, only two are missing, *i. e.*, 2×4 and 9×4 . Seemingly to make up for the omission of the 9×4 , the 10×4 occurs twice. This may be represented as follows:

$1 \times 4 = \text{He}$	$8 \times 4 = \text{S}$
$2 \times 4 = \text{missing, but represented by}$	$9 \times 4 = \text{missing, but replaced by}$
$(2 \times 4) + 1$	$10 \times 4 = \text{A}$
$3 \times 4 = \text{C}$	$10 \times 4 = \text{Ca}$
$4 \times 4 = \text{O}$	$11 \times 4 = \text{Sc}$
$5 \times 4 = \text{Ne}$	$12 \times 4 = \text{Ti}$
$6 \times 4 = \text{Mg}$	$13 \times 4 = \text{Cr}$
$7 \times 4 = \text{Si}$	$14 \times 4 = \text{Fe}$

Of the atomic weights given in the table only one is divisible by 2, which is at the same time not divisible by four. Seven, or one-fourth of

¹ For the final equation including n' see section 3 of the summary.

the atomic weights, are divisible by 3, though the threes are not evenly spaced like the fours; three are divisible by 5, and two of these, argon and calcium, have the same atomic weight. Five are divisible by 7, and two by 9, and every possible multiple of 16 appears. According to this the most important numbers are 4 and 3, which is in accord with the equation given for the atomic weights, 3 being an important secondary unit.

Of the twenty-six elements given in this table, it is found that the equation gives the atomic weights of nine, or more than a third, with no difference between the calculated and determined values, and for six other elements the difference is practically within the limits of error of the determinations. For the three elements, Be (+1.1), N (—0.99), and argon (—3.88), the differences in the first two cases are practically equal to the weight of a hydrogen atom, and for argon the difference, when allowance is made for a possible change of the packing effect, is the weight of a helium atom. The deviations of magnesium (0.32), silicon (0.3), and chlorine (0.46), are somewhat large, the largest deviations being that of chlorine, which is equal to 1.3% of its atomic weight. These deviations are also exceptional in that they are greater on the basis of oxygen as 16 than they are on the basis of hydrogen as 1.00.

If these six cases of deviation, three of which can be explained as due to a deviation in the number of hydrogen or helium units, are neglected, it is found that for the other twenty elements the equation gives the atomic weights with so great an accuracy that the average deviation is only 0.045 unit, which is practically equal to the average probable error in the experimentally determined values as given by Landolt-Börnstein.

It has been seen that for the first twenty elements the average increase in weight is 2.00, or exactly the same increase as is found for the uranium or the thorium radioactive series. For the heavier elements the increase is somewhat more rapid. The increments are tabulated in Table II.

TABLE II.—THE CHANGE IN THE ATOMIC WEIGHT WITH THE ATOMIC NUMBER.

Change of atomic number.	Final element.	Atomic wt.	Average increment.
0-10	Ne	20	2.0
10-20	Ca	40.07	2.007
20-30	Zn	65.37	2.53
30-40	Zr	90.6	2.53
40-50	Sn	119.0	2.84
50-60	Nd	144.3	2.53
60-70	Yb	172.0	2.52
70-79	Au	197.2	2.80
79-92	U	238.5	3.20

The table shows that the increment 2.00 occurs twice, and 2.52 four times in the table. The increment in general increases with the atomic number.

As has been stated, if the first nine elements are considered, the aver-

age deviation of the atomic weights ($O = 16$) from whole numbers is only 0.019 unit, which is an extremely small deviation. If the last ten elements in Table I of the preceding paper are taken, it is found that the deviation, though much larger, is still small, and is equal to 0.075 unit. The last of these ten elements is cobalt, the second element in the eighth group for the first occurrence of the eighth group in the periodic table. Table III shows that at this point the deviation suddenly jumps to a relatively large value, being 0.32 for nickel, 0.43 for copper, and 0.37 for zinc, with an average of 0.247 for the ten elements beginning with nickel and ending with rubidium. The average deviation for the next ten elements, beginning with strontium and ending with cadmium, is also 0.247 unit, for the ten from indium to cerium it is 0.199, and for the

¹ For a complete table of the lighter elements see Table II of the preceding paper.

twelve elements from tantalum to uranium, it is 0.260 unit. However, the value of Table II, as it stands, is very slight on account of the large probable errors in many of the atomic weights. This can be remedied by the choice of only such elements from the table as have accurately determined atomic weights. If thirteen elements are thus chosen as follows: nickel, copper, zinc, arsenic, bromine, rubidium, strontium, rhodium, silver, cadmium, iodine, caesium, and barium, the average deviation is 0.248 unit, while the theoretical deviation calculated on the basis that the atomic weights show no tendency to be near whole or any other special numbers, is 0.250 unit. Therefore, the tendency for the atomic weights to approximate whole numbers, which is very marked for the elements from helium up to an atomic weight of 59 (cobalt), seems to altogether disappear at the atomic weight 59 (beginning with nickel) and is not found for any of the elements which have an atomic weight higher than this value.

The reason for this abrupt change at the atomic weight 59, is not apparent. It may be in some unknown way connected with the first appearance at this point of new series, possibly formed by disintegration instead of aggregation; to a change in the effect of packing, or, if atoms exist which are lighter than hydrogen, it might possibly be due to their inclusion. If the first suggestion is considered, it is found that when the elements of high atomic weight are reached several series are known to exist. Thus the isotopes of lead, lead from radium and radium B differ in atomic weight by eight units, the isotopes radium F and radium A differ by the same amount, and radio-thorium and uranium X_1 differ by six units. If the members of the actinium series could be included, some of these differences in the weights of one species of atom would be made even larger. Where such differences exist in the weights of the different atoms having a single atomic number, it cannot be expected that any very simple relations can be found to exist for atoms of a high atomic weight, except where it is possible to compare the weights of the members of a single series, such as the uranium-radium, the thorium, or the actinium radioactive series.

It is quite possible that these differences of series go downward in the periodic system to relatively low atomic weights. Thus Aston claims to have separated neon, with an atomic weight 20.2, into neon and meta-neon, the atomic weights for which have been found by Thomson to be 20 and 22, so that the deviation of neon from the law of the approximate whole number by the amount +0.2 is probably only an apparent one. It is of interest that the difference between the atomic weights of neon and meta-neon, as found by Thomson, is two, which is the same as the average increment in the weights of the lighter elements, and is equal to the average difference between the weights of isotopes in the radioactive

series. This average difference has been supposed to be also the actual difference between any two adjacent isotopes as listed below under any single atomic number:

Atomic number.

- 82. Lead from Ra, Lead from Th, Ra D, Th B, Ra B.
- 83. Bi, Ra E, Th C, Ra C.
- 84. Ra F, Th C, Ra C, Th A, Ra A.
- 86. Th Em, Ra Em (Nt).
- 88. Th X, Ra, Ms Th.
- 90. Ra Th, Io, Th, UX₁.

However, these assumed differences of two have depended upon the fact that the atomic weights used for uranium and thorium have been 238.5 and 232.4, or a difference of practically 4 plus 2. The latest determination of the atomic weight of uranium by Hönigschmidt¹ gives a value of 238.18, which would not accord with this relationship for the individual differences. The difference between two isotopes belonging to a single radioactive series is, however, not affected by this result, and may still be assumed as four. However, in radioactive changes where a helium atom is lost, the new atom which is formed is not exactly four units lighter than the parent atom, since the packing effect varies with the change. How this effect varies in these heavy atoms cannot be told from the data now available, since the accuracy of the atomic weight determinations is not sufficient for this purpose, but the variation may be calculated approximately from the heat evolved in all cases where the heat change can be determined. It is of course self-evident that for deductions in regard to such atomic weight relations, the percentage accuracy must be much greater than is necessary for the study of the lighter elements. The difference between Hönigschmidt's values for uranium and for radium² (at. wt. = 225.97) is 12.21, or 0.21 more than the weight of three helium atoms.

Now that certain elements have been found to exist in isotopic forms, it becomes apparent that still other elements may do the same in cases which have not been recognized, so that in dealing with any single species of element it is uncertain whether this is an individual with respect to its atomic weight. The great regularity with which the elements follow the relationships given in these papers, up to an atomic weight of 59, suggests that with the exception of the cases of neon, silicon, magnesium, and chlorine, isotopes probably do not exist to any large extent for any of these elements, if they exist at all. There is still another possibility which suggests itself, and that is that the different atoms of a single atomic species differ in weight among themselves, and that the atomic weights as found are simply statistical averages. If this were true, the constancy

¹ *Z. Electrochem.*, **20**, 449 (1914).

² *Sitzungsb. kais. Akad. Wien.*, **121**, *Abt. IIA*, 1973 (1912); *Monatsh.*, **34**, 283 (1913).

of the results obtained in atomic weight determinations which after all is not of an extremely high order, would be due to the fact that in a single determination such an enormous number of atoms is used. For example, if in one determination the weight of silver chloride obtained were 7.16 g., the number of chlorine or silver atoms in the precipitate would be 3×10^{22} , or thirty thousand billion billion. The statement of the above idea is not meant to be understood as an advocacy of such a theory, but only to point out the possibility that such might be the case.

Increment from Series 3 to Series 4 = 5He (4He for K and Ca)

Increment from Series 4 to Series 5 = 6He

Table IV gives Series 2, 3 and 4 of the periodic system, built up by adding the weight of one helium atom for each change of two places to the right, and by adding enough multiples of the weight of a hydrogen atom to make up the atomic weight. In order to make the relationship apparent a symbolical representation has been used, He being taken to stand for the weight 4, and H for the weight 1.00. Built up in this way, the atomic weights of all of the members of the even numbered groups (with the exception of beryllium) may be represented by a whole number of symbols He, while all of the atomic weights in the odd groups may be represented by 3H plus a whole number of symbols He.

In the fourth, or argon series, the atomic weights begin to increase more rapidly than in the second and third series. This effect is first seen in the case of argon, which with a calculated atomic weight of 36, has instead a weight of practically forty, or too much by the weight of one helium atom. This effect dies out in potassium and calcium, and then appears again in scandium, titanium and the other members of this series. It becomes apparent in another way on studying the increment of weight in passing from a member of one series to the corresponding member

of the series below it. Thus the second member in each group is obtained from the first by adding 4He . In going from the second to the third member of the group the increase is the same (4He) to give potassium or calcium, but is 5He to give argon, titanium, vanadium, chromium, and manganese.¹ This in a sense explains how the atomic weight of argon comes to be greater than that of potassium, and practically equal to that of calcium. In going from the third to the fourth member of each group, it is necessary to add 6He , but the increase in this case seems to be due to the interposition of the eighth group elements, iron, cobalt, and nickel.

While both the law of the approximate whole number, and the hydrogen-helium system here presented, become suddenly much less accurate beginning with the element nickel, this does not necessarily mean that the hydrogen-helium system breaks down at this point, since there are several possible causes, already mentioned, which may account for the sudden increase in the deviations. The eighth group fills the position of a transition group between the seventh group and the first, which shows that it fills exactly the place of the zero group in the other series. The first member of the eighth group tried thus has an even number as its atomic number. The second member has an odd, and the third an even number, which gives to the first group an odd atomic number. This is entirely in accord with the system, which would fail at this point if there had been two instead of three members in each position in the eighth group.

According to the rule that the atomic weights of the elements increase alternately by 3 and by 1, then since iron has a weight of 56, that of cobalt should be 59 (detd. = 58.97), nickel should be 60 (detd. = 58.68), and copper 63 (detd. = 63.57). The first large negative deviation among the elements of even atomic numbers, of any of the actual atomic weights from the theoretical value, is thus found for the element nickel. Now it has been found that if it is studied from the standpoint of its behavior toward X-rays, nickel behaves as an element of a considerably higher atomic weight than the determined value. The wave lengths of the strong K radiations as found by Moseley are proportional to the reciprocals of the squares of the atomic weights. If cobalt is taken as a standard of reference (the square of the atomic weight and wave length being taken as 100 for this element), the values, part of which were calculated by Kaye,² come out as follows:³

¹ In comparison with the other members of the same series it is potassium and calcium rather than argon, which are exceptional.

² "X-Rays," 200.

³ This table could be extended by including the values of the nuclear charge, when it would be seen that the wave lengths seem to be determined by the nuclear charge as found by Moseley, rather than by the atomic weight.

	Al.	Si.	Cl.	K.	Ca.	Ti.	V.	Cr.	Mn.
(Atomic weight)	21.1	23.0	36.1	44	46	66	75	78	86
1/Wave length.....	21.5	25.2	37.8	47	53	65	72	78	85
	Fe.	Co.	Ni.	Cu.	Zn.	Rh.	Pd.	Ag.	
(Atomic weight).....	90	100	99	116	123	304	328	334	
1/Wave length.....	92	100	108	116	124	298	314	321	

The atomic weight of nickel, if calculated from the value 108 as given in this table, comes out as about 61.2, while the other elements from titanium up to and including rhodium, give a very close agreement. The principle as given above is derived from Whiddington's result that the energy of a characteristic X-ray is roughly proportional to the atomic weight, and from the quantum theory of radiation, according to which the energy of a radiation is inversely proportional to its wave length.

A study of the packing effects, as given in Table II of the preceding paper, shows that where an atom is built up entirely of helium atoms, then, on the average, the decrease in mass is practically due entirely to the primary formation of the helium atoms, and not at all to the aggregation of these into atoms which are heavier. From this point of view an atom composed entirely of helium units would have extreme instability in so far as its disintegration into helium units, in *comparison* with its instability with reference to a hydrogen decomposition. Such an atom in a radioactive transformation should lose α -particles much more readily than hydrogen nuclei, in fact, if it is remembered that the alpha decomposition is itself not complete in any case, it will be seen that it is doubtful if such an atom would ever give a detectable hydrogen disintegration.

If the atoms are built up entirely according to the special system presented in Table IV, according to which the members of even numbered groups are in general aggregates of helium alone, then since all of the radioactive elements which are now known to give a simple alpha decomposition (that is without an accompanying beta change) belong to even numbered groups, they could not be expected to give hydrogen upon disintegration. Thus one of the chief objections to the theory that the atoms are hydrogen complexes, which is based on the fact that up to the present time no hydrogen has been detected as the product of any radioactive change, is seen to be not contrary to, but rather in accord with, the theory as presented in these papers. The exceptional case of beryllium shows, however, that even numbers of even numbered groups sometimes contain a hydrogen nucleus which was not contained in one of the helium nuclei from which the atom was built, so that there still remains the possibility, though the probability seems small, that hydrogen nuclei might be liberated from atoms belonging to these groups. There is no evidence that the particular system presented in Table IV holds exactly for the atoms of high atomic weight, but the general form of the system indicates at least that the atoms contain more helium than independent

hydrogen units, and this seems in accord with the fact that uranium loses α -particles in eight steps, and is changed into a form of lead, without any apparent loss of a hydrogen nucleus.

The stability with which the hydrogen nuclei which are not contained in helium groups, but which generally occur in threes (H_3 in Table II), are built into the complex atoms, is not indicated with any degree of accuracy, but in the case of lithium it seems to be great, for lithium shows the extremely large packing effect equal to 1.57%, which might seem doubtful but for the care taken by Richards and Willard¹ in the determination of this atomic weight.

The hydrogen-helium system here presented is entirely in accord with, but independent of, the astronomical theory that the order in which the elements appear in the stars is first nebulium, hydrogen and helium, then such of the lighter elements as calcium, magnesium, oxygen, and nitrogen, and finally iron, and the other heavy metals, although in the present system it has not been found necessary to include nebulium. Some of the nebulae give bright line spectra of nebulium, hydrogen and helium, such Orion stars as those of the Trapezium give lines for hydrogen and helium, while those that are more developed show magnesium, silicon, oxygen and nitrogen, and some of the other low atomic weight elements in addition. Bluish white stars such as Sirius give narrow and faint lines for iron, sodium, and magnesium, and the solar stars give much weaker hydrogen spectrum, and many more and stronger lines for iron and the heavy metals. The astronomical theory that the heavier elements are thus formed from those of smaller atomic weight is of extreme interest, but the evidence for it is somewhat uncertain, since it is possible that it is the difference in the density of the different elements which is the effective factor in causing the spectra to appear in the order in which they are found to occur. The relative brightness of the different lines also varies greatly, such lines as the calcium H and K lines being extremely strong, and this also interferes with the determination of the order of the appearance of the elements in the stars. On the other hand, the evidence presented in these papers, which seems to show that the elements are atomic compounds of hydrogen and helium, appears to give some support to the theory of the evolution of the heavier atoms from those which are lighter. The evidence for the hydrogen-helium system is, however, very much stronger and more complete than that for the evolution of the elements in the stars.

Summary.

1. The fundamental idea of this, the second paper on atomic structure, is to show that the system which has been found to apply to the atomic weight and valence relations of the members of each of the radio-

¹ Richards and Willard, *THIS JOURNAL*, 32, 4 (1910).

active series, also holds true for the lighter atoms. In a radioactive series it is found that a loss of an α -particle with a mass of four decreases the valence by two, and thus shifts the element two groups to the left in the periodic table, and decreases the atomic number by two. If this is true for the lighter elements, beginning with helium, then the addition of the weight of a helium atom for each increase of two in the atomic number ought to give the atomic weights of the elements belonging to the even numbered groups. The atomic weights found by this method are the same on the whole as the determined values, which shows that the theory accords with the facts.

2. The lithium atom, which is the first atom in the odd numbered group, is heavier than the helium atom by the weight of three hydrogen atoms. It would be very remarkable if the atoms of odd atomic number follow the same rule as those of even atomic number, but that they do is indicated by Table IV, which shows that for the odd numbered groups as well, each increase of two in the atomic number results in an increase of four in the atomic weight.

3. The atomic weights of the lighter elements are given with considerable accuracy by the equation

$$W = 2n + (1/2 + 1/2 (-1)^{n-1}),$$

where W is the atomic weight and n the atomic number. In the case of the heavier elements another term enters, so that the more general equation may be given:

$$W = 2(n + n') + [1/2 + 1/2 (-1)^{n-1}]$$

4. Of the 27 elements from helium to cobalt, 13, or nearly one-half, have atomic weights divisible by four, and these elements in general belong to even numbered groups in the periodic table. Of all the possible multiples of four only two are missing, *i. e.*, 2×4 and 9×4 , and seemingly to make up for the omission of the 9×4 , the 10×4 occurs twice. An explanation of the omission of the 2×4 and its occurrence as $(2 \times 4) + 1$ will be given in a later paper.

5. If the atomic weights increase by the weight of one helium atom for an increase of two in the atomic number, the average increase in the atomic weight per atomic number should be 2. That this is in accord with the facts is shown, for neon with an atomic number 10 has an atomic weight of 10×2 or 20, and calcium, with an atomic number 20, has an atomic weight equal to 20×2 or 40.

6. According to the first paper, the magnitude of the packing effect for helium is 0.77%, which is the same as the average of the packing effects for the first 27 elements, so that if a more complex atom is built of helium groups alone, then in general nearly all of the packing effect is due to the primary formation of the helium nucleus from four hydrogen

nuclei and two negative electrons, and almost no packing effect results from the aggregation of these helium nuclei into more complex atoms. On this view the helium nuclei must be very greatly more stable than the nuclei of the more complex atoms which they form, so that such an atom, made up entirely from helium units, should give helium and not hydrogen by its primary decomposition. This is in accord with the behavior of the radioactive elements when they disintegrate. It is of interest to note that the members of the radioactive series which are now known to give helium on decomposition, belong to the even numbered groups on the periodic table, and therefore to those groups which are shown in Table IV, as helium aggregates alone. That these heavy atoms must contain a considerable number of helium units is shown by the fact that uranium changes into lead by eight steps in which it loses α -particles.

7. The hydrogen-helium system gives an explanation of the fact that argon has an atomic weight of 40, which is higher than that of potassium, which has an atomic number higher by 1. A study of Table IV makes the reason apparent, and shows that in *comparison* with other members of Series 4 in the periodic table, it is potassium and calcium, and not argon, which are exceptional. In comparison with the members of Series 3, and potassium and calcium, it is of course the argon which is exceptional. As the atoms grow heavier there is a tendency to take on helium (or perhaps hydrogen) groups more rapidly than is the rule in the case of the lighter elements.

Later papers by one of the writers will consider the nuclear and non-nuclear electrons, and the relations of the periodic system to the hydrogen-helium system presented in this paper.

RECENT WORK ON THE STRUCTURE OF THE ATOM.

[THIRD PAPER ON ATOMIC STRUCTURE.]

BY WILLIAM D. HARKINS AND ERNEST D. WILSON.

Received March 27, 1915.

When Dalton¹ advanced his atomic theory of the constitution of matter, he thought of the atom as the ultimate material unit. The discovery of the phenomena of radioactivity, however, made it evident that this view was incorrect, and showed that the atom must be complex. The question of its structure has remained unsolved for a long time, and it is only very recently that there has been any experimental work upon which to base a theory. In this paper practically all of the important

¹ "On Chemical Synthesis, from a New System of Chemical Philosophy," Manchester, 1808, pp. 211-6, 219-20.

recent work bearing on this subject will be considered, and, wherever possible, the results due to the different investigators combined. As the results often seem to be contradictory, the difficulty of reaching any definite conclusion is great.

One of the first difficulties which arises in the attempt to develop an "atom model" is the fact that even at the present time we know nothing of the nature of positive electricity. The different characteristics of the negative electron have been known for some time, but the question of a positive electron is still open.

The first atom model was suggested by Lord Kelvin,¹ and consisted of concentric rings of rotating negative electrons in a sphere of homogeneous positive electricity the size of the atom. This model has come to be known as the Thomson atom, due to the fact that he developed it quite completely, and worked out in detail the number of electrons in the various rings necessary to give stable systems. The advantages of this construction lie in the relative simplicity of the mathematical calculation of the distribution and velocities of the electrons, as compared with the great difficulties involved in a satisfactory solution of such problems in connection with the later atom models. Thomson has shown that such an atom imitates to a large extent the properties of our known chemical atoms and explains why some are electropositive, others electronegative, and the variation of the chemical properties with the atomic weight.

One objection to this model, which also applies to the other models unless a rather questionable assumption is made, is that the atoms so formed would not be stable, for according to the electromagnetic theory, electrons in orbital motion must radiate energy, and hence at some time the atom would break up.

An objection that is even more important is that the positive spheres of Kelvin would have an electromagnetic inertia which would be negligible compared with that of even a single negative electron, leaving practically all of the mass of the atom unaccounted for on this theory.

The first theory of the constitution of the atom with any experimental work as a basis is due to Rutherford. He made use of the phenomenon of the scattering of alpha and beta particles in passing through matter.² The deflection is more marked for the beta than for the alpha particle, due to the smaller momentum of the former. There seems to be no doubt that the particles pass through atoms, and that their deflections are due to the intense electric field within the atom. Calculation shows that the distribution of the positive electricity assumed in the Thomson atom does not admit of sufficiently strong fields to deflect an alpha particle through a large angle, and the scattering of the alpha and beta rays in passing through thin sheets of metal had been attributed to a number of small scatterings. Geiger and Marsden,³ working with gold foil

0.00004 cm. thick, found that about 1 in 20,000 alpha particles was deflected at an average angle of 90° . Also, Geiger⁴ showed by the theory of probabilities that the most probable deflection was 0.87° , and that the chance of a 90° deflection was vanishingly small. In the theory of the Thomson atom the large deflections were considered as due to the accumulative effect of a number of small ones. The distribution of alpha particles deflected through large angles does not follow the probability curve. Also, after one collision the probability of the same ray suffering another in such a way as to give a larger deflection is very small.

Considering the deflections as due to a single encounter with an atom, Rutherford has obtained an expression for dm , the fraction of the total number of alpha particles which are deviated between p and $p + dp$.

$$dm = \pi/4 \, ntb^2 (\cot \phi/2 \csc \phi/2) dp$$

where n is the number of atoms per unit volume, t the thickness of the metal, b the distance from the center to which an alpha particle would penetrate if shot directly at the atom, and p the perpendicular distance from the center of the atom to the extension of the line of path of the approaching alpha particle. Geiger⁵ has shown this equation to be true between 30° and 150° .

Thomson considered the scattering as due to the accumulative effect of a number of small scatterings, and obtained the following expressions: The average deflection, θ , for a sheet of thickness t is $\theta = 3\pi b/8 \sqrt{\pi nt}$. The probability p_1 that the deflection is greater than ϕ is $p_1 = e^{-\phi^2/\theta^2}$.

Rutherford shows that the probability p_2 for the same thing based on the theory of a single scattering is

$$p_2 = \frac{\pi}{4} b^2 nt \cot^2 \frac{\phi}{2}$$

If $p_2 = 0.5$, $p_1 = 0.24$. If $p_2 = 0.1$, $p_1 = 0.0004$.

Thus the probability on Rutherford's assumption is greater than that on Thomson's. Both of these theories are developed on the assumption that the forces between the particles are electrical, and follow the inverse square law. Darwin has shown that this is the only law of force which is consistent with the facts.*

These considerations would seem to indicate that the large deflections actually found must be due to a single encounter with an atom, and in order to obtain the necessary strength of field, the positive charge would have to be concentrated at a small point instead of being evenly distributed throughout the entire volume of the atom, as in the theory of Thom-

* NOTE.—A recent paper by Hicks takes into account the magnetic forces also, and shows that their effect may be of the same order of magnitude as that of the electrostatic forces only. Any theory which is complete must take account of both. Calculations based on only one would seem to be of doubtful reliability. See Hicks, *Phil. Mag.*, Jan., 1915.

son. The negative electrons vibrate around this positive nucleus, forming a kind of miniature solar system. This is the type of atom first suggested by Nagaoka.⁶ From the measured deflections, Rutherford estimated that the charge on the nucleus was approximately equal to one-half the atomic weight of the element times the electronic charge. The large deflections are due to the alpha particle passing very close to the nucleus.

With beta rays the effects are slightly different, for since the force is attractive they increase speed on approaching the atom. By ordinary electrodynamics this involves a loss of energy by radiation, and an increase in apparent mass. Darwin showed that if the beta particle passed very close to the nucleus it would describe a spiral, and eventually fall in. This might explain the disappearance of swift beta particles in their passage through matter.

The case of the passage of the alpha particles through hydrogen is of particular interest,⁷ for, since the alpha particle is heavier than the hydrogen atom, the recoil due to the close approach of the atom and the particle should be very large. It was shown that, as a result of a collision, the hydrogen atom should attain a velocity of 1.6 times, and hence a range of about four times that of the alpha particle itself. Marsden⁸ actually found hydrogen atoms with a range of about 90 cm. in hydrogen in which the alpha particles had a range of only 20 cm.

From the data on the scattering of the alpha rays in passing through a gold leaf, it is possible to calculate an upper limit for the radius of the nucleus of the gold atom.

Ne = charge on the nucleus (positive).

R = the radius of the sphere of electric action.

Ne = the value of the negative charge surrounding the nucleus.

x = electric force at a distance r from the center.

v = potential force at a distance r from center.

Then $x = Ne \left(\frac{1}{r^2} - \frac{r}{R^3} \right)$ and $v = Ne \left(\frac{1}{r} - \frac{3}{2R} + \frac{r}{2R^3} \right)$.

m = mass of alpha particle.

u = velocity of alpha particle.

E = charge on the alpha particle.

Let the alpha particle be shot directly at the atom, being brought to rest at a distance b from the center. Then

$$\frac{1}{2} mu^2 = NeE \left(\frac{1}{b} - \frac{3}{R} + \frac{b^2}{2R^3} \right).$$

If N is assumed to be 100, which cannot be very far from the correct value for gold, the distance b for an alpha particle of velocity 2.09×10^9 cm. per second is found to be 3.4×10^{-12} cm. This gives a maximum value for the radius of the nucleus of the gold atom.

Darwin⁸ has made a similar calculation for the hydrogen atom and obtains the value 1.7×10^{-13} cm. for the diameter. This is smaller

than the diameter of the negative electron, which is ordinarily given as 2.0×10^{-13} cm. The question arises as to whether the mass of this positive nucleus is entirely electromagnetic, like that of the negative electron. The electrical mass of a charged body is $2e^2/3a$, where e is the charge, and a the radius. Using this formula the radius of the positive nucleus of hydrogen comes out to be $1/1830$ that of the negative electron. Rutherford⁹ suggests that it is probable that the hydrogen nucleus is the long sought positive electron.

Rutherford has shown that it is impossible to account for the high speed of expulsion of some of the alpha and beta particles if they come from a ring of atomic radius. They must come from a point very close to the center, which suggests that they are shot from the nucleus of the atom.

The present theory of the constitution of the atom is based on the facts given above. Each atom of matter is supposed to be made up of a positively charged nucleus around which rotate the negative electrons. In the heavier atoms there are negative electrons in the nucleus also. The nucleus is the seat of practically all of the mass of the atom, for the negative electrons contribute very little mass. Barkla,¹⁰ from his work on the passage of X-rays through matter, suggested that the charge on the nucleus is about $1/2 A e$, where A is the atomic weight of the element. Van den Broek,¹¹ and later Bohr,¹² suggested that the number of units of charge is $N e$ where N is the number of the element when the elements are arranged in order of increasing atomic weight, or what is now called the atomic number.

Moseley's¹³ work on the X-ray spectra of the elements is very important also, in helping to give an insight into the constitution of the atom. Working along the line first suggested by Laue,¹⁴ and Bragg,¹⁵ Moseley, and Darwin have developed an experimental method for determining the X-ray spectra of the elements by reflection from crystal surfaces. When an element is used as the anticathode in an X-ray tube, it emits a characteristic radiation of a frequency roughly 1000 times as great as that of the visible light waves. Each element is characterized by two different radiations which have been called the K radiation and the L radiation.¹⁶ The K radiation is composed of two lines which Moseley has called the α line and the β line. These are the ones used the most by him for purposes of calculation. The L radiation is not nearly as penetrating as the K radiation, and usually consists of about five lines.

Moseley recorded the spectra photographically, instead of using an electroscop for a detector as did Bragg, and he examined the X-ray spectra of the elements from aluminium to gold. He found a very remarkable relationship between the frequencies of the lines of the various elements. In going from one element to the next higher in atomic weight there was a shift of the two lines of the K series toward the violet. That is, there is

a change in the frequency of the spectrum lines with a change of the element. Moreover there is a very simple relationship between these frequencies. Thus considering the α line, the frequency is expressed by the formula

$$\nu = K(N - 1)^2$$

in which K is a constant, and N is a number which increases by one in passing from one element to the next higher in atomic weight. If 13 is chosen for the value of N for aluminium, and a corresponding value of K , N turns out to be the atomic number of the elements. Thus N determines the X-ray spectrum of any element. Moseley finds that between aluminium and gold the order of the elements according to N is the same as that of the atomic weights except where the latter would put the element out of place in the periodic table. Moseley finds only three unknown elements between aluminium and gold.

He has shown that neoytterbium and lutecium exist, but that Urbain's celtium is a mixture. According to his system thulium I and thulium II of Welsbach exist, but not thulium III. A homolog of Mn between Mo and Ru remains to be found as does another element between Os and W.

Moseley concludes that the number N is the charge on the nucleus of an atom, and that this charge increases one step at a time from one element to the next. According to this view it is perfectly possible to have two elements of very different atomic weight that have the same X-ray spectrum, providing only that they have the same nuclear charge.

Such elements would also be identical chemically, and so far as is known at the present time would have identical spark and arc spectra.

This seems to be borne out by the fact that Aston,¹⁷ working with J. J. Thomson, found two neons with atomic weights 20 and 22, which are otherwise identical, and have the same spectrum. He was only able to separate them by diffusion methods, which depend on the atomic weight and hence upon the density. Also Russell and Ross,¹⁸ and Exner and Haschek,¹⁹ working with a strong ionium solution, could not obtain any spectrum except that of thorium, of which ionium is an isotope.

This theory of the dependence of the chemical and physical properties of the elements on the nuclear charge is supported by recent work on the radioactive elements. The position of all these elements in the periodic table was an unsolved problem until it was shown that two or more elements could occupy the same place in the table. It has been supposed for some time that certain of the radio-elements were inseparable by any known chemical means. Fajans, Soddy, and others make this a general property of these elements, and treat each as the chemical analog of one or the other of the known elements. Two elements which occupy the same space in the periodic table and are inseparable by ordinary chemical means have been called "Isotopes" by Soddy.

The rule advanced by Soddy,²⁰ Fajans,²¹ and others, that the expulsion of an alpha particle causes the element to shift its position in the periodic table two places to the left, and to decrease in atomic weight by four units is also in accord with the theory if we consider that the alpha particle comes from the nucleus of the atom. Similarly the expulsion of a beta particle, which is a negative electron, would cause the element to shift its position in the table one place to the right, without any change of mass. In this case the positive charge on the nucleus is increased by one unit.

In radioactive changes the expulsion of a beta particle, which evidently is shot out of the nucleus, as is shown by its extremely high velocity, causes the element to move one group to the right in the periodic table, which means an increase of one in the atomic number. From this it seems evident that this gives a proof, at least for the radioactive elements, and probably in the case of all lower atomic weight elements, that an increase of one in the atomic number means an increase of one in the positive charge on the nucleus. It seems probable, therefore, that the number of positive charges on the nucleus is equal to the atomic number.

¹ According to recent work by Miss Meitner there seems to be considerable doubt as to the existence of RaC₄.

² This table gives only the isotopes of the radium series.

The work of Rutherford and Andrade²² serves to further confirm these views. The wave length of the soft γ rays from Ra B was determined, and also the X-ray spectrum of lead, with a view to determine the atomic numbers of these and the other radioactive elements. Ra B and lead were found to have the same atomic number, 82, as they gave the same X-ray spectrum. From Table I it is seen that there are several groups of elements having the same atomic number but with different atomic weights. These are tabulated at the bottom of Table I.

It will be noted that the atomic weight of lead, if its source is the uranium series of elements, should be 206.18, using the latest value of the atomic weight of uranium as 238.18. The atomic weight of lead has recently been determined by Richards,²³ who obtained the value 207.15 for ordinary lead, not radioactive. In analyzing the lead from a large number of radioactive minerals, mostly uranium, he obtained values varying from 206.4 to the ordinary value, 207.15. Soddy,²⁴ working with thorium minerals, obtained the value 208, which would be expected if the end of the thorium series is also lead. More recently Soddy²⁵ has started a more extensive investigation, and has obtained about 80 grams of lead from thorium minerals. He finds that the lead has a higher density than the ordinary lead. This is to be expected if the atomic volumes of the isotopes are the same. Richards found no difference between the spectrum of the lead of low atomic weight and the ordinary lead, but Soddy claimed to have found at least one line in the new material which was not given by the old. In some work as yet unpublished, done by Aronberg working with Gale and one of the writers, no difference was found between the spectrum of some lead from Carnotite and the ordinary lead, although the Zeeman effect was also investigated. In this investigation a 21 foot concave grating was used, and the wave lengths could be measured to 0.001 of an Ångstrom.

Lindemann* shows by means of simple thermodynamical reasoning that two elements of different atomic weight must differ either in their chemical or physical properties. Since Soddy has shown that the isotopic forms of lead have the same atomic volumes, and also, of course, the same chemical properties, it follows that the forces between the atoms, and therefore the vapor pressures and the melting points, must vary, and that Soddy's lead from thorite should have a melting point 1.54 degrees higher than ordinary lead. Lindemann concludes that the forces of attraction and repulsion between the atoms have their origin in the nucleus, while, as is generally considered, the chemical properties and the radius of the atom are conditioned by the external electrons. In isotopes the forces of attraction and repulsion are proportional to the atomic weight, that is, probably to the number of positive particles. These forces are, however,

* *Nature*, March 4, 1915.

not usually additive, but are so only in isotopes, so the nuclei of isotopes probably differ in their linear dimensions, but not at all, or very little, in the arrangement of the particles. The question as to the melting point of lead from carnotite is now being investigated by one of the writers of this paper.

The fact that α particles are expelled in so many of the transformations seems to show that the nucleus is composed, in part at least, of helium atoms. The energy of the expulsion of the alpha particles can be accounted for by their passage through the intense electric field around the nucleus. The primary beta particles probably arise from a disturbance of the nucleus, which must be very complex.

The general facts which seem to be proved by all this work described above are, that the nucleus is a fundamental constant of matter, and that the charge on the nucleus determines the character of the element. The atomic weight is not so characteristic as the atomic number or the nuclear charge. The atomic weight is a complex function of the number and configuration of the electrons. Those properties of matter such as gravitation and radioactivity, which are entirely beyond our control by any chemical or physical agents, are functions of the nucleus.

Up to this point, beyond the fact that the atom is a sort of Saturnian system, nothing has been said as to the arrangement of the electrons in the atom, or the distribution of the forces. The first attempt to treat this problem as one of mechanics, and to give a definite picture of the atom, was made by Bohr.²⁶ In his calculations, Bohr has used an atom of the Rutherford type, and has combined with the classical mechanics Planck's quantum hypothesis. While Bohr's work has been severely criticized, the very remarkable results he was able to obtain with hydrogen alone make it worthy of careful consideration. Bohr's success lies only in the consideration of atoms with one vibrating electron. The following is a simplified form of his analysis:

Let m = mass of the electron.

$-e$ = charge of the electron.

M = mass of nucleus.

E = charge on nucleus.

a = radius of ring of rotation of electrons.

ω = frequency of revolution of electrons.

Then, $2\pi\omega$ = angular velocity.

The kinetic energy of an electron can be expressed in two ways:

$$\frac{1}{2} m(2\pi\omega a)^2 \quad \text{or} \quad \frac{1}{2} eE/a.$$

The work necessary to remove an electron from its orbit to a position of rest at ∞ is:

$$eE/a - \frac{1}{2} m(2\pi\omega a)^2 = \frac{1}{2} (eE/a) = W.$$

Then

$$2a = eE/W \quad \text{and} \quad \omega = \frac{\sqrt{2}}{\pi} \frac{W^{3/2}}{eE\sqrt{m}}.$$

According to Newtonian mechanics, the energy W should go on increasing as energy is given out by radiation, until the orbit gets smaller and smaller and the electron falls into the nucleus; that is, " a " would decrease and ω increase. Here Bohr introduces the quantum hypothesis. He assumes that the angular momentum of the electron is constant, and equal to $\tau h/2\pi$, where τ is an integer, and h is Planck's constant; that is, the angular momentum of the electron in its orbit is

$$2\pi m\omega a^2 = W/\pi\omega = \tau h/2\pi.$$

This prevents continuous variations of W , a , and ω .

Then,

$$W = \frac{2\pi^2 m e^2 E^2}{\tau^2 h^2} \quad 2a = \frac{\tau^2 h^2}{2\pi^2 m e E}.$$

Much of the criticism of Bohr's work is directed at this point in his analysis. The idea of an electron undergoing accelerated motion without radiating energy is difficult to accept. There is also difficulty in obtaining any satisfactory physical picture of the process by which light is emitted when the electron changes from one steady state of vibration to the next, as described below.

In a neutral hydrogen atom τ is equal to 1. If this value is substituted in the second equation, the value for the diameter of the hydrogen atom is obtained as 1.1×10^{-8} cm., which is of the right order of magnitude.

The electron radiates energy only when it changes from one steady state of vibration to another, and then one quantum of energy is released; that is, for a sudden shrinkage from orbit of τ_2 to τ_1 , there must be a loss of energy $W = h\nu$ where ν is the frequency of the radiation.

$$h\nu = \delta W = W_{\tau_2} - W_{\tau_1} = \frac{2\pi^2 m e^2 E^2}{h^2} \left(\frac{1}{\tau_2^2} - \frac{1}{\tau_1^2} \right) \\ = \frac{2\pi^2 m e^2 E^2}{h^3} \left(\frac{1}{\tau_2^2} - \frac{1}{\tau_1^2} \right).$$

In the case of hydrogen, $E = e$. We can then calculate the value of the constant $2\pi^2 m e^2 E^2/h^3$ which is equal to 3.26×10^{15} . The well-known Balmer formula for the series of lines in the hydrogen spectrum is $\nu = K (1/\tau_2^2 - 1/\tau_1^2)$ in which K as determined by experiment is 3.29 times 10^{15} . This practical identity of Bohr's calculated value of the Rydberg constant and the experimental value is probably the greatest triumph of Bohr's work.

If the value 1 is assigned to τ_2 , and a series of values, 1, 2, 3, etc.,

given to τ_1 , the frequencies of a series of lines in the ultraviolet are determined. This series was not known at the time of Bohr's first work, but has since been found by Lyman of Harvard. (Not published.) The physical picture obtained of the production of this series of spectrum lines is as follows:

N represents the nucleus of the atom. The rings 1, 2, and 3 correspond to the orbits of the electron in the various steady states of motion. When an electron falls from one steady state to the next one of smaller radius of vibration, one quantum of energy is liberated. In the above spectral series, all the lines are formed by electrons falling from the second ring and beyond, all the way to the first ring. The first line in the series is due to an electron falling from the second to the first ring; the second line to an electron falling from the third to the first ring, and so on.

If $\tau_2 = 2$, and a series of values be assigned to τ_1 , the ordinary Balmer series for hydrogen results. For $\tau_2 = 3$, there results an infra-red series predicted by Ritz, and later discovered by Paschen. This model does not account for the Pickering series of lines which is ordinarily attributed to hydrogen, but Bohr shows that this series is accounted for by the helium atom.

Very recently another confirmation of Bohr's theory has been given by Evans²⁷ in his work on the spectra of hydrogen and helium. Bohr's formula, when modified so as to take account of the mass of the nucleus, is

$$\nu = \frac{2\pi^2 e^2 E^2 M m}{h^3 (m + M)} \left(\frac{1}{\tau_2^2} - \frac{1}{\tau_1^2} \right).$$

This makes a slight change in the value of the constant in passing from hydrogen to helium, and the ordinary Balmer series for hydrogen, which according to Bohr's original work could come from either of the two

elements, is found to be slightly different for the one than for the other. Thus it became very important to investigate carefully the spectra of these two elements, and see if this series could be detected in helium, and whether the slight differences just spoken of existed. Evans was able to observe the first few members of this series, and the measured values of the lines are very close to the theoretical.

Bohr²⁸ has also shown that if the principle of relativity is introduced, his formula takes the following form, which accounts for some of the extremely small errors found by Evans.

$$r = \frac{2\pi^2 e^2 E^2 m M}{h^3 (m + M)} \left(\frac{1}{\tau_2^2} - \frac{1}{\tau_1^2} \right) \left[1 + \frac{\pi^2 e^2 E^2}{c^2 h^2} \left(\frac{1}{\tau_2^2} - \frac{1}{\tau_1^2} \right) \right].$$

Helium is considered to have a charge on its nucleus of $2e$, or $E = 2e$. The atom with one positive charge has one vibrating electron. The following formula results for helium:

$$= K \left(\frac{1}{(\tau_2/2)^2} - \frac{1}{(\tau_1/2)^2} \right)$$

The physical interpretation is the same as for hydrogen. For various values of τ_2 , the following series result:

- $\tau_2 = 1$ —Extreme ultraviolet; not known.
- $\tau_2 = 2$ —Extreme ultraviolet; not known.
- $\tau_2 = 3$ —Two series, as τ_1 is odd or even. (The lines of the two series alternate.) These series were observed by Fowler in mixtures of hydrogen and helium, but had been attributed to hydrogen.
- $\tau_2 = 4$ —The lines of two series, alternating as τ_1 is odd or even. The first of these is the ordinary Balmer series, which evidently can come from either hydrogen or helium. The second is a series which was observed by Pickering in the star ζ -Puppis, and was attributed to hydrogen.

In the work of Evans which was mentioned, there is a further confirmation of Bohr's theory. By carefully adjusting conditions he was able to obtain the Pickering series of lines from absolutely pure helium, which should be the source of them, according to Bohr.

Balmer's series has never been observed in the laboratory beyond $\tau_2 = 12$, while in stellar spectra it extends to $\tau_2 = 33$. Therefore in vacuum tubes no hydrogen atoms exist of greater diameter than corresponds to $\tau_2 = 12$, or $2a = 1.6 \times 10^{-6}$ cm. For $\tau_2 = 33$, $2a = 1.2 \times 10^{-5}$ cm. Therefore, according to Bohr's theory, there are in the stars hydrogen atoms 1000 times the diameter of those on the earth.

Jeans³¹ points out that in the above work the value of M is supposed to be very great in comparison with m . If this is not true, the value of Rydberg's constant is given by

$$K = \frac{2\pi^2 e^2 E^2}{h^3} \frac{mM}{(m + M)}.$$

If M refers to the value for hydrogen, $2M$ is the value for helium. Then $K_H : K_{He} = \frac{4}{M + \frac{1}{2}m} : \frac{1}{m + M}$. From the best observed value of the ratio K_H/K_{He} , M/m is given as 1836 ± 12 , which is in close agreement with the experimental value.

The above calculation would seem to be inconsistent with the idea of the atom as developed by Rutherford, for he states that practically all of the mass of the atom lies in the nucleus. In that case, the value of M for helium would not be *twice* but *four* times the value for hydrogen, and the helium nucleus would consist of four positive and two negative electrons.

Bohr extends his calculations to the lithium atom, and in considering only one vibrating electron obtains good results. In all of his work, however, when more than one electron is considered, his results are not correct. One of the serious objections to Bohr's theory is that he has been unable to explain the ordinary spectrum of hydrogen. Nicholson²² has extended Bohr's calculations to every possible mode of vibration in attempting to secure a formula or formulas, giving the lines of the ordinary hydrogen spectrum, but has found that they can be accounted for by no possible vibration.

Perhaps the most fundamental objection to Bohr's work lies in the fact that he has combined two basically different kinds of mathematics in working out this theory. It might be possible under such conditions to obtain results which are absolutely incorrect, for the two are contradictory.

Nicholson claims to have proven both by the classical mechanics and by Bohr's mechanics that coplanar, concentric rings of vibrating electrons are unstable. That is, if there are to be two or more rings of electrons in an atom, they cannot lie in the same plane, which would make Bohr's theory untenable. This presents difficulties in still another way. If we consider valence as due to certain electrons which are ordinarily considered as being near the outside of the atom, these electrons would either have to be in an outer ring, by themselves, or else have some peculiar properties different from the other electrons in the ring. J. J. Thomsen not only believes in the existence of more than one ring of electrons, but in some work yet unpublished, states that he has actually counted the number of rings in certain atoms. This claim of Nicholson's would seem to be wrong, but it may be very true, as he says, that a large number of the vibrations in such a system are unsteady, and would result in the expulsion of an electron.

Bohr has not had better success in accounting for a large part of the

spectrum of helium than he had in the case of hydrogen. Helium has six Balmer series which are not explained. Bohr considered only the first electron in his calculations on this element, and Nicholson thought that possibly the rest of the spectrum might be due to the other electron. He therefore made the necessary calculations, but could obtain no other series. Two of the series of lines calculated for helium lie in the ultra-violet, and are not known. Lyman of Harvard, as a result of his investigations, states that helium has no Schumann region spectrum.

It is well to remember that Bohr attempts no physical picture or cause of the change of an electron from one steady state of vibration to the next. In his theory of spectra, the energy which goes into the spectrum is atomic energy. This would be a serious objection if it were not for the fact that it is very easy to think of it in a slightly different way. The energy which it is necessary to apply to hydrogen to give these spectral lines may be used to remove an electron from one of the inner rings of vibration to one farther out from the nucleus. This is equivalent to increasing the atomic energy, and the increase, which came from an outside source, is given out as monochromatic radiation when the electron falls toward the nucleus.

Of the work on the structure of the atom none is more interesting than that of Nicholson, a number of his predictions from a theoretical standpoint having been confirmed in a most spectacular way. His work is also of extreme interest to chemists, since it deals with elements which have not as yet been discovered on the earth. For a considerable time it has been known that there are at least two important elements which are recognized by their spectrum, but which have not as yet been discovered on earth. A number of spectral lines of unknown origin were known to be given by the corona of the sun, and these were attributed to an element coronium, while the lines of unknown origin emitted by the nebulae were supposed to be due to an element which was given the name nebulium. The chief line of its spectrum is the line $\lambda 5007$. Nicholson was able, by the assumption that certain lines belong to the spectrum of nebulium, to calculate the wave lengths of all of the other lines but two, for which he was altogether unable to account. Just at the time when Nicholson made his calculation, Wolf of Heidelberg was engaged in the study of these same lines in the spectra of the nebulae, and he found that certain lines, which had formerly been attributed to nebulium, acted differently from the others. He found, for example, that in the ring nebula in Lyra, discovered by Darquier in 1779, certain of these lines were emitted by the interior, and others by its outer part. The remarkable part of this discovery was that the two lines which were thus shown to have different origin from the true lines of nebulium, were just the two lines which Nicholson was unable to connect theoretically with the spectrum

of nebulium. Another of Nicholson's predictions, which was confirmed in a remarkable manner, was that of the existence of a new nebulium line of wave length 4352.9. On photographing the spectrum, Wright, of the Lick observatory, found this line, and on looking over his older photographs, he found the line on a plate taken several years before the prediction of its existence was made, but the line was so weak that it had escaped observation.

In an extremely long series of papers Nicholson³⁰ has arrived at a very comprehensive theory of spectra, and has applied it to such problems as cosmic evolution. It gives a picture of operations in vast nebulae, many light years in extent, in connection with atomic and subatomic structure; changes occupying milleniums of time are discussed in connection with those occurring in a fraction of a second. Its very comprehensiveness causes some skepticism, but the remarkable results he has obtained would seem, in part at least, to justify the theory.

Nicholson also uses an atom of the Rutherford type, in which the electrons are vibrating in orbits around the positive nucleus. All of Nicholson's work is, however, based on calculations made by the classical mechanics. The quantum hypothesis is not introduced to obtain any of the results, but in the course of his work, Nicholson shows how the results seem to be related to this hypothesis.

One of the interesting points of this theory is that the energy which goes into the spectrum is secured from the outside, and is not, as originally in the theory of Bohr, atomic energy. This would seem to be much more probable.

The electrons are considered as moving in a steady state, in a ring around the nucleus. Outside forces acting on these cause them to take up a vibration perpendicular to the plane of the ring. There are several modes of vibration, depending on the number of electrons in the ring. The strongest vibration would have a frequency equal to the frequency of the electrons in the ring. This is expressed by $q = \omega$, or $q/\omega = 1$. In vibrations of class zero the entire ring vibrates as a whole, always keeping parallel to its original position. The second class of vibration consists in the ring vibrating in halves. That is, there are two nodes and two crests in the wave which travels around the ring. It is evident that there are as many classes of vibrations as there are electrons in the atom. The vibrations of the higher classes would not be expected to be strong, and Schott has shown that the vibrations of a class higher than three would not ordinarily be strong enough to see. The mathematical analysis is largely the same as that developed by J. J. Thomson in his work on his atomic model, and will not be given completely here. Only the results which are used directly will be reproduced.

e = charge on an electron.

a = radius of the ring.

ν = no. charges in nucleus.

m = mass of an electron.

q/ω = frequency of revolution.

The equation for the period of vibration which Nicholson obtains is

$$mq^2 = e^2/8a^3 (8\nu + P_k + P_o)$$

where

$$P_k = \Sigma^{n-1} (\cos 2K \pi/n \csc^3 \pi/n)$$

and

$$P_o = \Sigma^{n-1} (1 \cdot \csc^3 \pi/n).$$

There may be as many values of the period as there are of P_k , which is as many as the number of electrons. k is called the class of the vibration.

The first atom which Nicholson considered was one in which the number of positive charges in the nucleus is four. That is, $\nu = 4$. This atom he has called nebulium. First consider the neutral atom, in which there are four negative electrons. The period equation may be written as

$$ma^3q^2 = e^2 [\nu + (P_k - P_o)/8], \quad k = 0, 1, 2, \text{ etc.}$$

If ω = the angular velocity of the ring, the force of an electron towards the center is $ma\omega^2$. The radial attraction of the positive nucleus is $\nu e^2/a^2$. The combined action of the other electrons gives a radial repulsion of $e^2S_n/4a^2$ where $S_n = \Sigma^{n-1} \csc \pi/n$. Therefore,

$$ma\omega^2 = e^2/a^2 (\nu - S_n/4) \quad \text{or} \quad e^2/ma^3 = \omega^2 (\nu - S_n/4)$$

is the equation for the steady state of the neutral atom. The period equations of this system then become

$$\begin{aligned} q^2/\omega^2 &= \frac{16}{15-2\sqrt{2}}, \quad k = 0 \\ &= 1, \quad k = 1 = 3 \\ q^2/\omega^2 &= \frac{8}{8+\sqrt{2}}, \quad k = 2 \end{aligned}$$

or

$$q/\omega = (1.146533, 1, 0.849778)$$

Correcting for a stationary observer, and introducing negative values of k ,

$$\begin{aligned} q/\omega &= (1.146533, 1.150222, 2, 2.849778, 4) \\ k &= 0 \quad k = -2 \quad k = 1 \quad k = 2, \quad k = 3 \end{aligned}$$

In wave lengths (C = velocity of light) and considering a vibration in the plane where $q = \omega$, which we would expect to be strong,

$$\lambda = 2\pi C/\omega (1, 0.872194, 0.86939).$$

The first value is for $q = \omega$, the second for $k = 0$, the third for $k = -2$.

The chief nebular line is $\lambda = 5006.9$. If this is chosen as the fundamental line, then $(5006.9)(0.872194) = 4367.0$ should be the next line of this set. A strong line is known at 4363.4. Also $(5006.9)(0.86939) = 4352.9$ should be the next. At the time of this work, no line was known at 4352.9 but it was afterward found by Wright³¹ of the Lick Observatory, and measured as 4352.3. Nicholson made similar calculations for this atom with 2, 3, 5, and 6 electrons. The results are given below:

	$q = \omega.$	$k = 0.$	$k = 1.$	$k = 2.$	$k = -2.$	$k = 3.$
$n = 6$	$\lambda = 2\pi C/\omega \times$		1	0.81934		(0.6666)
	$\lambda =$		4959. <i>a</i>	4063.2	
	Observed.....		4959	4059.0		
$n = 5$	$\lambda = 2\pi C/\omega \times$	1	0.80991			0.81573
	$\lambda =$	4743.0	3838.9 <i>a</i>			3869. <i>a</i>
	Observed.....	4740.0	3835.8			3869.
$n = 3$	$\lambda = 2\pi C/\omega \times$	1	0.9250			
	$\lambda =$	4026.8 <i>a</i>	3724.8			
	Observed.....	4026.8	3729.0			
$n = 2$	$\lambda = 2\pi C/\pi \times$	1	0.96826			
	$\lambda =$	3967.6 <i>a</i>	3841.5			
	Observed.....	3967.6	3835.8			

"*a*" placed after a wave length shows that this one was assumed for that particular series.

The first method of attack used by Nicholson is briefly this, as is seen from the previous work. Making use of the theoretical analysis, he obtains the ratios of the wave lengths of what might be called a series, but not their absolute values. If a value for one of them is assumed, the rest are given. The agreement in some cases is far from good, and later it was found necessary to consider certain of the lines as due to a different source than given here. It is not clear as to why in the series for $n = 5$ for instance, the line for $k = -2$ should appear, and not the one for $k = 2$, or for the vibrations which should be still stronger, $k = 1$.

It will be seen that there is an error of about 4 \AA° in a large number of these calculated wave lengths. Nicholson shows that, except in the case of the vibration of Class O, this can be accounted for by the fact that the velocity of the electron is not small compared with that of light, or at least is not small enough so that it can be neglected without error. He calculates that the error due to this cannot be greater than about one part in a thousand, which amounts to about 4 \AA° with the wave lengths considered.

Bromwich pointed out to Nicholson that in the case of the vibration of Class O, the mass of the electron and the nucleus did not cancel out, but that a correction term of the form

$$(1 + nm/M)$$

should be introduced into the period equation. If H is the value of M for a hydrogen atom, then

$$m/H = 0.00054 \text{ approximately.}$$

This makes it possible to calculate the atomic weight of nebulium, which gives the value 1.3.

Using this method of ratios, Nicholson has calculated the wave lengths of lines for systems of $\nu = 2, 3, 5$, and 6. For $\nu = 2$ and 3, the lines were found by Wolfe in the nebulae. $\nu = 5$ was found in the solar corona, where Nicholson accounted for 21 out of 27 lines found.

For the systems $2e, 4e, 5e$, and $6e$, calculations have been made for the atomic weight by the method described above. From the values obtained, it can be shown that the atomic weights of these simple ring systems are proportional to the squares of the number of charges on their nuclei. For the entire series, the results are as follows:

Element.....	Pr.H	Nu	Pf	Arc
Atomic no.....	1e	2e	3e	4e	5e	6e
Atomic wt.....	0.082	0.327	0.736	1.31	2.1	2.9
Ratio.....	1 ²	2 ²	3 ²	4 ²	5 ²	6 ²

Here is a relation involving N^2 as in Moseley's work.

Up to this point, Nicholson used his method of ratios, and thus calculated the wave lengths of the most of the unknown lines in the nebulae and the solar corona, and succeeded in securing approximate values for the atomic weights. No connection has as yet been shown to exist between the systems of different nuclear charge. This relation is brought out later. Also, no relation has been shown between the principal frequency of vibration of the systems of the same nuclear charge, with varying numbers of electrons. This relation is shown by the consideration of the energy of the systems involved.

As Nicholson points out, it is impossible to know the absolute energy of the atom,¹ but changes of energy may be used. By a very simple analysis Nicholson arrives at the following equation of energy of the atom, in which the term D is equal to the energy in a standard configuration:

$$\frac{1}{2} mn\nu^2 = ne^2/a (\nu - \frac{1}{4} S_n) + D$$

By the condition of steady motion,

$$ma^3\omega^2 = e^2 (\nu - \frac{1}{4} S_n) = m\nu^2.$$

Now, $\omega = 2\pi C/\lambda'$, where λ' is the principal wave length. This gives

$$mna^2\omega^2 \cdot \frac{2\pi}{\omega} = \frac{mn}{C} \left\{ \frac{e^2}{m} (\nu - \frac{1}{4} S_n) 2\pi C \right\}^{1/2} \lambda^{1/2}.$$

¹ Equations have been developed from the standpoint of both the electromagnetic theory and the theory of relativity, which give the total energy of an atom in terms of its mass, but it is of course, not certain that these equations are valid.

Therefore it is seen that the ratio of energy to frequency is proportional to $n(\nu - 1/4 S_n)^{1/2} \lambda^{1/2}$, and for convenience this will be called the atomic energy, E . Then $E = n(\nu - 1/4 S_n)^{1/2} \lambda^{1/2}$.

Now the calculation of E for the various atoms of protofluorine where $\nu = 5$, gives the following result:

	$n = 5.$	$n = 4.$	$n = 3.$	$n = 2.$
E	187.04	164.6	134.7	97.4

If 7.482 is chosen as the unit of energy, the number of units for the different systems is as follows:

	$n = 5.$	$n = 4.$	$n = 3.$	$n = 2.$	$n = 1.$	$n = 0.$
	25	22	18	13	7	0
Differences.....		3	4	5	6	7
Units per electron.....	5	5.5	6	6.5	7	.

It is now possible to calculate the wave length of the line of principal frequency for the system $n = 2$. For this system it is seen that there are 6.5 units of E per electron, therefore

$$E = 2 (6.5 \times 7.482) = 2 (5 - 1/4 S_2) \lambda^{1/2} \quad (S_2 = 1.000).$$

From this $\lambda = 5073$. A weak line is known at this point.

If the energy of one of these systems is decreased by radiation by certain discrete amounts, we would expect a series of lines of some sort to be the result. That is, a series of spectrum lines might emanate from atoms whose internal angular momenta have run down by discrete amounts from a standard. In the case of protofluorine with two electrons, the loss of energy would be expected to be large enough so that the series could be observed. The wave lengths of the lines of this series may be expressed by the formula

$$\lambda = (97.107/2 - 1.223r)^3 / (4.75)^2.$$

That is, the energy E is being decreased by an amount 2.2446 each time. The term r takes successively the values 1, 2, 3, etc. The series is as follows:

r	0	1	2	3	4	5	6
Calculated.....	5073	4725	4400	4086.5	3788	3506	3238
Observed.....	5073	4725	4400	4087.4	..	3505	..

All these are weak lines. It may be pointed out that this method of calculating a series is very similar to Bohr's method where he decreases the internal energy of the atom by discrete amounts to give the members of the series. Bohr has given some sort of an idea as to how this takes place, while Nicholson merely states that the energy is lost by radiation. Such vibrations as give rise to this type of series are vibrations in the plane of the ring, as in Bohr's model. It will be noted later that Nicholson makes considerable use of this method, even discarding his original identifications of some of the nebulium and protofluorine lines, and putting them into series of this type.

If Q equals the number of quanta of energy per electron, choosing as a unit the value $h/5$, where h is Planck's unit, a still more useful equation is obtained,

$$Q = E/n = \frac{\lambda^{1/2} (\nu - 1/4 S_n)^{1/2}}{0.06235}.$$

For the atom of protofluorine where $\nu = 5$, the various values of Q are as follows:

n	5	4	3	2
Q	600	658.5	718	778.5

These values of Q can easily be shown to be in the ratio of 10 : 11 : 12 : 13 : 14.

In the case of Pf just dealt with, the value of Q may be expressed by a function of the following type:

$$Q = A + Bn + Cn^2$$

where A , B , and C are constants. If such a formula is to be applied to other atoms than Pf, these terms may not be constants, but functions of the nucleus. Since the function E/n has been shown to be harmonic, it may be supposed that the function E/ν would be of the same general type, that is:

$$E/\nu = \alpha + \beta\nu + \gamma\nu^2,$$

where $\nu = n$, a neutral atom. Therefore the function E/n for any atom is of the form

$$E/n = A + B\nu + C\nu^2 - n(D + E\nu) + Gn^2.$$

Since E in all cases is very closely a multiple of Planck's unit, the constants A to G will be close to whole numbers. The divergencies might be due to the rotation of the nucleus of the atom as a whole, at the expense of the angular momentum of the system, which otherwise might be exactly a multiple of $h/2\pi$. Nicholson calculates the values of these constants from the case of Pf, and then uses this method for the recalculation of the lines of the system 4e, nebulum. He finds that it is necessary to change the source of a number of the lines from that given them by his first method. More of them are now thought of as coming from vibrations which fall into the type of series where the cube roots of the wave lengths differ by constant amounts, as in the series calculated for the system $\nu = 5$, $n = 2$. The value of Q for such series can be found from a formula of the type used in the series just referred to:

$$Q = (Q_n/18r),$$

where r is variable, taking successively the values 1, 2, 3, etc.

The law relating the number of quanta of positive and negative systems is:

$$(E/n)_{\nu-m} + (E/n)_{\nu+m} = 2(E/n)$$

A series might arise from negatively charged systems, from the energy disturbances due to the repulsion of negative electrons by the system. Such series might be expected to be quite strong. A neutral system would be unaffected by electrons, only becoming ionized by virtue of its own unstable vibrations.

Some very important relationships may be brought out by the consideration of the relations between the energy of the various neutral systems of different nuclear charge. If the principal wave length of the system is known, it is possible to calculate the value of E/n from the formula

$$E/n = \frac{\lambda^{1/2} (\nu - 1/4 S_n)^{3/2}}{(0.06235)}.$$

The values of E/n for the systems $\nu = 5, 4$, and 2 are 600, 576.08, and 374.04, respectively. These are three terms of the following harmonic sequence:

ν	5	4	3	2	1
E/n	600	576.08	500.76	374.04	195.92
Difference.....	23.92	75.32	126.72	178.12	
Second difference..		54.40	54.40	54.40	

As stated before, it might be expected that these values of E/ν , which are obviously the same as E/n , could be expressed by the formula

$$E/\nu = \alpha + \beta\nu + \gamma\nu^2.$$

The following three equations can be solved for the constants:

$$600.00 = \alpha + 5\beta + 25\gamma \quad (1)$$

$$576.08 = \alpha + 4\beta + 16\gamma \quad (2)$$

$$500.76 = \alpha + 3\beta + 9\gamma \quad (3)$$

and $\alpha = -32$, $\beta = 254.4$, $\gamma = -25.6$. Therefore

$$Q = E/\nu = 254.4\nu - 25.6\nu^2 - 32.$$

If the values of E/ν for the systems 6e, 7e, 8e, 9e and 10e are calculated the following results are obtained:

ν	6	7	8	9	10
E/ν	572.52	493.64	363.36	181.68	-51.40

The fact that for $\nu = 10$ the energy is negative points to the fact that there are only 9 simple ring systems possible. If the first one is left out of consideration, and hydrogen is not put in the periodic table, the number of simple ring systems is the same as the number of groups in the first two rows of the periodic table. It will be shown later that the simple ring system 1e is very closely related to hydrogen so that leaving them both out of consideration at this point has some justification, particularly as the place of hydrogen in the table is very uncertain.

Knowing the value of E/ν for the various systems, it is possible to find their principal frequencies from the following formula:

$$\lambda = \left(\frac{E \cdot 0.06235}{\nu} \right)^3 \frac{1}{(\nu - 1/4 S_n)^2}$$

	6	7	8	9
ν				
λ	2613.57	1323.12	431.02	45.15

All these are outside of the range of observation, but it will be shown later that the first of these exists in the nebulae, and it has been given the name arconium. It will also be shown that the system $1e$ exists, and it has been given the name protohydrogen. Its principal wave length is calculated as 1823.55, which is exactly one-half the limit of the Balmer formula for hydrogen.

The system $2e$ is present in the nebulae, and in *Nova Persei*. The atom with nucleus $3e$ is also present in the nebulae, but its lines are not as strong as those of $2e$. The system $4e$ is nebulium and gives rise to the strongest nebular lines. Protofluorine, $5e$, has not been found in the nebulae, but is one of the main constituents of the solar corona. As just stated, $6e$, arconium, and the system $7e$ are found in the nebulae.

The remarkable agreement of these theories of Nicholson's with the facts would seem to indicate that there is here an extremely broad foundation for a system on which the building up of the chemical elements may rest. The relations between the energy of these systems seems to indicate that the principle of the constancy of angular momentum may be the physical basis of Planck's theory and also the basis of all the possible arrangements of electrical charges into the form of ordinary matter.

One of the most important and interesting pieces of work which Nicholson has done is in connection with the spectra of the Wolf-Rayet stars. These stars are considered by the astronomers as the earliest type known. They are regarded as being some sort of evolution product of the nebulae. The only ordinary elements which are present are hydrogen and possibly helium, although the last is not well represented unless, as Bohr suggests,* the Pickering series is due to this element. Nicholson shows that a number of Balmer series exist in these stars, and identifies them in a remarkable manner with the constants of the simple ring system called nebulium.

If the lines of these stars are examined they are found to contain a number of lines in the ratio of $5/4$. Thus:

$$\begin{aligned} 5285/4228 &= 1.2500 \\ 5813/4652 &= 1.2495 \end{aligned}$$

$$\begin{aligned} 5693/4555 &= 1.2499 \\ 5593/4473 &= 1.2503 \end{aligned}$$

If the Balmer formula is considered for one special case the following relationship is found:

$$\lambda = \lambda_0 m^2 / m^2 - 1$$

For $m = 2$ and 4 the following results:

$$\lambda_2 = 4/3 \lambda_0 \quad \lambda_4 = 16/15 \lambda_0 \quad \lambda_2/\lambda_4 = 5/4$$

* This suggestion is confirmed by the work of Evans.

This suggests that Balmer series exist in the Wolf-Rayet stars, and a simple calculation gives the following:

$$\lambda = (4104, 3963.5) m^2/m^2 - 1$$

A further examination of the lines leads to the following four series:

$$\lambda = (4104, \text{ or } 3963.5) \left(\frac{m^2}{m^2 - 1} \text{ or } \frac{m^2}{m^2 - 0.3286} \right)$$

It was found in the previous work that the three main vibrations of the neutral nebulium atom had frequencies in the following ratio:

$$q^2/\omega^2 = 1, 1.3145, 0.8496$$

Now $0.3286 = 1.3145/4$. This shows that these series are in some way related to the nebulium atom. It seems probable that another series or rather two series might exist in which the term 0.3286 was replaced by one-fourth of the other ratio for the third line of the neutral atom.

$$0.8496/4 = 0.2124.$$

The formula would then be

$$\lambda = (4104, 3963.5) m^2/m^2 - 0.2124.$$

Lines calculated for $m = 2$, and 3 give lines which are known in these stars, thus confirming the theory.

In general then, the formula for the Balmer series in the Wolf-Rayet stars may be written as

$$\lambda = (4104, 3963.5) \left(\frac{m^2}{m^2 - q^2/4\omega^2} \right).$$

A search for another limiting frequency gives the value 5254. We now have nine Balmer series which may be written as

$$\lambda = (4254, 4104, 3953.5) \left(\frac{m^2}{m^2 - q^2/4\omega^2} \text{ or } \frac{m^2}{m^2 - 1} \right).$$

A consideration of the limiting wave lengths gives still another way of expressing these formulae. If they are written in wave numbers their differences are seen to be constant.

$$10^8/\lambda_0 = 25227, 24366.5, 23506$$

with the constant difference 860.5. Therefore $\lambda_0^{-1} = A + Bn$ where n takes integral values. Substituting values for this and rearranging it, the following formula for the Balmar series in the Wolf-Rayet stars is obtained:

$$\lambda = \frac{2\lambda_0}{1 + nd} \left(\frac{m^2}{m^2 - q^2/4\omega^2} \text{ or } \frac{m^2}{m^2 - 1} \right)$$

in which $\lambda_0 = 5007$, the principal wave length of the neutral atom of nebium, n takes successive integral values, and $d = 0.08609$ and is not arbitrary, but is calculated from data involved in the consideration of the neutral nebium atom.

The above equation is one of the most remarkable and important points of Nicholson's work, for in it he succeeds in bringing together the simplifying systems which are not known on the earth, and our ordinary elements.

It is evident that a change in the term n means a change of some sort in the atom. It is also evident that it must be of a character that the force between the component parts does not change. It seems inevitable that the change must consist in a change in the nucleus, which does not alter its charge. It is significant that the simple ring systems seem to be incapable of giving rise to Balmer series, and the only logical conclusion is that they depend on the intimate structure of the nucleus. The elements which give rise to Balmer series may then be looked upon as the evolution products of the simple ring system on which the value of λ_0 depends. This is considering λ_0 as belonging to any simple ring system and not to nebulium alone.

Nicholson shows that the simple ring system $1e$ can have only one vibration frequency, $q = \omega$. This has already been calculated as $\lambda = 1823.35$, which is exactly one-half of the limiting wave length of the Balmer series for hydrogen. From the formula

$$\lambda = \frac{2\lambda_0}{1 + nd} \left(\frac{m^2}{m^2 - 4} \right),$$

it is seen that, to derive the hydrogen Balmer formula, n must be equal to 0. That is, hydrogen would appear to be the first evolution product of the system $1e$, protohydrogen.

It should be noted that Nicholson has in a rather round-about way succeeded in evaluating the Rydberg constant even more closely than did Bohr. He has not, however, attempted to give any physical picture of the mechanism of the production of the Balmer series.

While up to the present time the evolution products of the other systems are not known in general, it is likely that they may be some of our terrestrial elements. The lines due to a number of the evolution products of nebulium are shown in the Wolf-Rayet stars.

No work has yet been published connecting helium with the simple ring systems, although from the fact that it appears in the nebulae and the stars about the same time as does hydrogen, it seemed likely that it is one of the early evolution products of one of the systems. In some work as yet unpublished Nicholson has succeeded in showing that helium is the evolution product of the system $2e$.

From the progressive changes of the spectra of the stars, and other evidence which points to their age, it seems likely that all of our common elements are more complex forms of matter than the simple ring systems and hydrogen, and are built up from them. In such spectra the elements make their appearance in the order of their atomic weights.

According to Nicholson's idea, then, our ordinary terrestrial elements are evolution products of the simple ring systems found in the nebulae and the stars. That is, they have nuclei which are complex, containing both positive and negative electrons. This is in good accord with other facts but it does not agree with Rutherford's idea that the nucleus of the hydrogen atom may be the positive electron. If the astronomical evidence is admitted, it may be safely assumed that in the novae and nebulae, where the temperature is supposed by Nicholson to be very high, the complex atoms are unstable, breaking up into simple ones, or if the process is looked at from the other point of view, as these hot bodies cool the simple ring systems condense, becoming more complex and giving rise to the elements known on the earth.

The only very important papers on atomic structure which have not been considered are those of Stark. His work has been omitted on account of lack of space, and because he has not as yet been able to obtain from his results any very definite picture of the structure of the atom. Another reason is that this work is already available in book form³¹ which is not true of the material presented in this paper. Stark's greatest discovery is that of the electrical Zeeman effect, or the Stark effect, which is the decomposition of the spectral lines by means of a static electrical charge. Up to the present time this effect, which has been made to give a much greater separation of the components of the lines than has been obtained by the Zeeman effect, has been obtained only in the spectra from canal or positive rays. However this is probably due to the fact that this is the only method which has been found for securing the high field strengths which are essential. In Stark's work he has used a potential fall of from ten to seventy-four thousand volts per centimeter.

OSMOTIC PRESSURE AND CONCENTRATION IN SOLUTIONS OF ELECTROLYTES, AND THE CALCULATION OF THE DEGREE OF IONIZATION.

BY STUART J. BATES.

Received March 17, 1915.

I. Introduction.

Ostwald's dilution law, which is obtained by the application of the law of mass action to solutions of electrolytes, involves the concentration of the ions and that of the undissociated molecules. The large divergence from this law which strong electrolytes exhibit may hence be due to the behavior of the ions, to that of the undissociated molecules, or to that of both. This so-called anomalous behavior may be simply expressed by saying that for one or for both of these molecular species van't Hoff's law,

$\pi V = RT^1$ does not hold, for if all of the molecular species entering into an equilibrium obey this law, the law of mass action is a thermodynamic necessity.²

It is the purpose of this paper to develop and apply methods for determining the numerical relation which holds, in the place of that given by van't Hoff's law, between the osmotic pressure of the ions and their concentration, and the similar relation for the undissociated molecules. The divergence from the law of mass action may hence be split up into two distinct parts which may to a great extent be studied separately. The calculations will be based upon the commonly accepted assumption that the degree of ionization may be determined from conductance and viscosity data. Other assumptions which may be employed as a basis upon which to calculate the degree of ionization, for example, the assumption that the ions are normal, that is that van't Hoff's law is obeyed, will be considered and the conclusions to which they lead with respect to the behavior of the solute discussed.

Data which may be used for the calculation of the relation between osmotic pressure and concentration are conductance³ measurements, together with determinations of one of the colligative properties such as osmotic pressure, freezing-point lowering, electromotive force of concentration cells, etc. It will not be necessary to introduce, in order to carry out these calculations, any assumptions other than those already generally accepted. In addition to those of thermodynamics these are (1) that in dilute solutions of a di-ionic electrolyte the osmotic pressure due to each of the two ions is the same, and (2) that the degree of ionization (γ) is given by the conductance-viscosity ratio, the concentration of each ion being $C\gamma$ and that of the undissociated molecules $C(1 - \gamma)$. These assumptions are discussed below, where it is shown that the most reliable data support them and can be best interpreted by their aid.

There is a choice of systems to be used in discussing the properties of solutions. Any one, of vapor pressure, osmotic pressure, thermodynamic potential, activity, etc., may be employed. None of these possesses a theoretical advantage over the others, for all must involve the same assumptions or experimental data, and all lead to the same conclusions. Osmotic pressure is used here because it may be readily visualized, because of its general use among chemists and because of the relative simplicity of its thermodynamic treatment. The results may, of course, be readily "translated" into one of the other "languages," that of activity, for example. Mols per unit volume of solution is the most suit-

¹ π = osmotic pressure, V = volume containing one mol of solute, R = gas constant, T = absolute temperature.

² Washburn, *THIS JOURNAL*, 32, 485 (1910).

³ Whenever possible the conductance data should be corrected for viscosity.

able unit of concentration to employ since then the quotient, osmotic pressure divided by concentration, has the dimensions of energy and may be readily introduced into thermodynamic relations.

2. The Method of Calculation.

Outline of the Method.—If it be assumed that, in a solution of a di-ionic electrolyte, the osmotic pressure due to one of the ions is equal to that due to the other, then thermodynamics yield for equilibrium in solution the rigorous relation,¹

$$\frac{2d\pi_i}{C_i} - \frac{d\pi_u}{C_u} = 0 \quad (1)$$

where π_i and π_u are the osmotic pressures due to the ions at the concentration C_i and the undissociated molecules at the concentration C_u , respectively. By the aid of the same assumption the relation

$$\pi = 2\pi_i + \pi_u, \quad (2)$$

follows, *i. e.*, the total osmotic pressure (π) of the solution is the sum of two effects, one the osmotic pressure of the ions, the other that of the undissociated molecules. If now C_i and C_u are calculated from conductance data, and if the total osmotic pressure of the solution be known (either from direct measurements or from freezing-point determinations), it is possible to determine for any concentration interval for which data are available the relation between π_i and C_i and the relation between π_u and C_u , for there are two equations and but the two unknown quantities π_i and π_u . The fact that one of the equations is a differential equation makes their solution somewhat lengthy, but none the less rigorous.

The methods of performing these calculations are necessarily somewhat complicated. The remainder of this section gives in detail and with an example, mathematical methods which have been found convenient for solving the above equations; it may be omitted by readers not particularly interested in these methods. The assumptions involved and the conclusions to be derived are discussed in nonmathematical terms in the following sections.

Calculation of Osmotic Pressure from Freezing-point Data.—There are very few accurate direct measurements of the osmotic pressures of aqueous solutions of electrolytes. However, many careful determinations have been made of the freezing-point lowerings (Δt_f) of such solutions. From the resulting data, the osmotic pressures of these solutions may be readily and accurately calculated by means of the following equation:²

$$\pi = 12.06(\Delta t_f - 1.78 \cdot 10^{-3} \Delta t_f^2 - 2.5 \cdot 10^{-6} \Delta t_f^3) \quad (3)$$

¹ See Washburn, *THIS JOURNAL*, 32, 484 (1910).

² Washburn, *Ibid.*, 32, 499 (1910).

Thus the osmotic pressure of the solute¹ at the freezing point of the solution may be computed. It is most convenient to compare the osmotic pressures at the common temperature 0°. The temperature correction may be calculated from the Helmholtz equation

$$d\pi = (\pi - q) dT/T,$$

where q is the heat evolved on adding unit volume of solvent to an infinitely large amount of the solution. In general, the error which is involved in assuming $q = 0$, is smaller than is the probable error of the freezing-point determinations.² The temperature correction may hence be taken as

$$\Delta\pi = \pi\Delta t_f/273.1$$

and by combining this relation with Equation 3 we have for the osmotic pressure at 0° the equation

$$\pi = 12.06(1 + 0.00188 \Delta t_f) \Delta t_f. \quad (4)$$

This equation gives within a few hundredths of one per cent. the osmotic pressure at 0° of solutions as concentrated as 0.2 N and within 0.2 or 0.3% that for solutions up to 0.5 N .

Solution of the Equations.—The differential Equation 1 may be written thus:³

$$2(1 - \gamma)d\pi_i - \gamma d\pi_u = 0. \quad (5)$$

By differentiating Equation 2, multiplying through by γ and adding the result to (5) we get

$$d\pi_i = \gamma/2 d\pi. \quad (6)$$

Now since from differential calculus

$$d\left(\frac{\pi}{C_i}\right) = \frac{C_i d\pi - \pi dC_i}{C_i^2} \quad (7)$$

hence

$$\frac{d\pi}{dC_i} = \frac{\pi}{C} + \frac{d(\pi/C_i)}{d \ln C_i} \quad (7a)$$

and from (6)

$$\frac{d\pi_i}{dC_i} = \frac{\gamma}{2} \frac{d\pi}{dC_i} \quad \frac{\gamma}{2} \left[\frac{\pi}{C_i} + \frac{d(\pi/C_i)}{d \ln C_i} \right] = 1/2 \left[\frac{\pi}{C} + \frac{\gamma}{2.303} \frac{d(\pi/C_i)}{d \log C_i} \right]. \quad (8)$$

¹ As derived by Washburn the osmotic pressure in Equation 3 is that of the solvent. However, by employing the Duhem relation $N_w V_w d\pi_w + N_s V_s d\pi_s = 0$, and the fact that $N_w V_w = N_s V_s$ the osmotic pressure of the solute may be substituted for that of the solvent (water) in the original differential equation and in those which follow.

² In the case of the common salts whose heats of dilution have been determined by Rumelin, *Z. physik. Chem.*, **58**, 449 (1907); Bishop, *Phys. Rev.*, **26**, 169 (1904) or Magie, *Ibid.*, **35**, 265, 272 (1912) the error for solutions more dilute than 0.2 N is less than 0.05%.

³ γ = degree of ionization.

This is the equation used for determining $d\pi_i/dC_i$, *i. e.*, the rate of change of the osmotic pressure of the ions with their concentration. The ratio π/C in Equation 8 may of course be calculated directly from the data. The term,

$$\frac{\gamma}{2.303} \frac{d(\pi/C_i)}{d \log C_i},$$

which is small in comparison with the other, may be readily determined by either of two methods. Values of π/C_i may be plotted against those of $\log C_i$ and tangents to the curve graphically determined, or the obvious algebraic method may be employed. Having determined $d\pi_i/dC_i$ for a number of concentrations, values of π_i/C_i may be determined by integration, either graphic or algebraic.

In order to determine the similar ratios for the undissociated molecules, a procedure similar to the above might be employed. In practice, however, it is more convenient to use a different method. By eliminating K , C_i , and C_u from Storch's equation [$C_i^n/C_u = K$] from the differential equation derived from this, (C_i and C_u being taken as the variables) and from Equation 1, the relation

$$\frac{d\pi_u}{dC_u} = \frac{2}{n} \frac{d\pi_i}{dC_i} \quad (9)$$

is obtained. That is, having determined $d\pi_i/dC_i$ and values for n^1 over any given concentration range, it is possible to calculate $d\pi_u/dC_u$ and hence by integration to determine the osmotic pressure of the undissociated molecules as a function of their concentration.

Calculation of Osmotic Pressure from Electromotive Force Measurements.—For the electromotive force (E) of a concentration cell with electrodes reversible to the cation and involving transference, thermodynamics gives the equation²

$$FdE = N_a[V_c d\pi_c + V_a d\pi_a]. \quad (10)$$

Here F is the faraday, N_a the Hittorf transference number of the anion,³ V_c and V_a the volumes containing one mol of the cation and anion, respectively, and π_c and π_a the osmotic pressures of the cation and anion, respectively. If it be assumed that the two ions behave in a similar manner as regards their osmotic pressure, then, writing $1/C_i$ for V_c and for V_a , the following relation results:

$$dE = \frac{2N_a}{F} \frac{d\pi_i}{C_i} \quad (10a)$$

Hence,

¹ It has been shown that n changes with the concentration and methods for determining this exponent have been developed. Bates, THIS JOURNAL, 35, 519 (1913).

² Washburn, THIS JOURNAL, 32, 495 (1910).

³ For cells involving no transference, N should be replaced by unity.

$$\frac{d\pi_i}{dC_i} = \frac{F}{2N_a} \frac{dE}{d \ln C_i} \quad (11)$$

By transformations similar to those employed above (Equations 7 and 7a), the following may be obtained:

$$\frac{dE}{d \ln C_i} = \frac{E}{\ln C_i} + \ln C_i \frac{d(E/\ln C_i)}{d \ln C_i}$$

Hence, from Equation 11

$$\frac{d\pi_i}{dC_i} = \frac{F}{2N_a} \cdot \frac{1}{2.303} \left[\frac{E}{\log C_i} + \log C_i \frac{d(E/\log C_i)}{d \log C_i} \right] \quad (12)$$

By plotting values of $E/\log C_i$ against those of $\log C_i$, $\frac{d(E/\log C_i)}{d \log C_i}$ at any concentration may be determined, and hence, by means of Equation 12 $d\pi_i/dC_i$ may be computed. The calculation of π_i/C_i , of $d\pi_u/dC_u$ and of π_u/C_u is then exactly similar to that indicated in the discussion of the freezing-point data.

Example.—There is a much greater supply of accurate data concerning the freezing-point lowering of solutions available, than there is of that with regard to the electromotive force of concentration cells. The application of the above methods will hence be illustrated for the former kind of data only.

Table I gives the details of this calculation for solutions of potassium chloride. In the first column is given the concentration in equivalents per liter (C), in the second the corresponding value of the freezing-point lowering divided by the concentration in mols per 1000 grams of water. From 0.001 *N* to 0.05 *N* these values were interpolated by Flügel from his own excellent measurements.¹ The value given by him for 0.1 *N* (the most concentrated solution which he investigated) does not agree very well with his values for the more dilute solutions, neither does it agree with the careful measurements of Jahn,² Loomis³ or Barnes.⁴ Hence for this concentration the value in Column II is the mean of Flügel's value and that given in the compilation of Noyes and Falk⁵ as the best value. For the higher concentrations the data is taken from the compilation of Noyes and Falk. It is based largely upon the work of Jahn, of Loomis and of Barnes.

Employing the density data of Freund,⁶ values of $\Delta t_f/C$ were next calculated and then by the aid of Equation 4 values of $\pi/C \div RT$, these are

¹ *Z. physik. Chem.*, 79, 583 (1912).

⁴ *Trans. Nova Scotian Inst. of Science*, 10, 153.

⁵ *THIS JOURNAL*, 32, 1011 (1910).

⁶ *Z. physik. Chem.*, 66, 580 (1909).

given in Column III. By dividing these by the degrees of dissociation,¹ values of $\pi/C_i \div RT$ were obtained, which were then plotted against values of $\log C_i$, the tangents $\frac{d(\pi/C_i) \div RT}{d \log C_i}$ given in Column V were determined from this curve. Values of $d\pi_i/dC_i \div RT$ were then calculated by means of Equation 8. The figures for n were calculated from conductance data and were used to compute values of $d\pi_u/dC_u \div RT$ by means of Equation 9.

In order to integrate the coefficients in Columns VI and VIII, values of $\log (1 - d\pi_i/dC_i \div RT)$ were plotted against values of $\log C_i$, and those of $\log (d\pi_u/dC_u \div RT - 1)$ against values of $\log C_u$. The curves which

Fig. 1.—The Osmotic Pressure-Concentration Relations of the Ions and of the Undissociated Molecules of Potassium Chloride.

¹ Within the experimental error, the degrees of ionization of potassium chloride solutions of the same concentration are the same at 0° and at 18°. Since the conductivity data at the higher temperature is much more consistent with itself, the degrees of ionization calculated for 18° have been used in the present computations.

are given in Fig. 1 are straight lines. For the ions the greatest percentage deviation from the linear relation is 0.15%, that for the undissociated molecules is 0.30%. These are well within the experimental error of the freezing-point determinations. The equation for one line is

$$\log (1 - d\pi_i/dC_i \div RT) = 0.207 \log C_i - 0.258,$$

hence,

$$d\pi_i/dC_i \div RT = 1 - 0.0552 C_i^{0.207}$$

and integrating

$$\pi_i/C_i \div RT = 1 - 0.0457 C_i^{0.207}. \quad (13)$$

In a similar way the equation

$$\pi_u/C_u \div RT = 1 + 0.464 C_u^{0.0632} \quad (13a)$$

was obtained.

From these equations, values of $\pi_i/C_i \div RT$ and of $\pi_u/C_u \div RT$ were calculated; these are given in Columns IX and X. The osmotic pressures of the ions and of the undissociated molecules were then calculated at each concentration, these added together and divided by the concentration, giving the figures in Column XI. The percentage difference between the values thus calculated and those observed (Column III) are given in the last column. It is evident that the above numerical equations express the data very exactly. The greatest percentage difference, that at 0.001 *N*, corresponds to an error in the freezing-point determination of 0.00001°, the next largest, that at 0.2 *N* to an error of less than 0.0015°.

3. Results of the Calculation.

The results of calculations based on freezing-point data¹ for a number of representative di-ionic² electrolytes are given in Table II. They are given as ratios such as $d\pi_i/dC_i \div RT$, that is as deviations from van't

¹ The data for the dilute solutions of potassium chloride, of sodium chloride and of sodium chlorate are due to Flügel (*Loc. cit.*) at the higher concentrations in these cases and in others the "best" values given in the compilation of Noyes and Falk (*Loc. cit.*) were employed. For potassium nitrate up to and including 0.1 *N* the data of Adams (*THIS JOURNAL*, 37, 481 (1915)) were employed, above 0.1 *N* those of Roth were used. The calculations in the case of sodium nitrate are based in part on the results of Loomis (*Wied. Ann.*, 57, 495 (1896)) but chiefly upon those of Roth (*Z. physik. Chem.*, 79, 599 (1912)). For cesium nitrate the determinations of Biltz and Meyer (*Ibid.*, 40, 218 (1912)), of Washburn and MacInnes (*THIS JOURNAL*, 33, 1686 (1911)) and of Roth were interpolated. In the case of lithium chloride the results of Jahn (*Z. physik. Chem.*, 50, 129 (1904); 59, 31 (1907)) and of Washburn and MacInnes were employed. For the most dilute solutions of copper sulfate and of magnesium sulfate the data of Hausrath (*Ann. phys.*, [4] 9, 522 (1902)) and of Bedford (*Proc. Royal Soc.*, 83A, 454 (1910)) were interpolated, for the moderately concentrated solutions the "best" values of Noyes and Falk were used.

² The probable presence of complex ions makes the application of the above methods to salts of higher type impossible without the introduction of simplifying assumptions.

Hoff's law simply as a matter of convenience and comparison. The terms normal and abnormal, meaning agreement with or deviation from the requirements of this law or from proportionality between activity and concentration, are employed throughout this paper because they are in general use and because they offer a convenient means of discussing the results. These terms are, however, somewhat misleading for they appear to indicate a certain necessary or at least expected behavior or relation.

The values show the manner in which the osmotic pressure of the ions and that of the undissociated molecules changes with their respective concentrations. For most purposes the rate of change with the concentration, *i. e.*, $d\pi_i/dC_i$ or $d\pi_u/dC_u$ is more useful than the integrated ratio π_i/C_i or π_u/C_u . It is the differential coefficient, not the fraction π/C , which is introduced into thermodynamic relations in order to drive the mass law, the Nernst equation, etc. Further, the differential ratio gives more accurate information regarding the properties of the solution at any given concentration than does the integrated ratio. The value of the former depends only upon the properties of the solution at the concentration in question, while that of the latter is influenced by and to a great extent depends upon the properties of the solutions of all concentrations from the infinitely dilute solution up to that in question. For example, the molecular freezing-point lowering has been used in discussing the degree of hydration of solutes at various concentrations. The more logical value to use, if such a method is applicable to the problem, is the rate of change of the molecular freezing-point lowering with the concentration.

The uncertainties in the values given for $d\pi_i/dC_i$ largely depend upon those of the freezing-point data, since they are but slightly influenced by errors in the conductance measurements.¹ The figures for potassium chloride, sodium chloride and sodium chlorate, the freezing-point lowerings of whose solutions was determined by Flügel, are probably accurate to a few tenths of one per cent. The errors in the case of the other salts are somewhat larger.

The uncertainty in the values for $d\pi_u/dC_u$ is considerably greater than that in the similar ratio for the ions. It depends largely upon the reliance which may be placed upon the conductance data and upon the value chosen for the equivalent conductance at infinite dilution (Λ_0). This follows from the fact that the calculation of the ratios involves values of n , which, particularly at low concentrations, are very sensitive to irregularities in conductance data and to errors in the value of Λ_0 . Thus, for potassium chloride a change of 0.05% in Λ_0 becomes one of about 1% in the differential ratio at 0.001 *N*.²

¹ It follows from the form of Equation 8 that the values determined for the above differential ratio are not affected by errors in the value chosen for the equivalent conductance at infinite dilution.

² See also Table II. *THIS JOURNAL*, 35, 526 (1913).

If the values for Λ_0 which were calculated by Kohlrausch are used, values are obtained for $d\pi_u/dC_u$ such that the deviation from van't Hoff's law is a minimum at about 0.002 N and that at lower concentrations the abnormality becomes greater. Other objections against such values have been presented.¹ Kraus and Bray,² as a result of a very thorough and extensive study of conductance data, rejected Kohlrausch's data for solutions more dilute than 0.001 N and chose an unusually small value for Λ_0 . If their view is correct the deviations of the undissociated molecules, particularly below 0.01 N , are much less than those given in Table II. The present author finds, however, that, at least in the case of potassium chloride, Kohlrausch's data from 1.0 N to 0.0001 N may be represented by an empirical equation, somewhat similar to that of Kraus, with an average deviation of but 0.03%.³ Hence, using the same type of argument as that employed by Kraus and Bray, the data within this range are accurate, and the Λ_0 value consistent with this equation is the most probable one. The value thus given is within 0.05% of that previously chosen by means of two different and independent methods.⁴ It is believed that the uncertainty in the values for $d\pi_u/dC_u \div RT$ due to errors in the conductance data or in the Λ_0 values is, in general, less than 1%.

The values of Table II show that, even in solutions as dilute as 0.001 N , neither the ions nor the undissociated molecules obey van't Hoff's law, though with decreasing concentration both become more nearly normal.

Behavior of the Ions.—The osmotic pressure of the ions is less than that calculated from this law. This is true in every case except for solutions of lithium chloride 0.1 N and above; hydration is evidently the cause of this exception. The behavior of the ions may be represented within the error of the freezing-point determinations by an equation of the form

$$d\pi_i/dC_i = RT (1 + kC_i^m). \quad (14)$$

As is to be expected, the greater the hydration of the salt and the higher the concentration, the greater the deviation from this relation. In all cases where a regular deviation occurs at high concentrations it is in the direction predicted by hydration effects, and it is least for the slightly hydrated salts. In Table III are given for each of the salts (except lithium chloride) values of the constants k and m which fit the data. The average of the percentage deviations which are irregularly distributed⁵ is given for each salt in the last column of Table III. These deviations

The results given in Table II for copper sulfate and for magnesium sulfate show, not only that the osmotic pressure of the doubly charged ion is less than that calculated from van't Hoff's law, but also that it is much less than that determined for univalent ions at the same concentration. This result, expressed in terms of activity, has been pointed out by Lewis and Lacey,¹ who measured the electromotive force of copper sulfate concentration cells. Their experimental results indicate a deviation even greater than that calculated from freezing-point data.

In order to carry out the above calculations it is necessary to assume that the osmotic pressures of the two ions in a solution of a di-ionic electrolyte are the same. If such an assumption is not made it is apparently impossible with our present methods to solve the main problems connected with the theory of solutions. Otherwise the variables are too numerous for the number of independent experimental methods as yet developed. The results warrant the conclusion that up to moderate concentrations the assumption is justified. At concentrations below 0.05 *N* the behavior of the chloride ion, as calculated from the data for potassium chloride agrees within the experimental error with that derived from sodium chloride. The behavior of the sodium ion is the same whether calculated from the data for sodium chloride or for sodium chlorate. For the nitrate ion the data for potassium nitrate give the same results as the data for sodium nitrate and for cesium nitrate. The data for copper sulfate and for magnesium sulfate give agreeing results for the sulfate ion.

At higher concentrations hydration has an effect upon the osmotic pressure of the various constituents of the solutions, and since the degree of hydration varies from salt to salt the same agreement is not to be expected in concentrated solutions. As to whether or not hydration has the same influence upon the osmotic pressure of both ions it is impossible to judge from the present calculations.

Behavior of the Undissociated Molecules.—The undissociated molecules have an osmotic pressure considerably greater than that calculated from van't Hoff's law. At moderate concentrations the salts do not be-

¹ THIS JOURNAL, 36, 804 (1914).

have similarly. In the case of the chlorides the deviations continue to increase with the concentration, for the nitrates a maximum is reached about $0.02 N$. This somewhat surprising result, that the behavior of the least hydrated is the most complex is connected with the fact that the exponent n is for these salts a minimum at about $0.02 N$.

Since n may be calculated from conductance data alone, and since the deviation in the case of the ions is relatively small and may be extrapolated to more dilute solutions with a considerable degree of accuracy, hence values of $d\pi_u/dC_u \div RT$ may be calculated to within 1 or 2% for solutions more dilute than those for which freezing-point data are available. In this way it may be shown that in solutions more dilute than $0.01 N$ the undissociated molecules of the various uni-univalent salts behave in practically the same manner and that at $0.0001 N$ the deviation from van't Hoff's law is still about 15%.

For solutions more dilute than $0.01 N$ an empirical equation, of a form similar to that which holds for the ions, expresses the relation between the osmotic pressure of the undissociated molecules and their concentration. In the cases of potassium chloride¹ and of sodium chloride the equation has a considerably greater range.

The behaviors of the undissociated molecules of copper sulfate and of magnesium sulfate are remarkable in two particulars. First they show an almost constant deviation from van't Hoff's law from $0.001 N$ to $0.02 N$. In the second place they obey this law much more closely than do the undissociated molecules of uni-univalent salts, in fact above $0.01 N$ they are more nearly normal than are the ions into which they dissociate.

Effect of Hydration.—Hydration is usually considered to increase the osmotic pressure or the freezing-point lowering of a solution largely by lessening the amount of "free" water in the solution. Table II shows that it affects the osmotic pressures of the several constituents in a given solution to quite a different extent. The influence which hydration has on the ions is less than its influence on the undissociated molecules. Thus in the case of the most highly hydrated salt lithium chloride and the slightly hydrated salt cesium nitrate at $0.3 N$, the difference between the values of $d\pi/dC$ is 16% for the ions and 38% for the undissociated molecules. It is thus evident that hydration has some effect besides that due to the removal of "free" water.

4. Application to Chemical Equilibrium.

The law of mass action, the Nernst equation for the electromotive force of concentration cells, and the laws of the constancy of the solubility product and of constant concentration of the undissociated molecules are derived by combining certain thermodynamic equations with

¹ Equation 13a expresses the results for potassium chloride up to $0.5 N$.

van't Hoff's law. Above, it was shown that another empirical relation of the form,

$$d\pi/dC = RT(1 + kC^m), \quad (15)$$

more exactly expresses the relation between osmotic pressure and concentration for the various molecular species present in a dilute solution of a di-ionic electrolyte. Although this is probably as convenient an equation as any that can accurately express the results, it is not thought that any particular theoretical significance can be attached to its form.

The combination of one such equation for the ions and of one for the undissociated molecules with the thermodynamic equation (1) yields an integrated equation containing five constants. Such an equation could almost certainly be made to agree with conductance data, though the calculation of the constants would be rather laborious. Since the fundamental equation (15) is more efficiently tested by means of conductance and freezing-point data combined by the method of the preceding sections, the five constant equations will not be applied to conductance data alone.

The application of equations similar to (15) to the data regarding the effect of the presence of one salt upon the solubility of another is of interest, since it should give evidence concerning the influence of one constituent of a solution upon the osmotic pressure of another. The full discussion of this subject is a lengthy matter and will not be entered upon here.

By combining an equation for the ions of the form (15) with the thermodynamic equation (10) and integrating, the relation¹

$$E = 2N_eRT/F [\ln C_1/C_2 + k/m (C_1^m - C_2^m)] \quad (16)$$

is obtained for the electromotive force of a concentration cell. This relation reduces to the Nernst equation when $k = 0$.

For potassium chloride solutions, with electrodes reversible to the anion at 13°, the numerical equation obtained from (13) is

$$E = 0.05634 \log C_1/C_2 - 0.00653 (C_1^{0.207} - C_2^{0.207}). \quad (17)$$

In Table IV values of E observed by Jahn² are compared with those calculated from the Nernst equation and those determined by means of Equation 17. Those calculated by the latter method agree with the data much better than do those deduced from the Nernst equation. The agreement of Equation 17 with the data is of course not proof independent of that drawn from freezing-point data that Equation 13 expresses the behavior of the ions of potassium chloride. It shows that the freezing-point data and the electromotive force measurements are consistent with each other.

¹ Here C_1 and C_2 are the ion concentrations of the two solutions.

5. Calculation of the Degree of Ionization.

The above calculations show in a quantitative manner the deviations from van't Hoff's law which the ions and the undissociated molecules exhibit if it be assumed that the degree of ionization is given by the conductance ratio. Jahn,¹ and recently Lewis,² have considered it to be more reasonable to assume that the concentration of the ions is proportional to their osmotic pressure or activity, than that it is proportional to the electrical conductance of the solution. Thus the latter calculated the degree of ionization at moderate concentrations, such as 0.1 *N*, upon the assumption that the concentration-activity ratio has at 0.1 *N* the same value that it has in more dilute solutions, such as 0.02 *N*. For this latter solution the degree of ionization was calculated from conductance data.

Parallel to the assumption that the ions are normal is the one that the undissociated molecules are normal. The degree of ionization may be calculated from freezing-point data upon either of these bases. This may be conveniently done by the following method. By combining the equation $\pi_i = RTC_i = RTC\gamma$, which represents the first assumption, with Equation 6 the following relations are obtained:

$$2RT(\gamma dC + Cd\gamma) = \gamma d\pi,$$

whence

$$1 + \frac{d \log \gamma}{d \log C} = \frac{d\pi}{dC} \div 2RT \quad (18)$$

The corresponding relation for the calculation upon the assumption that the undissociated molecules are normal is

$$1 + \frac{d \log (1 - \gamma)}{d \log C} = \frac{d\pi}{dC} \div RT. \quad (19)$$

Values for $d\pi/dC$ may be readily determined from freezing-point data by employing an equation similar to (7a), the differential ratio $\frac{d(\pi/C)}{d \log C}$

here also being determined by a graphic method. In this way $\frac{d \log \gamma}{d \log C}$

and $\frac{d \log (1 - \gamma)}{d \log C}$ may be computed for a series of concentrations.

¹ *Z. physik. Chem.*, **33**, 545 (1900).

² *THIS JOURNAL*, **34**, 1631 (1912).

If the value of the degree of ionization is known for one concentration, that for others may be accurately calculated. In order to obtain this value for one concentration, it may be assumed with Lewis that for the most dilute solution the conductance ratio gives the degree of ionization. It is better, however, if the data be sufficiently accurate, to determine this by a process of trial from the following considerations. The osmotic pressure of the undissociated molecules (or of the ions, if the assumption is that the molecules are normal) may be calculated in two ways: (1) by subtracting that of the ions calculated from the relation $\pi_i = RTC_i$, from the total osmotic pressure, (2) by calculating n by the method previously given,¹ then π_u/C_u by the aid of Equation 6 and finally the osmotic pressure of the undissociated molecules. Different values are chosen for the degree of ionization at the lowest concentration, until these two methods give agreeing results.

Values for the degree of ionization and for $d\pi_u/dC_u \div RT$, for solutions of potassium chloride, calculated upon the assumption that the ions are normal, are given in Table V. The probable error of the degree of ionization, and above 0.02 *N*, of that of the differential ratio, is about 1%. The results show that the deviation of the undissociated molecules from van't Hoff's law is practically as great in the very dilute solutions and greater above 0.005 *N* in this case than it is when the degree of ionization is calculated from conductance data.

TABLE V.—CALCULATION OF THE DEGREE OF IONIZATION ASSUMING THAT (A) THE IONS ARE NORMAL, (B) THE UNDISSOCIATED MOLECULES ARE NORMAL.

0.2	72.7	1.43	43.9	3.+

Table V also gives the results of calculating the degree of ionization upon the assumption that the undissociated molecules are normal. In this case the degree of ionization for the very dilute solutions is greater than that calculated from conductance data, while at higher concentrations it is much less. In this case the uncertainty of the degree of ionization at 0.001 *N* is about 0.2%. Although at low concentrations the ions are practically normal, at higher concentrations their osmotic pressure is very much greater than that calculated from van't Hoff's law.

¹ THIS JOURNAL, 35, 524 (1913).

There are then, among others, the following three assumptions which may be employed for the calculation of the degree of ionization of solutions of strong electrolytes:

- (1) The degree of ionization is given by the conductance viscosity ratio.
- (2) Van't Hoff's law is obeyed by the ions.
- (3) Van't Hoff's law is obeyed by the undissociated molecules.

Experimental data show that in general only one of these assumptions can be true in the case of strong electrolytes. The acceptance of any one compels the rejection of the other two.

In view of the fact that many text-books and journal articles still present a misleading discussion of the calculation of the degree of ionization from freezing-point data, and since this calculation assumes that assumptions (2) and (3) are both true, it seems desirable to show in another way that the acceptance of one necessarily leads to the rejection of the other.¹ The differentiation of the mass law relation $C_i^2/C_u = K$ and the elimination of K from this equation and the derived differential equation gives

$$2dC_i/C_i - dC_u/C_u = 0.$$

This relation must hold if the mass law is obeyed. By eliminating C_i and C_u from this equation and from the thermodynamic equation,

$$2d\pi_i/C_i - d\pi_u/C_u = 0, \quad (1)$$

it is seen that the necessary and sufficient condition that the law of mass action hold over a certain concentration range is that at all concentrations

$$d\pi_i/dC_i = d\pi_u/dC_u.$$

The computation of the mol-number i from freezing-point data, and the calculation of the degree of ionization on this basis, assumes that both the ions and the undissociated molecules are normal. That is, it assumes

$$d\pi_i/dC_i = d\pi_u/dC_u = RT,$$

which is equivalent to assuming that the law of mass action holds. The results derived from such calculations do not obey this law and hence the method is inconsistent and theoretically incorrect. That the degree of ionization calculated by this method, in some cases, shows good agreement with that calculated from conductance data, is due to the fact that the deviation of the ions in one direction practically balances that of the undissociated molecules in the other, as far as the total osmotic pressure is concerned. It has long been recognized that actual gases are not "perfect" gases. Unfortunately the idea that, in general, solutes may be treated as normal or "perfect" solutes is much more persistent.

The probability of the validity of each of the above three assumptions will now be briefly considered.

¹ For a somewhat similar discussion see Washburn, *THIS JOURNAL*, 32, 484 (1910).

The Conductance Method.—Kohlrausch's principle of the independent migration of ions affords a theoretical basis for the first assumption. It gives an idea of the mechanism of electrical conduction in solutions and of the factors upon which it depends, *viz.*, the number of carriers, the charge upon each and their mobility in the given solution.

The determination of transference numbers supports the conductivity method of calculating the degree of ionization. It shows that at least up to about 0.1 *N* there is no certain change in the relative mobilities of the ions. These values may not be determined by the ordinary gravimetric method or by the less accurate moving boundary method. These give the Hittorf or ordinary transference numbers, whose value is affected by the amount of water carried by the ions as water of hydration. The true transference number must be determined by the aid of a reference substance. These values change much less with the concentration than do the Hittorf numbers.

It is probable that in concentrated solution the true transference number of many salts is not the same as it is in dilute solution. Two causes operate to bring this about: (1) the relative sizes of the ions change, due to a change in the degree of hydration with the concentration; (2) the change of the viscosity of the solution may affect the two ions unequally. Thus lithium chloride, which of the common uni-univalent salts shows the greatest change in its true transference number, is also the most highly hydrated and its solutions show the greatest relative viscosity. Even in the case of the much discussed hydrogen ion the best evidence indicates that its mobility is constant.¹ There appears then, to be no reason—except possibly that van't Hoff's law is not obeyed—for doubting that in principle the assumption of Kohlrausch is correct and that up to 0.1 *N* the degree of ionization may be calculated within a few tenths of one per cent. from the conductance data.

The Osmotic Pressure or Activity Methods.—Against the method of calculating the degree of ionization upon one or other of the assumptions that the ions or the undissociated molecules are normal may be urged, in the first place, the objection that the acceptance of one of these assumptions necessitates the rejection of the other. The choice between them is difficult to make. There is no more reason, either theoretical or experimental, for choosing one proposition than there is for choosing the other. They are exactly similar and apparently equally probable.

In the second place, there are a number of considerations which show that van't Hoff's law cannot be of general application. For this law to hold at different temperatures it is necessary that the heat of dilution (*q*) of the solution be zero. This quantity is usually small, but in general has an appreciable value. Even that part of the law corresponding to

¹ Kendall, *J. Chem. Soc.*, 101, 1275 (1912).

Boyle's law ($\pi = kC$) cannot in general be true for solutions. This would hold only in the case that at all concentrations the percentage change with the concentration of q and of π were the same. This is seldom, if ever, the case.

None of the more common relations between the colligative properties and concentration can hold for the solutions which are formed when two immiscible liquid phases are in equilibrium. For, if the laws of Raoult or of van't Hoff held, the concentration of each constituent would be the same in the two phases, that is, the phases would be identical.¹

Thirdly, there is no theoretical relation between any one of the colligative properties and concentration.² Thus the van't Hoff law, particularly for solutions of electrolytes, apparently cannot be derived from better established, more fundamental or simpler, assumptions. Although a number of derivations for this law have been given, some of them even claiming to be thermodynamic in character, all involve assumptions which are *a priori* no more probable than is van't Hoff's law. Thus many of them rest upon the assumption that corresponding to its concentration in the solution and directly proportional to it, each molecular species has a definite concentration in the vapor phase (Henry's law) and that in this phase each constituent obeys Boyle's law. Thus above a solution of potassium chloride, there would be, in the gaseous phase, potassium chloride molecules and potassium and chloride ions (hydrated of course) proportional in concentration to the concentration of the same species in the solution and obeying Boyle's law.³

If a satisfactory explanation of the mechanism of osmotic pressure could be suggested, corresponding to that generally accepted as the mechanism of electrical conduction, it would aid materially in discussing the relation between osmotic pressure and concentration. The similarity in form between van't Hoff's law and the gas laws is no argument in favor of the former; osmotic pressure is not due to the unordered heat motions of the molecules of the solute; its origin is not similar to that of the pressure in the case of a gas.⁴

It is an empirically established fact that in the case of many dilute solutions of nonelectrolytes, the osmotic pressure is practically propor-

¹ Washburn, *Trans. Am. Electrochem. Soc.*, 22, 330 (1912).

² Rosanoff and Dunphy (*THIS JOURNAL*, 36, 1411 (1914)) claim to have shown that for an infinitely dilute solution Raoult's law follows from the Duhem-Margules equation. In their argument they confuse finite quantities and differentials; their proof involves the equating of infinitesimal quantities to unity!

³ The laws of thermodynamics which appear to some to demand the existence of such species in the vapor phase, must be applied with great caution to such phenomena, because these laws can be applied to molecular phenomena only when a relatively large number of molecules are involved.

⁴ Findlay, "Osmotic Pressure," p. 69, Longmans, Green & Co. (1913); Washburn, "Principles of Physical Chemistry," p. 161, McGraw-Hill (1914).

tional to the concentration. In general, the more nearly the solute and solvent resemble one another, the more nearly is van't Hoff's law obeyed. The expectation that the ions and the undissociated molecules of strong electrolytes should obey this law is based entirely upon analogy. This analogy cannot hold for both molecular species; it must break down in one case or in the other, or in both. There is, apart from conductance data, apparently no means of telling which of these alternatives to choose. It seems, then, reasonable to accept fully the evidence afforded by such data, to the effect that neither the ions nor the undissociated molecules are normal, and to calculate the degree of ionization from conductance measurements.

6. The Deviation from the Law of Mass Action.

It was shown above that the necessary and sufficient condition that the law of mass action hold over a given concentration range is that $d\pi_i/dC_i = d\pi_u/dC_u$ at each concentration. This condition is fulfilled when both molecular species obey van't Hoff's law. Calculations show that under none of the three assumptions used for calculating the degree of ionization (see page 1439) does the above relation hold. This is simply another way of stating the fact that the law of mass action does not hold in solutions of strong electrolytes. This fact has been considered by some to constitute a serious objection against the theory of electrolytic dissociation. The validity of the well-known expression for equilibrium in solutions of electrolytes is, however, no more a necessary consequence of this theory than is van't Hoff's law. The arguments against the theory based on the deviation of the strong electrolyte from the mass law have been, to a great extent, founded upon a misunderstanding of the basis for that law and have been given much more weight than their importance justifies.

It is apparently fairly generally held that even though the mass law is not obeyed at ordinary concentrations, it must, for thermodynamic reasons, hold for the infinitely dilute solution. Even in this case there is no theoretical reason why $d\pi_i/dC_i$ should equal $d\pi_u/dC_u$. The calculations which have preceded show that these ratios at ordinary concentrations may be expressed by equations, which, when extrapolated to infinite dilution, do give the same value (RT) for both. This empirical fact probably affords the best basis for the belief that at infinite dilution the law of mass action is obeyed by solutions of strong electrolytes.

It should be noticed that the magnitude of the deviation of the strong electrolyte from the normal behavior depends greatly upon the way in which this deviation is expressed. The equilibrium expression C_i^2/C_u increases with the concentration. Thus for potassium chloride it increases from 0.026 at 0.0001 N to 0.55 at 0.1 N , an increase of 2100%. Table I shows that this behavior, when expressed in terms of a deviation from van't Hoff's law, is accounted for by a deviation at 0.1 N of 3.3% for the

ions and of 37% for the undissociated molecules. The percentage deviation, when expressed in terms of osmotic pressure, is smaller than when expressed, as Lewis¹ has done, in terms of activity; this follows from the logarithmic relation between the two.

The fact that the ratio $\frac{d\pi_i}{dC_i} / \frac{d\pi_u}{dC_u}$ is, for many salts, nearly constant over a considerable concentration range is connected with the fairly general application of Storch's equation. This ratio, as is seen from Equation 9, is equal to $n/2$, n being the exponent in Storch's equation. The quantity $2-n$ is evidently another measure of the deviation of strong electrolytes from the law of mass action.

Arrhenius² has discussed this deviation in terms of the dissociating power of the solution and has explained it as being due at least in part to neutral salt action. Walden³ has been somewhat more specific and ascribes the change of dissociating power to a change in dielectric constant of the solution with change in concentration. It makes but little difference which we refer to as the cause of the deviation from the mass law, the change in dissociating power, or the departure from van't Hoff's law. There cannot be a change in dissociating power so defined, without a deviating from van't Hoff's law and *vice versa*.

Each method of discussing the behavior of the strong electrolyte offers its own advantages. The discussion in terms of osmotic pressure and concentration is valuable because it employs easily definable and readily measured quantities, but particularly because it differentiates between the behavior of the ions and that of the undissociated molecules, and shows the extent to which each is responsible for the deviation from the various simple equilibrium relations.

7. Summary.

1. Methods are developed and applied, by means of which the osmotic pressure of the ions and of the undissociated molecules at various concentrations are calculated for solutions of electrolytes. Conductance data, together with measurements of one of the colligative properties of the solution are employed for the calculation.

2. The assumptions involved in these calculations, besides the laws of thermodynamics, are that (a) in a solution of a di-ionic electrolyte the two ions behave similarly as regards their osmotic pressure-concentration relations, and that (b) the degree of ionization (γ) may be calculated from conductance and viscosity data, the concentration of the ions and of the undissociated molecules being $C\gamma$ and $C(1 - \gamma)$, respectively.

² "Theories of Solution," p. 172, Yale University Press (1912); *J. Chem. Soc.*, 105, 1414 (1913).

³ THIS JOURNAL, 35, 1649 (1913).

3. The differential ratio $d\pi/dC$ gives more exact information regarding the properties of the solution at any given concentration than does the direct relation π/C between osmotic pressure and concentration, and for many purposes is more important.

4. The uncertainties in the values for the ions and for the undissociated molecules, due to errors in the freezing-point and conductance data and in the value chosen for the equivalent conductance at zero concentration, are discussed.

5. The osmotic pressure of the univalent ion is in general a few per cent. less than that calculated from van't Hoff's law. That of the undissociated molecules of strong uni-univalent electrolytes is considerably greater; even at 0.0001 N the deviation is about 15%.

6. The bivalent ions deviate much more from van't Hoff's law than do the univalent ions. On the other hand, the undissociated molecules of bi-bivalent salts rather closely obey that law; their deviation is practically constant between 0.001 N and 0.02 N .

7. At concentrations up to about 0.05 N the various univalent ions behave practically the same as regards their osmotic pressure-concentration relation. The same applies to the bivalent ions. Thus assumption (a) of paragraph 2 above, is supported.

8. The relation between osmotic pressure and concentration for both univalent and bivalent ions may be expressed, within the experimental error of the freezing-point determination, by an equation of the form $d\pi_i/dC_i = RT(1 + kC_i^m)$. In dilute solution a similar relation expresses the behavior of the undissociated molecules. In the case of potassium chloride the agreement is such that between 0.001 N and 0.5 N the total osmotic pressure calculated from such relations agrees with the experimental values with an average deviation of but 0.10%.

9. Hydration increases the osmotic pressure of both molecular species in the solution but influences that of the undissociated molecules to a greater extent than it does that of the ions. It hence has some effect other than the removal of "free" water from the solution.

10. Applications of the empirical relation between osmotic pressure and concentration to various equilibria are pointed out. That to electromotive force phenomena is illustrated.

11. The validity of the assumption used in the above calculations that (a) the degree of ionization is given by the conductance-viscosity ratio is discussed. The results to which this leads are compared with those which follow when the degree of ionization is calculated from freezing-point data upon either of the assumptions that (b) the ions are normal, or that (c) the undissociated molecules are normal. From the nature of the experimental data it follows that only one of these three assumptions can be true.

12. It is shown that assumption (a) has better theoretical and experimental support than have either of the other two assumptions.

13. The calculation of the degree of ionization from freezing-point data by the aid of the mol-number i assumes that assumptions (b) and (c) of paragraph 11 both hold and hence is theoretically incorrect.

14. It follows from the thermodynamic expression for equilibrium in solutions of electrolytes, that the necessary and sufficient condition that the law of mass action hold over a given concentration range is that $d\pi_i/dC_i = d\pi_u/dC_u$ for all solutions within this range.

15. There is nothing in the simple form of the electrolytic dissociation theory which necessitates the conclusion that the ions and the undissociated molecules of electrolytes obey van't Hoff's law. If they do not obey this law, the law of mass action cannot be followed. Hence the fact that solutions of strong electrolytes deviate from the requirements of the mass law is no argument against the theory of electrolytic dissociation.

16. The deviations from the law of mass action may be conveniently discussed in terms of the deviation of the ions and of the undissociated molecules from van't Hoff's law.

POTASSIUM CHLORIDE CONCENTRATION CELLS.

BY DUNCAN A. MACINNIS AND KARR PARKER.

Received March 27, 1915.

1. Purpose and Outline of the Investigation.

As a method for studying salt solutions, the determination of the electromotive force of concentration cells has the advantage, when compared with the freezing-point measurements, that the temperature at which the determination is carried out is not fixed, and may be kept constant at any desired point. This advantage is shared by vapor-pressure lowering and osmotic-pressure measurements, but the experimental difficulties have been found to be great in these determinations, particularly so when dilute solutions are investigated. It is, therefore, rather surprising that this method of attack of problems connected with salt solutions has not received more attention, since the thermodynamic relations connecting the results of the measurements of the electromotive force of concentration cells with the colligative properties of the solutions may readily be derived. The presence of liquid junctions in most concentration cells, and the uncertainty as to the method of correcting for them, may have contributed to the comparative neglect of this field. The present investigation was undertaken with the double purpose of measuring the free energy of dilution of potassium chloride by the electromotive

force method, and of investigating liquid junctions connecting salt solutions of different concentrations, by comparing the electromotive forces of cells in which these junctions are present with similar measurements on cells constructed so as not to involve this somewhat troublesome point of contact.

Among the few investigations yielding results suitable for interpretation in connection with the study of strong binary electrolytes is the accurate and much-discussed work of Jahn¹ on concentration cells of very dilute solutions of potassium and sodium chlorides and hydrochloric acid. Determinations of the electromotive force of concentration cells of hydrochloric acid have been made by Tolman and Ferguson.² Bell and Feild³ and Cumming⁴ have investigated cells containing silver nitrate solutions. There are, of course, many other measurements of the electromotive force of concentration cells in the chemical literature, but they deal with a single pair of solutions, are of doubtful accuracy, or else the solutions involved contain polyvalent ions. The latter introduce complexities which it is out of the province of the present paper to discuss.

Two forms of concentration cells have been investigated. The first, of which the following is typical:⁵

consists of two nonpolarizable electrodes in equilibrium with solutions, of concentrations C_1 and C_2 , which are connected by a liquid junction. Cells of this type were employed in Jahn's researches, and are usually called "concentration cells with transference."

The second variety, "concentration cells without transference," may be represented by the following example:

These are composed of two independent cells, and involve no liquid junction. This latter type has been the subject of a research by Tolman and Ferguson.⁶

The cells without diffusion are capable of simpler theoretical interpretation, as will be shown in the next section. There is, however, the experimental difficulty of finding a reversible electrode for *both* the ions of

⁵ In this paper the conventions adopted in the bibliography by Abegg, Auerbach and Luther, "Messungen electromotorischer Kräfte galvanischer Ketten" will be followed. A vertical line represents a junction; solid-liquid or liquid-liquid. A positive value for the E. M. F. means that current tends to flow from right to left through the cell.

⁶ *Loc. cit.*

the electrolyte, and for uni-univalent electrolytes this condition has, so far, been met only in the case of cells involving the halogen acids.

The development of the alkali metal amalgam electrodes by Lewis and Kraus¹ has made it possible to investigate cells of the following form:

a series of which, using various values of the concentrations C_1 and C_2 , are dealt with in this paper. Electromotive force measurements on the corresponding cells with transference:

have also been made. The results of these measurements will be considered in the light of the equations which will be derived in the next section.

2. Thermodynamics of Concentration Cells.

The thermodynamic differential equations connecting the osmotic work and the electrical energy for the two kinds of concentration cells may be derived most readily by the use of the thermodynamic engine devised by Washburn.²

Fig. 1 represents the engine used for deriving the equation for the concentration cells with transference. The chamber G contains the salt solution, KCl for instance, at the concentration C . The osmotic pressures of the ions at this concentration may be represented by Π_{K^+} and Π_{Cl^-} . D represents a reversible electrode, such as silver covered with a layer of silver chloride. The cylinder A is fitted at one end with a membrane a permeable only to the potassium ion. The piston in the cylinder permits the passage of water only. The solution between the piston and the membrane consists, therefore, of a solution of potassium ion in osmotic equilibrium with the solution in chamber G . The membrane b is permeable only to chloride ions. The other half of the engine is similar to that just described, except that the vessel G' contains the salt at the concentration $C + dC$, and the ions have the osmotic pressures $\Pi_{K^+} + d\Pi_{K^+}$ and $\Pi_{Cl^-} + d\Pi_{Cl^-}$. A movement of the piston $A - A'$ from left to right is, obviously, against the osmotic pressure $d\Pi_{K^+}$. An electrolytic connection with the vessels G to G' is afforded by the liquid junction as shown.

If the key K is closed and one equivalent F of electricity is allowed to pass, one equivalent of chloride ion will be formed at the electrode D and a like amount will be removed from the solution by electrolysis at electrode D' . The passage of the electricity across the liquid junction will be accomplished by the movement of η_K equivalents of potassium

¹ Lewis and Kraus, *THIS JOURNAL*, 32, 1459 (1910). See also Lewis and Keys, *Ibid.*, 34, 119 (1912); 35, 340 (1913).

² *THIS JOURNAL*, 32, 467 (1910).

ion in the direction of the current (from G' to G) and the migration of $(1 - \eta_K)$ equivalents of chloride ion in the reverse direction, where η_K is the Hittorf transference number of the cation. Thus the total effect of the operation of the cell will be the transfer of η_K equivalents of potassium chloride from the solution of the concentration $C + dC$ to one of

Fig. 1.

Fig. 2.

the concentration C . To compensate for this change and to maintain a constant difference of concentration the pistons $A - A'$ and $B - B'$ are moved reversibly toward the right, withdrawing η_K mols of each ion from chamber G and forcing them into chamber G' . As the electrical energy must be equal to the osmotic work, the following relation holds:

$$FdE = \eta_K (V_{K^+} d\Pi_{K^+} + V_{Cl^-} d\Pi_{Cl^-}) \quad (1)$$

in which E is the electromotive force and V_{K^+} and V_{Cl^-} are the volumes of solution containing one gram equivalent of ion.

Fig. 2 is a thermodynamic engine for the cells without transference. It is similar to that shown in Fig. 1 except that the liquid junction has been replaced by the electrodes $N - N'$, which, in the case under discussion, are potassium amalgam electrodes. The concentrations of the salt are C and $C + dC$ in the chambers G and G' as before. On closing keys K_1 and K_2 and allowing F coulombs to pass, one gram equivalent each of potassium ion and of chloride ion will be formed in chamber G and a like amount will be removed by the electrodes from chamber G' . To maintain equilibrium the pistons $A - A'$ and $B - B'$ must be moved reversibly toward the right, each through a volume containing one gram

equivalent of ion. Equating the osmotic work and electrical energy we have:

$$FdE = V_{K^+} d\Pi_{K^+} + V_{Cl^-} d\Pi_{Cl^-} \quad (2)$$

an expression which differs from (1) only in the fact that it does not contain the transference number η_K . Equations 1 and 2 are as far as we can go using purely thermodynamic reasoning.

If we assume that the ions are normal solutes and the solutions are dilute, *i. e.*, that $\Pi = RT/V = CRT$ (C = concentration) hold for each ion, Equation 2 becomes $FdE = 2RTd\ln C$, which on integration gives:

$$E = 2RT/F \ln C'_i/C_i \quad (3)$$

for the electromotive force of concentration cell without transference, in which C_i and C'_i are the concentrations of either ion in the two solutions.

With the further assumption that η_K is independent of the concentration, the integration of Equation 1 gives the familiar Nernst equation:

$$E = 2\eta_K RT/F \ln C'_i/C_i \quad (4)$$

3. The Concentration Cells without Transference.

As already mentioned, the concentration cells without transference that have been investigated may be represented by:

These cells involve (a) reversible silver-silver chloride electrodes and (b) reversible potassium amalgam electrodes.

(a) **Silver halide electrodes** have been thoroughly investigated by Jahn¹ and by Halla.² In most particulars the directions for their construction given by the latter have been followed. A disadvantage of the forms used by both these investigators was the limited extent of surface exposed to the solution, since they were made from a single piece of silver or platinum wire. As the tendency to polarize when small currents are applied and the electrical resistance of the solid liquid boundary both decrease with an increase of surface, the electrodes represented by $R - E$ and $R' - E'$ in Fig. 3 were used. They consist of a piece of platinum gauze of about three square centimeters area, welded to a platinum wire which made contact with mercury through a seal in a glass tube. The gauze was plated with a thick coating of silver from a $KAg(CN)_2$ solution, using a current density of about 0.5 ampere per square decimeter of surface. The electrodes were then thoroughly washed and allowed to stand twenty-four hours in pure water. They were next made anodes in a dilute potassium chloride solution, to which a few drops of hydrochloric acid had been added. After electrolyzing five or ten minutes with a current of 5 to 7 milliamperes per electrode, the electrodes were covered with a coating

¹ *Z. physik. Chem.*, **33**, 545 (1900).

² *Z. Electrochem.*, **17**, 179 (1911).

of silver chloride, of a reddish brown color, the shade of which was the same whether the electrolysis was carried out in the light or in complete darkness.

Forty electrodes were made in this manner in sets of eight. Electrodes chosen at random from different sets were checked against each other

Fig. 3.

frequently, with the result that "normal"¹ electrodes were always found to be within a few tenths of a millivolt of each other. When polarized

¹ Two kinds of abnormal electrodes were encountered (a) those which became abnormal because of the attack of a parasitic mold, and (b) those in which a white

by the application of one millivolt they returned to their original potential in a few minutes. New electrodes from one set generally showed potential differences of only a few hundredths of a millivolt. There was a slight ageing effect noticed, the older electrodes being electropositive to the newer ones. As this effect was always in the same direction and of the same magnitude within 0.05 mv. no error arose from this source, since similar electrodes were always opposed to each other.

(b) **The alkali metal amalgam electrode** employed is represented by *X* in Fig. 3. It differs from that used by Lewis and his associates only in having two capillary outlets *J* and *J'* for the amalgam, in order that it could be used in the two half cells at one time. To fill the electrode cell with the amalgam, the amalgam reservoir shown in Fig. 4 was inverted and connected by a T-tube to *O* in Fig. 3. The other branch of the T-tube was then connected to the Gaede pump. After exhausting and thoroughly drying the cell, the stopcock to the amalgam reservoir was opened and the amalgam was run from the reservoir. Dry, pure nitrogen was then introduced through the tube marked *N*₂. The surface of the amalgam either remained bright after the introduction of the nitrogen or else an exceedingly thin film slowly formed over the surface.

Fig. 4.

The potassium amalgam was prepared by a method which is a simplification of that used by Lewis and Kraus.¹ A diagram of the vessel used for this purpose is shown in Fig. 4. It consists of a distilling flask with allotropic silver chloride appeared to be formed in place of the "normal" plum colored AgCl.

(a) Some of the electrodes were attacked by an organism after some weeks, although the solutions in which they were placed were made up from conductivity water and pure KCl. The electrodes so attacked invariably became electrically different from the "normal" ones, developing in some cases a potential difference as high as 10 mv. This potential difference was always in the same direction, negative to the "normal" electrode. The mold was investigated by Dr. F. L. Stevens of the Botanical Department of the University of Illinois and, although conditions were very unfavorable for its development and culture, was identified as a parasitic mold (*Aspergillus*).

(b) The second class of "abnormal" electrodes appeared to have an allotropic form of AgCl on their surface. This form of AgCl, white in color and unaffected by diffused daylight even after weeks of exposure, sometimes appeared in spots on a "normal" electrode and sometimes covered the entire surface. These electrodes were always electronegative to the "normal" electrodes by varying amounts. The electrodes were all prepared under like conditions and the reason for the development of this modification of AgCl on some electrodes and on certain spots on a "normal" electrode is not clear.

¹ THIS JOURNAL, 32, 1459 (1910).

a stopcock fitted to its neck and a capillary tube, *P*, of about 0.4 mm. bore, sealed at one end to the delivery tube of the flask and at the other end to the tube *M* with an internal diameter of 6 mm. Pure mercury was first poured into the carefully dried apparatus. Pellets of potassium were placed in the tube *M*, which was then fused together at upper end. These pellets can be conveniently made by forcing a cork borer into a piece of the metal and then pushing the resulting small cylinder of the metal directly into the tube *M* by means of a closely fitting glass tube. The surface of the metal thus obtained was covered with a very thin film of oxide. The whole apparatus was next evacuated through the tube *R* by means of a Gaede pump. The pumping was continued for half an hour or more, during which time the apparatus was gently warmed to aid in removing the last traces of air and moisture from the mercury, after which the side tube from *M* to *D* was slowly and uniformly heated with a small, free flame. The potassium soon melted and passed through the capillary, collecting as a brilliant spot of metal in the bend of the tube at *D*. The capillary was then sealed off at *P* and the whole apparatus inverted, thus bringing the potassium and mercury into contact. The amalgamation took place quietly, little heat being evolved. When solution was completed, the apparatus was shaken for some time in order to be sure that the resulting amalgam was uniform. In appearance the surface to the amalgam was as bright as the mercury from which it was prepared. Amalgams of various concentrations were prepared from the stock amalgam by diluting, *in vacuo*, with pure mercury.

4. Design and Operation of the Cell.

The apparatus for the concentration cell without transference is shown in Fig. 3. The design finally adopted is the result of considerable preliminary experimenting, as it was found that there were a number of obstacles in the way of realization of complete reversibility at the amalgam electrode. One of the greatest difficulties was the side reaction:

It thus takes place a rapid drop of the potential between the electrode and solution must follow, since the concentration of the amalgam is thereby lowered and the ion concentration in the immediate vicinity of the electrode is increased. This difficulty was, it is believed, entirely overcome by having a constantly moving amalgam. The arrangement of the cell also permits the immediate removal of the drops of amalgam as they get detached, since they fall directly into bulb *D* and thence into the residue flask. Streams of fresh solution, run in through the tubes *G* and *G'*, were made to pass by the amalgam electrodes. This made sure that measurements were carried out with solutions uncontaminated by the passage of the amalgam. The air spaces in the bulbs *D* and *D'* permitted

the worker to observe the rapidity of the flow of the solution and prevented short circuiting through the rejected material or through the thermostat water. It was found that readings of the voltage of this cell became constant within about 0.05 millivolt when the flow of amalgam was about thirty drops per minute. After this an increase in the rate of flow had no influence on the results. The rate of flow of the solution was also found to have no influence, above a certain minimum. It is apparent that the effect of the side reaction given above was eliminated by this arrangement and also that the amalgam had time to come to electrical equilibrium in the short time that it was in contact with the solution. The formation of hydrogen was never observed in the cell, even when very few drops of amalgam per minute were passing.

The separation of each half cell into two portions, C , K and C' , K' , made it possible to leave the Ag , AgCl electrodes in contact with solution with which they were in equilibrium and which was also not disturbed by the solution flowing past the amalgam electrodes. The bent connecting tube aided in preventing mixing.

Early in the investigation it was recognized that oxygen dissolved in the solutions can influence the results on account of the side reaction:

and for this reason the solutions were prepared so that they came in contact with the air for only a very short time. The effect of this side reaction is the same as the previous one, *i. e.*, to lower the electromotive force, since the addition of potassium ions to both solutions will lower the ratio of the ion concentrations.

The solutions were made at first by collecting the water very hot in "Resistenz-glas" bottles from the still used for preparing conductivity water, pumping out the air remaining above the water and replacing it by pure nitrogen. The correct amount of salt necessary to make a solution of the required strength (in mols per liter) with all weights calculated to vacuum standard, was then added in a small glass capsule and allowed to dissolve. A small amount of air was carried into the solution in this last operation. Table I gives measurements of the E. M. F. of the cell:

Ag	AgCl, KCl 0.5 N	KHg _x — KHg _x	KCl, AgCl 0.005 N	Ag
----	--------------------	-------------------------------------	----------------------	----

the solutions in which were made as has just been described, using amalgams of widely varying concentration in the amalgam electrode.

TABLE I.

Conc. of amalgam	0.02% approx.	0.002% approx.	0.0002% approx.
E. M. F.	+0.10603 ± 0.00001	+0.10600 ± 0.00001	+0.1060 ± 0.0005

These figures indicate that the electromotive force is independent of the concentration of the amalgam within wide limits. The amalgam in

the last determination was too dilute to allow the most accurate measurements to be made. When, however, the results of several series of determinations similar to the above, and involving solutions of different concentrations, were plotted, irregularities appeared which could only be explained by assuming that the small amount of dissolved oxygen remaining in the solution reacted instantaneously with the amalgam, lowering the potential at both amalgam-solution boundaries. As can be seen from Table I this effect is, however, surprisingly constant. Accordingly, the final measurements were made using solutions from which every trace of oxygen was excluded.

Fig. 5.

The apparatus used for preparing the air-free solutions is shown in Fig. 5. The stopper of the "Resistenz-glas" bottle *A* is fitted with two tubes. Tube *B*, which reaches to the bottom of the flask, is used for the delivery of the solution to tube *G* of Fig. 3. Tube *C*—*C'* is in two parts, which may be shut off from each other by a piece of carefully cleaned rubber tubing and a pinchcock, represented by *F*. Both parts are fitted with stopcocks, as shown. In making the solution, the water was collected by placing the outlet from the still well within the mouth of the bottle and regulating the flow through the condenser of the still so that the water was collected as hot as possible and the air originally in the bottle was displaced by the large volume of steam which was evolved. When the bottle was nearly full, the stopper was inserted, the tube *B* filled with water, and the water boiled for fifteen or

twenty minutes by evacuating through the outlet from tube *C*. After this pure nitrogen was run in through this tube and the water allowed to cool with a pressure of this gas upon it. The required amount of salt was then weighed out into the capsule *E* and placed above the pinchcock in the tube *C'*, which was then closed at its upper end. After the air had been removed from this space by evacuating and filling with nitrogen several times, the capsule was made to drop into the water by opening the pinchcock *F*. The water in tube *B* was then displaced by nitrogen and the bottle was shaken until the solution was uniform.

Table II gives a summary of the results obtained from cells in which the solutions used were prepared in the manner just described.

TABLE II.—THE ELECTROMOTIVE FORCE OF POTASSIUM CHLORIDE CONCENTRATION CELLS WITHOUT TRANSFERENCE AT 25°.

"	"	0.05 "	0.002%	0.005 "	"	— 0.11085

The amalgam concentrations are approximate.

The electromotive force measurements were carried out with a Leeds & Northrup potentiometer which had been calibrated by the Bureau of Standards. The Weston Standard cell used was compared several times during the investigation with a similar cell which had recently been calibrated by the same Bureau. The measurements were carried out in a thermostat kept constant within 0.01°. The thermometer used was also calibrated by the Bureau of Standards.

5. The Concentration Cells with Transference.

Cumming and Gilchrist¹ have described the best conditions for the formation of liquid junctions giving reproducible results. These are (a) the use of wide tubes in making the connections, (b) the formation of a new boundary shortly before the measurements are taken, (c) the mechanical mixing of the solutions at the boundary. The cell used for the purpose in this investigation is shown in Fig. 6. The vessels *M* and *M'* contain the identical silver-silver chloride electrodes used with solutions of the corresponding concentrations in the cells without transference. The tubes *L* and *L'*, of about 5 mm. internal diameter, are brought together

Fig. 6.

in the small vessel *K* which contains a solution formed by mixing together equal parts of the solutions contained in *M* and *M'*. The tubes can be readily filled by pressing the rubber stoppers deeper into the vessels *M* and *M'* or by placing a slight air pressure on the surface of the solutions by means of tubes (not shown) which pass through the stoppers. The "time change" which is apparently always present where a liquid

¹ *Trans. Farad. Soc.*, 9, 174 (1913).

junction is involved, was less than one millivolt per hour, and as new boundaries which gave the original reading could readily be obtained, it is believed that maximum values of the electromotive force were measured in each case.

The results of these measurements are given under Table III.

6. Purification of Materials.

Mercury.—The mercury used in this investigation was purified by passing it in a thin stream through a tube, a meter long, filled with dilute nitric acid, and then distilling with diminished pressure in a current of air.

Potassium Chloride.—A well known manufacturer's best grade of potassium chloride was recrystallized one or more times from conductivity water, and the mother liquor drained off with the help of a centrifuge. It was always fused immediately before using.

Nitrogen.—Since most of the operations carried out in this work were found to be disturbed by the presence of oxygen, even if present in very small amounts, a rather large volume of an inactive gas was found to be a necessity. Nitrogen was found to fill all the requirements. It was prepared from sodium nitrite and ammonium chloride as described by Tucker and Yang¹ and kept over water in a gasometer. To remove the small amount of oxygen remaining, as well as the moisture present, it was passed through a train consisting of sulfuric acid, soda lime, copper heated to redness, and when necessary, through U-tubes filled with P_2O_5 . The copper, which had been reduced by hydrogen from copper oxide, was contained in a quartz tube. The latter was a convenience as it could be heated and cooled rapidly without danger of breaking.

7. Discussion of Results.

On page 1448 we obtained the differential equation

$$FdE = \eta(V_1 d\Pi_1 + V_2 d\Pi_2)$$

connecting the osmotic work and the electromotive force of a "concentration cell with transference," and the expression

$$FdE = V_1 d\Pi_1 + V_2 d\Pi_2$$

¹ *Orig. Comm. 8th Int. Congr. Appl. Chem.*, 21, 121 (1912).

for a "concentration cell without transference." From these equations it is apparent that whatever the relations between II and V may be the ratio:

$$\frac{\text{E. M. F. of cell with transference}}{\text{E. M. F. of cell without transference}}$$

for cells containing the same pair of salt solutions, should be equal to the transference number of one of the ions. By referring to the derivation of the equations it can be seen that in the present case the ratio gives the transference number of the cation. The derivation, however, involves the assumption that thermodynamics can be applied to the cell containing the liquid junction. This, in the authors' minds, needed proof, since this point of contact of two solutions of different concentrations is certainly not in the ordinary sense of the word a system in equilibrium. Table IV gives values of the above ratio, and also, from Noyes and Falk's¹ most useful compilation, the values of the transference number obtained by the Hittorf and by the moving boundary methods.

TABLE IV.—COMPARISON OF THE TRANSFERENCE NUMBERS OF THE CATION IN KCl, AT 25°, OBTAINED BY THE E. M. F., HITTORF, AND MOVING BOUNDARY METHODS. .
Transference numbers.

Concentrations.	E. M. F. ratio.	E. M. F.	Hittorf.	Mov. boundary.
0.5 — 0.05	53.57/107.4	0.498	496	...
0.1 — 0.01	54.00/108.9	0.496	496	0.493
0.05 — 0.005	54.70/110.85	0.494	496	0.493

From these figures it is evident that the thermodynamic theory as outlined is confirmed within the experimental error. This method for the determination of the transference number was first suggested by Helmholtz.²

The general applicability of this method for obtaining transference numbers may be tested by comparing the value it gives of the transference number of the hydrogen ion in hydrochloric acid with that determined in the usual way. Jahn³ has found the E. M. F. of the following cells with transference at 18°:

Ag		AgCl, HCl		HCl	AgCl		Ag	E. M. F.
"	"	0.03330 N	"	0.003329 N	"	"	"	—0.09162 ± 0.00005
"	"	0.01665 N	"	0.001665 N	"	"	"	—0.09235 ± 0.00005

and Tolman and Ferguson's⁴ paper contains measurements of the voltage of the cell without transference:

Hg		HgCl, HCl		H ₂ — H ₂		HCl, HgCl		Hg	E. M. F.
"	"	0.02 N	"	1 atm. 1 atm.	"	0.002 N	"	"	—0.1109 ± 0.001

at the same temperature. Making a linear interpolation from the elec-

² *Ges. Abh.*, 1, 840; 2, 979.

³ *Loc. cit.*, page 1446.

⁴ *Ibid.*, page 1446.

tromotive forces of the first mentioned cells for a value of the voltage of the cell:

we obtain -0.09210 . The ratio $0.09210/0.1109$ is 0.830 , which agrees, well within the experimental error, with the directly determined transference number 0.833 , as given by Jahn¹ and by Drucker and Krsnjavi.²

On applying the integrated equations:

$$E = 2\eta RT/F \ln C'_i/C_i \quad (4)$$

$$E = 2RT/F \ln C'_i/C_i \quad (3)$$

for the electromotive force of a concentration cell with and without transference, respectively, to our data, and calculating ion concentrations in the usual way from conductance measurements, we do not find the same agreement of the theory with the results of experiment. It is found that in every case the calculated values of the electromotive force are too high. This is shown in a slightly different ways in Table V, in which the ratio of the ion concentrations C'_i/C_i obtained from the electromotive force measurements by means of Equation 3 are compared with the same ratios calculated from conductance data. Column I of the table gives the salt concentrations involved. Column II contains values of the ratio C'_i/C_i computed from the conductance measurements of Kohlrausch and Maltby³ at 18° . The measurements by Melcher⁴ on KCl solns. at 25° show that little error is involved in assuming that the ratio does change appreciably in the temperature range, 18° to 25° . The ratio as calculated from electromotive force measurements is placed in the last column. The values of R , T_0 , and F used in obtaining these last figures are $8,316$, 273.1 , and $96,500$, respectively, the last being the value of the Faraday recommended by Bates and Vinal⁵ for general use. It will be observed that the salt concentrations have the same ratio: 1 to 10, in each pair of solutions. The figures in italics refer to Jahn's work at 18° .

TABLE V.—RATIOS OF ION CONCENTRATIONS OF POTASSIUM CHLORIDE SOLUTIONS CORRESPONDING TO VARIOUS TEN TO ONE SALT CONCENTRATIONS.

⁴ *THIS JOURNAL*, **33**, 1669 (1901).

⁵ *Ibid.*, **36**, 916 (1914).

From these figures and from Fig. 7, where the ratios are plotted as ordinates, and the higher concentration of each pair of solutions as abscissae, it can be seen that, although the ratios differ widely when calculated by the two methods, both sets of figures are apparently approaching the same value: 10, which would be the ratio of the ion concentrations of two solutions both near infinite dilution, but whose total salt concentrations were in the proportion 10 to 1. In other words, the Nernst equation can be used to calculate the electromotive force of concentration cells of potassium chloride only when the solutions involved are near infinite dilution.

Fig. 7.

the electromotive force of concentration cells of potassium chloride only when the solutions involved are near infinite dilution.

Equations 3 and 4 may also be written

$$E = 2RT/F \ln a'/a$$

and

$$E = 2\eta RT/F \ln a'/a$$

where a and a' are the "activities"¹ of the ions. In this form the equations are, by definition, thermodynamically valid, provided the positive and negative ions in any solution have the same activity. The figures in the last column of Table V are therefore activity ratios. It is evident that the "activity" ratios approaches the "concentration" ratios as the solutions become more and more dilute.

In order to obtain an idea of the magnitude of the "activities" of the ions at various concentrations let us assume provisionally that at 0.001 N the activity of the ions is equal to their concentration as calculated by multiplying the total salt concentration by the conductivity ratio: Λ/Λ_0 . From this value, and the activity ratios given in Table V, we can calculate the activities corresponding to the salt concentrations 0.01 N and 0.1 N . The following table gives, for the concentrations mentioned, the values of the "activity" calculated as has been described, the usually accepted degrees of dissociation, and the "thermodynamically effective" degrees of dissociation which are obtained by dividing the activity by the corresponding total concentration.

¹ Lewis, *Proc. Am. Acad.*, 43, 259 (1907).

Salt conc.	"Activity."	Degrees of dissociation.	"Thermodynamically effective" degrees of dissociation.
0.001 <i>N</i>	0.000979	97.9	(97.9)
0.01 <i>N</i>	0.00885	94.1	88.5
0.1 <i>N</i>	0.0738	86.1	73.8

Readers of Lewis' recent paper on "The Activity of Ions and the Degree of Dissociation of Strong Electrolytes,"¹ will recall that he decides from thermodynamic considerations on the basis of solubility and freezing-point measurements, that 74% is the effective or "corrected" degree of ionization of a 0.1 *N* solution of potassium chloride. The close agreement (0.2%) of this value with the one for the same concentration given in the table is not, as might appear at first sight, an independent piece of evidence in favor of this low degree of ionization, but simply means that measurements on all the colligative properties must lead to the same values of the activity of the ions if thermodynamic reasoning is employed.

That the conductivity method does not give the same degree of dissociation as the electromotive force or related methods has been known for some time, and has been explained in a number of ways. Jahn believed that the E. M. F. method gives the correct measure of ionization and accounted for the higher results from conductance data by assuming that the ions "speed up" as the concentration increases. Another explanation, which also starts from the lower values of the degree of ionization as the correct ones, makes use of the hypothesis that in addition to the usual conduction by ions the undissociated molecule also takes part in the conduction by a series of rapid dissociations and recombinations, usually known as the Grotthus chain effect. This would, obviously, increase as the salt concentration increases. Most of the investigators in this field, however, regard the conductivity ratio Λ/Λ_0 (or this ratio multiplied by some function of the viscosity) as the degree of dissociation, and consider the decreasing activity of the ions as the concentration increases as being due to a change of the nature of the solution as a solvent medium, due, in part at least, to the charges on the ions. Walden and others have shown that it is probable that the dielectric constant of water increases when electrolytes are added. It seems quite possible that neither degree of dissociation is the correct one and that all the influences mentioned may have their effect.

8. Summary.

The electromotive forces of the cells without transference:

have been measured and compared with measurements of the voltage of the cells with transference.

¹ THIS JOURNAL, 34, 1631 (1912).

With the same solutions in cells of both types, the ratio of the potentials is shown to give accurate values of the transference number of the cation.

The measurements indicate that the "activities" of the ions from potassium chloride are much lower than the concentrations as calculated from conductance measurements. The values of the "activity" and of the concentration, however, apparently approach the same limit for very dilute solutions.

THE DROP WEIGHT METHOD FOR THE DETERMINATION OF THE SURFACE TENSION OF A LIQUID.

BY J. LIVINGSTON R. MORGAN.

Received April 12, 1915.

This method for the determination of the surface tension is one of the results of the extended, *purely experimental and statistical*, investigation of the relationship between the falling drop weight and the surface tension of a liquid, reports of which have appeared from time to time from this laboratory.¹ As no description of this method, in its present form, has appeared in any one place, however, for it has developed only gradually; and since some misunderstanding appears to exist concerning it; it is thought desirable that a brief résumé of the conditions necessary for its holding, in the light of the searching and conclusive, experimental tests to which it has been subjected in this laboratory, be presented here. This résumé will perhaps be of advantage also, in that it will render the future work published from this laboratory more intelligible; and, further, will make the method available to those other workers who may wish to determine accurate surface-tension values.

The drop weights considered throughout this work are those found by aid of the apparatus already described in some detail in *THIS JOURNAL*,² which enables one to determine with a high degree of precision the weight of any desired number of drops of liquid falling from any sharp-edged capillary dropping tip, at any fixed temperature below 90°; and that, *free from any effect of evaporation*, even when within but a few degrees of the boiling point of the liquid. The drops here are always formed very slowly, at any rate immediately before their fall, so that they drop unaided and of their own weight alone.

¹ See Morgan and co-workers, "The Weight of a Falling Drop and the Laws of Tate," in a series of eighteen papers, *THIS JOURNAL*, 30, 33 and 35 (1908-1913).

² Morgan, *THIS JOURNAL*, 33, 349-62 (1911).

As the result of an experimental study of some two hundred especially purified liquids and solutions, for more than one hundred of which the surface tensions (lying between 15.3 and higher than 76 dynes per centimeter), for purposes of comparison, are known from some other method; liquids which include those of every conceivable type, and possessing every property which could possibly and adversely influence the behavior; it has been found that *under certain definite conditions*, the drop weights of liquids from any one dropping tip are proportional to their surface tensions, at the same temperature.

Expressed mathematically, this relationship is

$$\frac{\gamma_{C_6H_6,t}}{w_{C_6H_6,t}} = \frac{\gamma_{H_2O,t'}}{w_{H_2O,t'}} = \frac{\gamma_{l,t''}}{w_{l,t''}} = \text{Constant}, \quad (1)$$

where, although the surface tension γ in the numerator of any one ratio must be at a temperature identical with that for the drop weight value w in its denominator, the γ values can be at any desired temperature, t , t' or t'' , and need not be even on the same portion of the scale.

Transforming this equation, we find

$$\gamma_{l,t''} = \left(\frac{\gamma_{C_6H_6,t}}{w_{C_6H_6,t}} \right) w_{l,t''} = \left(\frac{\gamma_{H_2O,t'}}{w_{H_2O,t'}} \right) w_{l,t''} = \text{Constant} \times w_{l,t''}; \quad (2)$$

the surface tension of any liquid at any temperature is equal to its falling drop weight from any one tip at that temperature, times a constant, the value of which is found once for all for that tip, and is equal to the ratio of the surface tension of some standard liquid to the drop weight of that liquid, both at some one, like, temperature.

This is one of Tate's laws which has been under *experimental* investigation in the series of papers alluded to above, and which has been *proven* to hold rigidly, under the definite conditions discussed below, for so many liquids. As is apparent, the method is a *relative*, not an absolute one, and consequently it must be standardized by aid of some selected liquid, preferably one which can be readily obtained in the pure state, and which has a comparatively high boiling point. Benzene and water have been employed in general for this purpose, for in addition to fulfilling the above requirements, they differ greatly as far as concerns the magnitude of the surface tension, and thus inspire increased confidence, perhaps, in the range of the method.

In order that the surface tensions of these liquids, for standardization purposes, may be readily calculated to the temperature at which their drop weights may have been found experimentally, use is made of the following interpolation formulas:

$$\gamma_{C_6H_6,t} = 30.514 - 0.1321t + 0.000082t^2,$$

$$\gamma_{H_2O,t} = 75.872 - 0.1547t - 0.00022t^2,$$

where γ is expressed in dynes per centimeter, and t may have any value up to 80° .

The above equation for benzene represents the average of *all* the results of *all* the accurate workers with benzene by the capillary rise method, and was obtained from them by aid of the method of least squares; it thus leads to the most accurate and representative average value of the surface tension of benzene at any temperature up to 80° .¹ The equation for water is that found by Morgan and McAfee² after standardizing their tip with benzene, and gives results which are in excellent agreement with the best results on water found by observers using other methods.

Conditions Necessary for the Holding of $\gamma_{l,t} = \text{Constant} \times w_{l,t}$.

The conditions necessary for the precise holding of the equation, $\gamma_{l,t} =$

¹ This equation, which is most convenient for laboratory purposes, gives results which are perfectly in accord with those obtained by aid of the *general*, empirical equation found by the author to hold *rigidly* for the average values of γ , even up to the critical temperature of benzene. This equation is

$$\gamma_{C_6H_6,t} = 2.115 \left(\frac{288.5 - t - 6}{(78/d_t)^{1/2}} \right),$$

where γ_t and d_t are the surface tension in dynes and density of benzene at the temperature of observation, t ; 78 is the molecular weight of benzene; 288.5 is its observed critical temperature; and 2.115 and 6 are constants. The density of benzene, for use in this formula, can be found up to 100° by aid of the relation $d_t = 0.9002 - 0.001066t$.

The equation for the work of any *one* observer alone is found to be identical with the above, except as to the value, 2.115, of the constant, which is slightly different for each observer, but *constant* throughout the temperature range studied by him. With a characteristic constant for each observer, in fact, this equation is found to give results which agree with the most remarkable accuracy with the observed values of $\gamma_{C_6H_6}$ of that observer at all temperatures (see Morgan, *Z. physik. Chem.*, 1915).

The *average* equation to give the *average* result of the surface tension of benzene of *all* observers, then, is the above, in which the *average* value of *all* the individual, slightly differing, constants is used, *i. e.*, 2.115.

Applying this form of equation to the drop weight results of benzene, from any one tip, *under the conditions discussed below*, it is found that the relationship

$$w_{C_6H_6,t} = K \left(\frac{288.5 - t - 6}{(78/d_t)^{1/2}} \right)$$

also represents with very great precision the drop weights in milligrams at various temperatures from that tip, *the value of K being constant and characteristic for any one tip, and independent of the temperature.*

Comparison of these two equations, for $\gamma_{C_6H_6}$ and $w_{C_6H_6}$, at every identical temperature, then, shows that, *independent of the temperature*, since all terms except γ , w , 2.115 and K would be identical

$$\frac{\gamma_{C_6H_6,t}}{w_{C_6H_6,t}} = \frac{2.115}{K} = \text{Constant},$$

for any one tip, t to have any desired value. In other words, Equation 1, as far as concerns the surface tension and drop weight of benzene from any one tip is thus shown to be rigidly true at all temperatures.

² This JOURNAL, 33, 1275-90 (1911).

constant $\times w_{l,t}$ have been most thoroughly investigated from the experimental and comparative point of view. In other words, it has been found experimentally just what conditions are necessary in order that, within the narrow limits of error of the drop weight estimation, the ratios $\frac{\gamma_{C_6H_6,t}}{w_{C_6H_6,t}}$, $\frac{\gamma_{H_2O,t'}}{w_{H_2O,t'}}$, and $\frac{\gamma_{l,t''}}{w_{l,t''}}$, where the sub-letter l represents *any* liquid, may be equal and constant in value, regardless of the values of t , t' and t'' ; or, what amounts to the same thing, that the values of $\gamma_{e,t''}$, as calculated from $\gamma_{l,t''} = \left(\frac{\gamma_{C_6H_6,t}}{w_{C_6H_6,t}} \right) w_{l,t''} = \left(\frac{\gamma_{H_2O,t'}}{w_{H_2O,t'}} \right) w_{l,t''} = \text{Constant} \times w_{l,t''}$, may agree with those found at that temperature by some other method. The latter form here, naturally, is the one employed directly in the drop weight method for surface tension, and at the same time leads, perhaps, to a more satisfactory test of the truth of the general relationship; for by aid of the equation giving the change in surface tension with the temperature (which can be readily found from its results at several temperatures), the values of γ_l at the various temperatures can be found by interpolation, and then compared with those found directly at those temperatures by the various other observers.

The conditions found necessary here, in few words, have to do with the *approximate* diameter of the dropping tip, and the drop weight and density, *i. e.*, with the volume of the drop on the tip. Whenever the above law holds, it is observed that the relation of drop volume to tip diameter is such that the drop forms with a "normal," bag-like profile, with sides which are parallel for at least a portion of their length. When the drop volume on the tip is so small that the drop runs rapidly to a point, and its sides are nowhere parallel, the law fails to hold; and the same is true when the drop volume for the tip is so large that the drop, at its lower extremity, bulges beyond an imaginary continuation of the walls of the tip.

At first glance it might seem, perhaps, that this imposed condition of "normal" drop profile would limit very materially the number of liquids which could be studied on any one tip; but actual experiment has shown that with *any* tip lying between certain approximate limits of diameter, the liquids excluded, by reason of abnormal drop volume, would be insignificant in number; and would only be those which possess drop volumes that are excessively small, *i. e.*, which have average or small surface tensions, accompanied by very high densities.

The purely experimental and comparative study, with various liquids, of a number of tips (17) lying in diameter between 3 and 8 mm. has shown that for *general purposes*, only those between 4.5 and 5.5 mm. leads to satisfactory results. With *any* tip lying between these limits of diameter (4.5 and 5.5 mm.), however, it is found that the law holds rigidly, so long as the drop volume on the 4.5 tip is at least equal to 0.0196 cc., and on the 5.5

to at least 0.0239 cc., any intermediate diameter giving a volume which is in simple proportion to the diameter of the tip. These limits include ether, with its very small surface tension of 15.3 dynes, and drop volumes of, respectively, 0.0196 and 0.0239 cc., as well as water (and probably also considerably higher values), with its almost maximum surface tension, 76 dynes, and very large drop volumes of 0.083 and 0.1 cc.

The study of carbon tetrachloride in this connection, with its average surface tension value of 24.9 dynes, but excessive density, 1.576, giving on the 4.5 tip a volume of but 0.0143 cc. shows that the minimum volume on that tip can be reduced to this value, *i. e.*, considerably below that for ether given above. This volume, 0.0143 cc., is apparently the lowest limit for the 4.5 tip, however, for with a larger tip, carbon tetrachloride, which is very satisfactory in behavior on the 4.5 tip, cannot be considered to lead to very satisfactory results. In the same way we find that 0.0239 cc. is the absolute minimum for satisfactory work on the 5.5 tip, for with ether any increase in diameter above that shows a failure of the law to hold rigidly. When all the possible abnormal liquids of the type of carbon tetrachloride are considered, *i. e.*, liquids of average or small surface tension, accompanied by excessively high densities, we see that the number of liquids excluded from the rigid holding of the law, for any tip lying between 4.5 and 5.5 mm. is indeed a *minimum*, which certainly would not amount to more than a very small fraction of 1% of all liquids. Any such liquid on these tips, giving a volume smaller than those indicated, however, must be excluded from use on these tips; although, naturally, a smaller tip, standardized by aid of a similar liquid, would lead to satisfactory results by the method.

Although actual, average tip diameters, have been given above, it will be noted that they are *not necessary for, or even used in, the calibration of the tip*, that being accomplished simply from the relationship of a γ value, as interpolated from observed results, and a w value, found experimentally, both being at some one, like, temperature.¹ To find the approximate diameter of a tip, to ascertain whether or not it lies between the given limits (which were accurately determined by aid of a dividing engine), a micrometer may be held above the tip, and results, usually too high by about 0.1 mm., obtained, or it may be found in millimeters, with an accuracy of about 0.1% by aid of the drop weight diameter of tip re-

lation² for benzene at 27.8°, *viz.*, diameter = $\frac{wC_6H_6}{5.37}$.

¹ It is possible that a misunderstanding on this point was the cause of the unjustified criticism of the method by Lohnstein (*Z. physik. Chem.*, 84, 410-18 (1913)), and of his "discovery" of a 4% discrepancy in its results. For a reply in detail to that criticism, see Morgan (*Z. physik. Chem.*, 89, 385 (1915)) in a paper referred to above which was accepted for publication early in 1914, and which although delayed by the war, should certainly appear as of an early date in 1915.

² See Morgan and Cann, *THIS JOURNAL*, 33, 1065 (1911).

In connection with the tip diameter, it will be realized that there must be some one diameter which would give a value of the "Constant" in (1) and (2) equal to unity; in which case the measured drop weight in *milligrams* would also be the surface tension of that liquid, at that temperature, in *dynes*. This diameter can be calculated by first finding $\gamma_{C_6H_6}$ at 27.8° from the $\gamma_{C_6H_6,t}$ relationship, and then substituting that for $w_{C_6H_6}$ in the equation for the "diameter," and solving for that. The value thus found is 5.01 mm. Such a tip would save considerable time in the calculations, but such difficulty would probably be encountered in obtaining it of *just* that diameter, that it is better to do as has been done in the past, and employ a tip possessing a "Constant" which is either somewhat larger or smaller than unity, the actual diameter of which is known only approximately.¹

The above is a brief sketch of the method for the determination of surface tension from the drop weight which has been developed as the result of the series of investigations mentioned above. *For SEVENTY of the ONE HUNDRED specially purified liquids, for which the surface tension was known, liquids of every type and giving all possible values of drop volume within the given limits, the above equations, (1) and (2), have been found to hold rigidly, between the tip diameters of 4.5 to 5.5 mm., the calculated surface tensions agreeing with some value as found at the same temperature by the capillary rise method, within a few tenths of 1% at worst. And the same can be said of all the TEN solutions, for which surface tension results were at hand.*

In the case of the other thirty liquids for which the surface tensions were known, however, the agreement was not so good; in some few cases being worse than that usually found among the results of different workers on the same liquid by the same (capillary rise) method. These liquids in many cases were those which are difficult to obtain, or then to retain, in the pure state; in which case in *this* work, the liquid was redistilled or purified in some other way immediately before each drop weight measurement was made; *second*, some of these liquids had been studied by only one observer of capillary rise, and in a number of cases the results of this observer for other liquids were consistently either higher or lower

¹ The values for the "Constant" of the 4.5 tip is found to be 1.109, and that for the 5.5 to be 0.910; and the mean of these would also give constant = 1 for a tip of 5 millimeters.

The values of the "Constant," naturally, can also be employed to calculate the average diameter of the tip with an accuracy of about 0.1%, the value of the "Constant" being inversely proportional to the diameter of the tip. In this way we would have:

$$4.5 : \text{diameter} :: \text{"Constant"} : 1.109$$

or

$$5.5 : \text{diameter} :: \text{"Constant"} : 0.910$$

This is indeed the simplest and best method.

than those of other observers by the same method; *third*, none of these liquids showed any variation from the "normal" drop profile, and further, none possessed any property that was not possessed to the same or a greater extent by other liquids which gave satisfactory agreements.

For the above reasons it is considered that the comparison in the case of these thirty liquids *cannot as yet be considered as final*, for until surface tensions, which are known to be *accurate*, are at hand, it must be assumed that it is the fault of the values of this property, that the method which gives such precise results for the *seventy* liquids should suddenly and inexplicably give less precise values for the thirty liquids, which differ from them in no single property that could affect the relationship.

Ferguson,¹ after recognizing the precision of this method, and rightly criticizing the various attempted *theoretical* derivations of a drop-weight—surface tension law (which in all cases have been found to be in disagreement with the experimental results published from this laboratory)² brings up the question as to whether or not the drop weight method is affected by the so-called angle of contact, thought to affect the capillary rise method, but not others. The only answer that can be made to this question, as he recognizes, is that based upon experiment. Unfortunately, however, there are not enough data at hand from any method for surface tension other than that of capillary rise, which are sufficiently concordant to standardize and then test with precision any empirical relationship between these surface tensions and the drop weights at the same temperature. Until such data are at hand, and until the effect of the angle of contact is studied sufficiently to show that it *does* have any effect upon capillary rise, upon which at present there is no general agreement, we can only assume, from the seventy cases above, that the angle of contact either exerts a very small influence on the capillary rise results, and the drop weight method is not affected by it; or, that both methods are affected by it in the same way. There is no reason for assuming, as far as can be seen, that the seventy liquids are just those for which the angle of contact is nearly zero, while it has a larger value for the thirty; and that consequently the drop weight not being affected by it, *should* only agree in those cases where the angle is zero.

Until more definite information as to the angle of contact is at hand, the experimental results from this laboratory can only be taken as showing that the drop weight and surface tension, *as found by the capillary rise method*, are proportional.

A METHOD OF REDUCING SOME METALS IN CRYSTALLIZED FORM ON GLASS SLIPS AS PERMANENT MICROSCOPE MOUNTS.

By JAS. H. BOWMAN.

Received April 10, 1915.

The process applies to such metals as are reducible from solution by some other metal.

For some years I had intermittingly attempted the deposition of gold and silver in the crystallized forms known as fern and moss figures on glass slips for use as microscopic objects and had been partially successful. Finally I happened upon a method that gave quite satisfactory results in respect to both the perfection of the figures and the permanency of the mounts.

The metal with which I first obtained success was silver and the method used will indicate a general process which may be applied with variations in manipulation to gold, antimony, copper, bismuth, cadmium, tin, lead, etc., each metal requiring some modification of the treatment peculiar to itself.

Silver Crystals.—A solution is prepared by dissolving silver nitrate in distilled water—1 to 10—and adding an equal quantity of a concentrated solution of zinc nitrate. A small drop of the mixed solution is placed on a chemically clean glass slip and spread by drawing the end of another slip backwards and forwards over it until a thin film covers the desired portion of the slip. Then on filing a piece of metallic zinc in such manner that the filings fall thinly and somewhat evenly over the moist surface, reduction of the silver begins at once, each particle of the zinc becoming a center of crystallization as shown in Plate 1, Fig. 1. The zinc nitrate was introduced to prevent the drying of the solution by evaporation before the reduction of the silver becomes complete. The slip is placed, moist side upward, on a piece of damp filter paper and covered with a bell jar. Under the jar the moist atmosphere retards drying until crystallization is completed, which usually takes from 15 to 20 minutes. The slip is removed and allowed to dry in the air, not completely, however, as incrustations will form on the crystals—but until nearly dry. At this stage a few drops of a thin solution of Canada balsam in xylol, introduced at the side, is run over the preparation, the slide being slanted to allow the balsam to reach every part of the surface. It is then set aside to dry in a dust proof atmosphere.

In an hour or two it may be covered in the usual way practised with balsam mounts. The thin solution of balsam holds the delicate crystals of silver against disruption by the final covering and mounting process.

From the zinc centers radiating, fern-like, crystals spring. If the solution be too deep on the slip the reduced silver will remain an amor-

phous mass but with a filmy solution the fern-like crystals will be very beautiful, and have a bright metallic luster. If the zinc particles are too sparsely spread, silver nitrate will remain in solution and will, by reduction, blacken the balsam. This does not in any way impair the beauty of the slide as the black gives a good background for the crystalline centers of metals.

Gold Crystals.—Both fern-like and filamentous crystals of this metal are obtained by reducing gold chloride by zinc. A saturated solution of gold chloride is made and slightly acidulated with hydrochloric acid mixed with an equal quantity of concentrated solution of zinc chloride. A very small drop is placed on a cleaned slip and then treated in the manner described for silver. The areas of crystal growth should be close together, otherwise in the spaces amorphous gold will be reduced by the balsam and will give the mount a blemished appearance. The crystals form in about the same time as in the case of silver. If wire gold crystals are desired a very thin film of solution only must be used; by deepening the film, fern-like forms are obtained.

Copper Crystals.—The solution should be composed of a cold saturated solution of copper sulfate mixed with an equal part of concentrated solution of zinc chloride and acidulated slightly with hydrochloric acid. Treat as for silver above. In drying, there is a strong tendency to the formation of a green incrustation which ruins the mount, hence it is advisable to add the thin balsam solution while the mount is still quite moist. If time be not allowed for complete reaction, bubbles of hydrogen are formed and interfere with the perfection of the mount.

Lead Crystals.—A concentrated cold solution of lead acetate is mixed with an equal quantity of a 25% solution of glycerin in water. The subsequent procedure is similar to that for the other metals. There are two reasons for using glycerin. It prevents too rapid drying and the incrustation of the crystals and further it promotes the solubility of the difficultly soluble lead compound which is precipitated during the process. I do not know of any other agent than glycerin that will prevent the incrustation referred to. It should be noted that unless the crystal centers are close together resolution of the crystals is liable to take place.

Bismuth Crystals.—A concentrated solution of bismuth chloride is mixed with 25% of glycerin, treated as in the other cases. There is a tendency in this case for the reduced metal to be black and amorphous. It is a question of proper acidity which must be determined by trial.

Tin Crystals.—A concentrated solution of tin chloride mixed with an equal quantity of solution of zinc chloride, treated as in the case of silver.

Cadmium Crystals.—Proceed as in the case of tin.

The crystal clusters formed by this method have the reducing particle of zinc left in the center. This objection cannot be very well avoided.

Silver.

Gold.

Copper.

Lead.

Bismuth.

Tin.

During the process some of the zinc seems to be carried into the crystals, suggesting that the purity of the metal of the crystals increases as it gets further from the center. This is very noticeable in the examples of both gold and copper.

The crystals from these metals differ much in their branching and curving tendencies. In tin, the crystals are straight and the side growths are at right angles. Lead crystals show less tendency to side branching and curve but little. In gold, as well as in some of the other metals, the branching is quite arborescent. Are the crystals of tin an illustration of compounding by relay?

The crystals formed by this method are well represented in the accompanying plates—they are of some scientific interest and form brilliant microscopic objects when viewed by reflected light.

I owe the microphotographs to the kindness of Mr. J. T. Burt-Gerrans, of the University of Toronto. Each small division of the scale corresponds to 0.015 mm. on the slide.

A NEW TEST FOR COPPER.¹

By W. G. LYLE, L. J. CURTMAN AND J. T. W. MARSHALL.

Received March 18, 1915.

Introduction.

The test to be described in this paper is based on the insolubility of the copper salt of α -amino-*n*-caproic acid ($\text{CH}_3(\text{CH}_2)_5\text{CHNH}_2\text{COOH}$). Kudielka,² in 1908, prepared this acid and its copper, nickel and cobalt salts and determined their solubilities in water. In the course of their work on the quantitative determination of amino acids, Kober and Sugiura³ state that the insoluble complex which *n*-aminocaproic acid forms with copper may be useful in analytical work.

Some preliminary work on the part of the authors indicated that an aqueous solution of *n*-aminocaproic acid was an exceedingly valuable reagent for the detection of small amounts of copper. It was the object of this investigation to ascertain the most favorable conditions for the use of this reagent and to determine its applicability to solutions of salts of foreign metals containing small amounts of copper.

The reagent was prepared from commercial *n*-caproic acid by the method proposed by Abderhalden, Fuchs and Froehlich⁴ and further purified

⁴ *Z. physik. Chem.*, 86, 455 (1913).

through its copper salt. The solution used throughout our work was prepared by dissolving 0.67 g. of the acid in 100 cc. of water; the mixture was heated to facilitate solution and then filtered.

It was found that the precipitation of copper by aminocaproic acid was influenced considerably by the presence of free mineral acid. Since mineral acid is liberated as a by-product of the reaction, it was decided to employ a buffer in making the test. For this purpose a 40% solution of sodium acetate was found satisfactory.

The pure copper salt of *n*-aminocaproic acid was prepared. Evaporation of 1000 cc. portions of an aqueous solution of this compound gave residues from which the solubility of the salt at 18° was calculated to be of the order of 1 in 100,000.¹

Determination of the Sensitiveness of the Test.—By means of a graduated pipet definite amounts of a standard copper nitrate solution were introduced into a series of test tubes. 1 cc. of 40% sodium acetate and 1 cc. of aminocaproic acid solution were then added, the contents of the tubes shaken and allowed to stand. The results obtained are shown in Table I.

TABLE I.

Total Vol., 3 cc.; 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$; 1 cc. of Reagent.

No.	Mg. Cu.	Result.
1.....	1.000	Immediate grayish blue precipitate.
2.....	0.500	Immediate grayish blue precipitate.
3.....	0.010	Slight white precipitate.
4.....	0.005	Faint precipitate at end of 5 minutes.
5.....	0.004	Fair test in 5 min.; much better in 12 minutes.
6.....	0.003	Faint test in 5 min.; (limit) much better in 12 min.
7.....	0.002	Negative test in 5 min.; faintly positive in 12 min.
8.....	0.001	Negative test in 12 min.
9.....	0.000	Negative test in 12 min.

Comments.—The above experiments were repeated a number of times with the same results. The limit of the test in 5 minutes (0.003 mg. Cu in 1 cc. of the original solution) represents a concentration of 1 part in 333,000. While it requires some practice to recognize the test given by 0.003 mg. of copper, decided and unmistakable results are obtained with 0.004 mg. The precipitate has a tendency to agglutinate, to rise to the surface of the liquid and to creep up the walls of the tube when the latter is gently shaken. This characteristic property of crawling up the sides of the containing vessel makes possible the recognition of smaller amounts of precipitate than would be the case if the precipitate remained in suspension or settled to the bottom of the container. The "crawl" is best seen by gently shaking the tube and viewing it in good light against a

¹ Kudielka (*Loc. cit.*) found the solubility of the copper salt to be 3.6 parts in 100,000 at 23°.

dark background. In some of the preliminary tests with 0.004 mg. Cu, negative results were obtained. An examination into the causes showed that the greasy condition of the tubes prevented the precipitate from crawling. It is therefore imperative in making the test to have the tubes scrupulously clean. This was accomplished by first scrubbing with soap solution, rinsing, then treating with hot chromic acid mixture and finally rinsing a number of times with distilled water. The solutions to be tested for copper were always carefully examined for any particles in suspension that might be mistaken for a positive test and if not absolutely clear, the solution was filtered before adding the reagent.

A comparison of the sensitivity towards copper of *n*-aminocaproic acid and synthetic leucine was then made. A solution of Kahlbaum's synthetic leucine of the same strength as our reagent (0.67%), failed to give a precipitate with amounts of copper smaller than 0.03 mg. Thus the normal acid will detect about one-tenth the quantity of copper that can be recognized with the iso-derivative. The presence of moderate amounts of the iso-derivative was found to materially diminish the sensitivity of the reagent.

Behavior of the Reagent with Other Metals.—Having determined the limit of the test in solutions containing copper alone, our next step was to ascertain whether there were any other metals which would give the test. To this end, 1 cc. of a solution containing 100 mg. of the metal as nitrate or chloride was treated with 1 cc. of 40% sodium acetate solution and 1 cc. of aminocaproic acid. *Of all the common metals, zinc and mercury alone gave precipitates.* The test given by zinc under these conditions was very faint, but by diminishing the quantity of zinc to a few milligrams, surprisingly strong reactions were obtained.

This anomalous behavior of zinc salts necessitated a repetition of the above experiments with small quantities (1–10 mg.) of each of the metals. The results showed that mercury and zinc alone gave precipitates and therefore interfere with the test for copper. Methods for overcoming these interferences were devised and will be given later when these metals are considered.

Whether or not the presence of large amounts of foreign metals would interfere with the detection of relatively minute quantities of copper was the next point investigated. The general procedure was as follows:

To 1 cc. of the solution containing 100 mg.¹ of the foreign metal, 0.1 cc. of copper nitrate solution containing 0.01 mg. of Cu was added. To this mixture, 1 cc. of 40% sodium acetate and 1 cc. of aminocaproic acid were added. A control was run at the same time and in every case the results were checked by repeating the experiment. Following this pro-

¹ Because of the relatively small solubility of AlCl_3 , 2 cc. of solution were required to supply 100 mg. of Al.

cedure, good tests were obtained in the presence of Pb, Cd, Ni, Co, Mn, Ba, Sr, Ca and Mg, respectively. With lead solutions, a finely divided precipitate appeared in the controls at the end of 10 minutes, though they were perfectly clear at the end of 5 minutes. For this reason it was decided to remove the greater part of the lead with 1 cc. of 20% NaCl solution. After washing the precipitated lead chloride with 1 cc. of cold water, good tests and perfect controls were obtained.

Interferences.—It was thought that substances which form only slightly ionizable complexes with copper would interfere with its precipitation by aminocaproic acid. Experiments showed that an excess of KCN inhibits the test. In Table II the influence of ammonium salts is shown.

TABLE II.

Total Volume, 3 cc.; 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$; 1 cc. of the Reagent.

No.	Mg. Cu.		Result.
1-2.....	0.004	0.6 cc. 50% NH_4NO_3	Negative in 10 hours.
3-4.....	0.004	0.6 cc. 30% NH_4Cl	Negative in 10 hours.
5-6.....	0.004		Good test in 5 minutes.

Smaller amounts of ammonium salts were found to retard the formation of a precipitate. Substances containing amino groups were also found to interfere. Thus negative tests for 0.01 mg. Cu were obtained in the presence of 10 mg. of each of the following substances: Glycocoll, synthetic leucine, glycyl glycine, "Seiden peptone" and casein.

Sodium citrate was also found to interfere; but contrary to expectations good tests were obtained with 0.004 mg. Cu in the presence of relatively large amounts of tartrates.

The interference due to ammonium salts and organic matter may readily be removed by ignition.

Special Procedures.

Silver.—The addition of 1 cc. 40% sodium acetate solution to 1 cc. of a 10% Ag solution causes the precipitation of silver acetate. In the absence of sodium acetate, a test was not obtained with 0.01 mg. Cu in the presence of 1 cc. of 10% silver solution. It was therefore necessary to remove the silver before the test could be applied. This was accomplished by means of sodium chloride. The results of the experiments appear in Table III.

TABLE III.

Total Volume before Precipitating with 1 cc. 20% NaCl, 1.1 cc. To Filtrate Added
1 cc. 40% $\text{NaC}_2\text{H}_3\text{O}_2$, 1 cc. Reagent.

No.	Mg. Ag.	Cu.	Result.
1-2.....	100	0.00	Negative
3-4.....	100	0.01	Good

Bismuth.—A solution of $\text{Bi}(\text{NO}_3)_3$ in 10% conc. HNO_3 containing 100 mg. of the metal per cc. was used. One cubic centimeter of this

solution was found to be too acid to yield a precipitate in the presence of copper. The procedure which gave satisfactory results was as follows:

To 1 cc. of the bismuth solution 0.01 mg. of copper was added. The solution was then diluted to 20 cc. This caused a separation of basic salt. After standing for several minutes, 2 cc. NH_4OH (1-1) were added drop by drop and the mixture was filtered. The filtrate and washings were evaporated to a few drops,¹ taken up with water, filtered again through a very small filter and then treated with 1 cc. of sodium acetate and 1 cc. of the reagent. Good results were obtained in 5 minutes.

Antimony.—A 10% solution of antimony as chloride was used. The method employed was similar to that described above for bismuth. Good tests and controls were obtained.

Tin.—A solution of SnCl_4 containing 100 mg. Sn in 1 cc. was employed in all our tests with this metal. 1 cc. of this solution yields a precipitate when treated with 1 cc. of 40% sodium acetate. By precipitating the tin with NH_4OH or 40% $\text{NaC}_2\text{H}_3\text{O}_2$, nearly all the copper originally added either combined with, or was adsorbed by, the precipitate. This was shown by the blue color of the precipitate. We were unable, moreover, after repeatedly washing the precipitate with either water, or dilute NH_4OH , to get a test for copper in the combined filtrate and washings after concentration to 0.5 cc. when less than 0.1 mg. of Cu was originally present. By removing the ammonium salts from the filtrate, the test was rendered more delicate, but 0.02 mg. of copper always escaped detection. As nickel does not interfere with the test, it was thought that by adding a small amount of this metal (2-10 mg.) to the solution of copper and tin, it would be possible by means of an excess of potassium hydroxide to precipitate the copper with the nickel and thus keep all the tin in solution. This procedure, however, failed to detect 0.05 mg. of copper for the reason that the precipitated nickel adsorbed some tin which could not be washed out and which interfered with the final test. Based on the volatility of stannic chloride in hydrochloric acid solution, a method was found which yielded uniformly satisfactory results. The solution containing the tin and copper was treated with HCl and evaporated *just to dryness*; more HCl was then added and the solution again evaporated. After the third evaporation, 1 cc. of water was added and the solution treated with 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$ and 1 cc. of the reagent. The results are shown in Table IV.

TABLE IV.

No.	Mg. Sn.	Mg. Cu.	Result.
1.....	100	0.100	Strong test.
2.....	100	0.010	Strong test.
3.....	100	0.006	Good.
4-5.....	100	0.000	Negative.

¹ By removing the ammonium salts at this point, better results may be obtained.

Zinc.—Table V gives the results obtained with solutions of zinc of strength 100 mg. in 1 cc.

TABLE V.

Volume before the Addition of Reagent, 1.1 cc.; 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$; 1 cc. of Reagent.

No.	Mg. Zn.	Mg. Cu.	Results.
1-2.....	100 as $\text{Zn}(\text{NO}_3)_2$	0.01	Precipitate.
3.....	100 as $\text{Zn}(\text{NO}_3)_2$	0.00	Precipitate.
4.....	100 as ZnSO_4	0.00	Precipitate.
5-6.....	200 as ZnSO_4	0.10	Immediate precipitate.
7-8.....	200 as ZnSO_4	0.00	Negative in 1 hour.

These results find their explanation in the acidity contributed by the zinc salt. 200 mg. of Zn gave a higher hydrogen ion concentration to the solution than that given by 100 mg. and as a consequence no precipitate was obtained in Experiments 7 and 8. If this explanation be correct, 1 mg. of Zn should give a better test than 100 mg. Experiments showed not only that this was the case, but also that *n*-aminocaproic acid is a fairly sensitive reagent for the detection of small amounts of zinc as shown in Table VI.

TABLE VI.

Solution ZnSO_4 . 1 cc.; 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$; 1 cc. of Reagent.

No.	Mg. Zn.	Result.		
		1 min.	2 min.	5 min.
1.....	0.05	Good.	Strong.	Strong.
2.....	0.03	Negative.	Good.	Very good.
3.....	0.02	Negative.	Negative.	Very faint (limit).
4-5.....	0.01	Negative.	Negative.	Negative.

The results in Table VI show that under the conditions employed in testing for copper, the reagent is capable of detecting 0.02 mg. of zinc. Since the reagent is sensitive to small quantities of zinc, there was need for a means of differentiating between zinc and copper if the test were to be applied to unknown solutions. After some experimentation, it was found that zinc does not precipitate when the hydrogen ion concentration (*p*-nitrophenol as indicator) exceeds $10^{-5.5}$. If to an acid solution of zinc containing aminocaproic acid and a drop of *p*-nitrophenol solution (0.04%), sodium acetate be added, a yellow color will develop which deepens on further addition of acetate. When the color is only a faint yellow, ($\text{C}_\text{H}^+ = 10^{-5.2}$) no zinc will come down. Not until sufficient sodium acetate has been added to give a strong yellow color ($\text{C}_\text{H}^+ = 10^{-5.8}$) will the zinc precipitate in 5 minutes. The results in Table VII show the reliability of the method.

TABLE VII.

Volume, 2 cc.; One Drop *p*-Nitrophenol; Adjusted to Light Yellow Color with Sodium Acetate and 0.1 *N* HCl; 1 cc. Reagent.

No.	Mg. Zn.	Mg. Cu.	Result.
1-5.....	1.0	0.000	Negative in 5 minutes.
6-10.....	1.0	0.004	Positive in 5 minutes.

Mercury.—The following solutions were used in the experiments with mercury, *viz.*: Solution A, Hg 10% (as nitrate) in 2% conc. HNO_3 ; Solution B, Hg 10% (as chloride) in 5% NaCl solution;¹ Solution C, Hg 1% (as chloride) in H_2O .

1 cc. each of solutions A, B and C was treated with 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$ and 1 cc. of the reagent. A fair test was obtained with solution A, B was negative, while solution C gave a strong test.

These results indicated that the presence of NaCl prevented the precipitation of the mercury. To further test this conclusion the following experiments were made:

TABLE VIII.

Volume after the Addition of 1 cc. of 40% $\text{NaC}_2\text{H}_3\text{O}_2$, 3 cc.; 1 cc. of the Reagent.

10-11.....	1	0.00	0.5-0.1	Negative.	

TABLE IX.

Experiments with HgCl_2 solutions. 1 cc. 40% $\text{NaC}_2\text{H}_3\text{O}_2$; 1 cc. Reagent.³

No.	Mg. Hg. (Sol. B).	Mg. Cu.	20% NaCl cc.	Result.
1-2.....	100	0.00	0.0	—
3-4.....	100	0.01	0.0	+
5 ⁴	1	0.00	0.0	Immediate heavy ppt.
6 ⁵	1	0.00	0.5	Negative in 10 min.
7 ⁵	1	0.00	0.1	Negative in 10 min.

The results of the table show that the addition of NaCl will prevent the formation of basic salt or aminocaproate in solutions of mercury. Before concluding our work with this metal we determined that small amounts may also be prevented from precipitating by regulating the acidity as in the case of zinc.

Iron and Aluminum.—In the presence of 100 mg. of either of these metals in the form of chlorides, we were unable to get positive tests with

¹ The NaCl was added to increase the solubility of HgCl_2 .

² The addition of NaCl to the Hg solution causes the formation of an exceedingly faint cloud, due probably to HgCl_2 in suspension. The solution clears up somewhat on the addition of the aminocaproic acid. However, in no case was this cloud found to interfere with the test. In the many experiments made, the controls never showed the characteristic "crawl;" while in the presence of copper decided tests were obtained.

³ In tests 1-4 the volume of the solution before the addition of the reagent was 2 cc.

⁴ In tests 5-7 the volume of the solution before the addition of the salt was 1 cc.

⁵ At the end of 10 minutes, 9 mg. of Hg were added slowly from a pipet to these tubes. No precipitate formed in 10 minutes.

0.05 mg. of copper or less. This is due to the fact that before the acidity can be depressed sufficiently to permit the precipitation of small amount of copper (C_H^+ about 10^{-4}) these metals (also Cr) separate in the form of hydroxides and mask the reaction. After much experimenting the following procedure was found efficient: 100 mg. of Fe or Al in the form of their chlorides were mixed with 0.05 mg. Cu as nitrate. The mixture, the volume of which was about 2 cc., was slowly poured with constant stirring into 3 cc. NH_4OH (1-1); the solution was filtered through a fluted filter and the precipitate washed with 2 cc. of water. The combined filtrate and washings were evaporated to dryness and the ammonium salts removed by heating with KOH. The solution was then made acid with HCl, evaporated to one drop, taken up with 1 cc. of water, and tested in the usual manner. By this procedure good tests were consistently obtained in 3 minutes.

Chromium.—A 10% solution of Cr as $Cr(NO_3)_3$ was used in this work. 1 cc. of this solution to which 0.05 mg. of copper were added failed to give the test. Precipitation with NH_4OH , as in the procedure for Fe and Al, did not serve in this case, owing to the appreciable solubility of $Cr(OH)_3$ in ammonia. The filtrate always contained sufficient chromium to confuse the test.

To determine whether the oxidation of the chromium to chromic acid would eliminate the interference of this metal, tests were made for copper in the presence of K_2CrO_4 . The results showed that 100 mg. of Cr as chromate did not prevent the precipitation of 0.01 mg. of Cu. Subsequent experiments, however, starting with the metal as nitrate and oxidizing to chromate with sodium peroxide did not give consistent results.

After oxidation it was necessary to make the mixture acid in order to keep the copper in solution. In this connection a difficulty was encountered in attempts to adjust the acidity; for the test, even when 1 cc. of 40% sodium acetate is used, cannot be applied if the initial acidity is too great. Again, the strong color of the chromate solution does not permit the use of the indicator, without which it would be impossible in an unknown solution to determine whether the test were due to the presence of copper or zinc. It was, therefore, necessary to remove the CrO_4 . The chromate was dissolved in about 10 cc. of water, 1 cc. of NH_4OH (1-1) added, the mixture heated to boiling and an excess of $BaCl_2$ added. This procedure appeared sound, first because the presence of barium would not interfere with the test, and second, because $BaCrO_4$, being crystalline, would not adsorb appreciable quantities of copper. The filtrate from the $BaCrO_4$ was evaporated just to dryness, taken up with 1 cc. of water and refiltered through a very small filter into a test tube. 1 drop of *p*-nitrophenol was then added, the acidity adjusted to a faint yellow and 1 cc. of the reagent added. The following results were obtained:

No.	Mg. Cr as K ₂ CrO ₄ .	Mg. Cu.	Mg. Zn.	Results.
1.....	100	0.05	0.0	Good test in 1 min.
2.....	100	0.00	0.1	Negative test in 5 min.

At the expiration of 5 minutes the contents of Tube 2 were divided into two portions. 0.02 mg. of Cu added to one portion gave a good test, showing that the conditions were favorable for the precipitation of copper. To the other portion 0.1 *N* NaOH was added till a strong yellow color developed. A copious precipitate was then obtained, showing the presence of zinc.

Nickel and Cobalt.—The reagent is capable of detecting 0.01 mg. of copper in the presence of 100 mg. of either of these metals.¹ Although the aminocaproates of nickel and cobalt are fairly insoluble,² these salts are not formed under ordinary conditions when $C_{H^+} > 10^{-7}$. Thus they are much more sensitive to acid than the corresponding zinc salt and, consequently, conditions permitting the differentiation between copper and zinc will completely prevent the precipitation of nickel and cobalt. Although the results showed that under our conditions (1 cc. 40% sodium acetate³ as buffer) nickel and cobalt remained in solution, a small decrease in the hydrogen ion concentration, such as might be caused by a trace of alkali in the sodium acetate or by heating the mixture, would bring about a slight precipitation of these metals. Consequently, in an unknown solution, when 1 cc. of 40% sodium acetate is used as a buffer, a positive test cannot be regarded as conclusive for copper, because of the possible presence not only of zinc but also of nickel and cobalt. The strong color of solutions of nickel and cobalt precludes the use of *p*-nitrophenol as an indicator for adjusting the acidity. We know of no feasible method whereby a separation of 0.01 mg. of copper from 100 mg. of nickel or cobalt can be effected. We therefore recommend in such cases the following procedure. To the neutral or faintly acid solution add 1 cc. of 40% sodium acetate and 1 cc. of aminocaproic acid. Allow the mixture to stand for about one-half hour.⁴ The precipitate, which may consist of aminocaproates of Cu, Zn, and traces of Ni and Co, is collected on a small filter, thoroughly washed, and then dissolved in hot dilute HCl. The filter is well washed, the combined solution and washings concentrated, *p*-nitrophenol added, the acidity adjusted to a pale yellow, and finally 1 cc. of aminocaproic acid added. A precipitate proves the presence of copper. Following this procedure, good tests were obtained

¹ With some preparations of the nitrates of nickel and cobalt, only very faint tests were obtained in 5 minutes; on standing for 10 or 15 minutes, however, the tests improved decidedly.

² According to Kudielka (*Ibid.*), the solubility of the nickel salt is about 29 parts in 100,000; that of the cobalt salt is 21 parts in 100,000.

³ Kahlbaum's zur Analyse.

⁴ This is to insure complete precipitation; frequent agitation is advantageous.

from solutions containing 0.02 mg. of copper and 50 mg. of nickel or cobalt in a volume of 1 cc. In the absence of copper, this method gave good controls.

Procedure for Unknowns Containing all Metals.—We do not know of a systematic procedure whereby any of the sensitive reagents hitherto employed for the detection of minute amounts of copper can be applied to solutions containing all the common metals. The great difficulty encountered in such cases is to be found in the tendency of precipitates, particularly those of a gelatinous character, to adsorb appreciable quantities of copper. Based on our experience with the test when applied to the metals individually, we would suggest the following procedure, observing the precautions necessary in quantitative work. After the removal of the silver group by means of HCl, the filtrate and washings are treated with an excess of KOH, heated and filtered. The precipitate is then dissolved in HCl and evaporated to a few drops. More HCl is added and the solution again evaporated to a few drops. The diluted solution is then poured into an excess of NH_4OH and filtered. The filtrate is evaporated to dryness and boiled with KOH to remove ammonium salts. The solution is then acidified with HCl and heated to dissolve the CuO .¹ 1 drop of *p*-nitrophenol is added, the acidity adjusted and test applied.

Remarks Concerning the Comparative Merits of the Reagents for Copper.—*N*-Aminocaproic acid possesses an important advantage over all the other reagents used for the detection of small amounts of copper in that, when the simple precautions to avoid the interference of zinc or mercury are taken, the test is highly characteristic and specific for copper.

It appears to be more delicate than the ammonia test according to the figures given by Pritz, Guilanden and Withrow,² and it possesses the further advantage that the interference of nickel may be readily overcome. Experiments with 0.004 mg. of copper gave decided tests with *n*-aminocaproic acid, but with ferrocyanide the tests were not evident except when compared with the blank; moreover, with ferrocyanide, the color, even with considerable amounts of copper, could not be distinguished from that of the control when examined at night. Again with the ferrocyanide test there are many more metals which interfere than is the case with aminocaproic acid. Solutions containing amounts of Fe, Ni, Co, Pb, Cd, Mn small enough to permit the use of an indicator may be tested directly with aminocaproic acid. Thus the almost universal presence of traces of iron, which would prevent the direct use of the ferrocyanide test, will

¹ If the solution is colored, and the indicator cannot be satisfactorily employed, recourse must be had to the procedure recommended for Ni and Co.

² THIS JOURNAL, 35, 168 (1913).

not interfere in the least with the aminocaproic acid test. Ammonium sulfide has¹ also been recently shown to be an exceedingly sensitive reagent for copper, but the large number of metals which interfere materially limits its usefulness. At the present time the cost of *n*-aminocaproic acid greatly exceeds that of the other reagents, but it is believed that its great usefulness will serve to cheapen it considerably. It is moreover a simple matter to recover the acid from waste solutions; so that the same supply can be used repeatedly.

Experiments are now in progress in this laboratory to determine the behavior of the rarer elements with *n*-aminocaproic acid and also the conditions under which the reagent may be applied as a specific test for zinc. The use of this reagent for the purposes of quantitative analysis is also under consideration.

Summary.

1. It has been shown that an aqueous solution of normal aminocaproic acid is an exceedingly sensitive reagent for the detection of copper. With this reagent 0.004 mg. of copper may be detected with certainty.

2. Mercury and zinc are the only other common metals which yield, under the conditions specified, a precipitate with the reagent. The interference of the former may be overcome by the addition of sodium chloride, the latter may be prevented from precipitating by adjusting the acidity of the solution.

3. Procedures have been given for the detection of small amounts of copper in the presence of relatively large quantities of foreign metals.

4. The reagent is more specific for copper than any of the other reagents heretofore proposed; and possesses an advantage over the ferrocyanide test in that small quantities of iron do not interfere with its use.

PERMANGANATE DETERMINATION OF IRON IN THE PRESENCE OF FLUORIDES—THE ANALYSIS OF SILICATES AND CARBONATES FOR THEIR FERROUS IRON CONTENT.²

By O. L. BARNESBY.

Received February 15, 1915.

The permanganate titration of ferrous iron in the presence of chlorides has attracted attention for a considerable period of time because of the economic importance of the determination of iron, the ease with which iron ores dissolve in hydrochloric acid and the rapidity of conducting the permanganate titration. While the titration of iron with permanganate in hydrochloric acid solution has been studied by many inves-

¹ THIS JOURNAL, 35, 168 (1913).

² Read at the New Orleans Meeting of the American Chemical Society.

tigators,¹ the titration of iron in hydrofluoric acid solution has not received the attention which it merits, especially considering that this titration has been the source of much solicitude to the geologist, petrographer and chemist for many years. Hydrofluoric acid is the most efficient reagent known at present for the decomposition of a silicate. A permanganate solution is one of the most convenient oxidizing solutions available for oxidation. However, it is generally recognized that when ferrous iron is titrated with permanganate in hydrofluoric acid solution the end point is fleeting and the result high or worthless. Consequently any procedure which increases the accuracy of the titration of ferrous iron with permanganate in fluoride solution has direct application to a very important method of analysis. This study has for its object an improved determination of ferrous iron in fluoride solution and its application to the analysis of silicates and carbonates for their ferrous iron content.

Mitscherlich² proposed to decompose the mineral by heating with strong sulfuric acid in a closed tube for a considerable length of time, thus yielding ferrous sulfate, which was subsequently titrated with permanganate. Hillebrand and Stokes³ as well as de Koninck⁴ have shown that this method may give erroneous results in the presence of sulfides which cause the reduction of ferric to ferrous iron, which is later titrated, thus yielding a high percentage. Vogt⁵ mentions a similar reducing action of sulfides, Cu_2S being the specific reference.

J. P. Cooke, Jr.,⁶ first used sulfuric and hydrofluoric acids for the decomposition and analysis of silicates for their ferrous iron content. The method as proposed by him is in general use to-day. This method, in brief, consists in the decomposition of the silicate with sulfuric and hydrofluoric acids in an atmosphere free from oxygen and titration with permanganate. The air must be excluded to prevent the oxidation of the iron during solution. Cooke passed carbon dioxide through the so-called "Cooke water bath" with inverted funnel cover to exclude the air, added the acid, heated the water in the bath to boiling, shut off the flow of carbon dioxide, allowing the steam to keep the air away from the sample undergoing attack, waited until the silicate was thoroughly decomposed, then passed cold water through the bath to cool the solution, meanwhile passing carbon dioxide, diluted and then titrated the ferrous iron with permanganate.

This method has several faults: (1), rigid care must be exercised to prevent partial oxidation of the dissolving ferrous iron during the decomposition period; (2), the end point may be more or less indefinite or fleeting; (3), certain naturally occurring substances must be absent or the results are vitiated.

Pratt¹ has attempted to obviate the first-mentioned difficulty by avoiding the use of the water bath and heating the platinum crucible containing the sulfuric and hydrofluoric acids directly, conducting carbon dioxide into the crucible by means of a platinum tube. By the direct heating process he was able to diminish the time of heating to about ten minutes. However, too great concentration of solution was found detrimental, as the strong, hot sulfuric acid had a tendency to oxidize ferrous sulfate. Hillebrand² obtained good results by this method.

Hillebrand² gives an excellent discussion of the detrimental influence of sulfides, vanadium and organic matter, stating that the titration is "entirely unreliable in the presence of organic matter." This author has also studied the effect of grinding upon the ferrous content of minerals, finding that fine pulverization decreases the quantity of ferrous iron found, which he attributes to the heat effect.

Gage³ seeks to improve the titration of the iron by the addition of calcium phosphate to precipitate the fluorine as calcium fluoride. Fromme⁴ adds a large amount of finely divided silicic acid, thus converting the hydrofluoric acid into fluosilicic acid. Dittrich⁵ used potassium sulfate with silicic acid to remove influence of the fluorine. Dittrich and Leonhard⁶ studied the use of the three previously mentioned reagents, recommending the use of 10 g. of finely divided silicic acid and 20-25 g. of potassium sulfate in a volume of 100 cc. which contained also 2 cc. of sulfuric acid. Deussen⁷ mentions that manganous sulfate, to a certain degree, does away with the source of error. However, this use of manganous sulfate has been shown to be not only of no value but of great detriment by several authors.⁸ Hillebrand⁸ states that

"It is possible to titrate ferrous iron in the presence of sulfuric acid, and as much as 5 to 7 cc. of 40% hydrofluoric acid in a total volume of 200 to 400 cc., almost if not quite as exactly as in sulfuric acid alone, provided the iron solution is diluted with air-free water and the titration made immediately after adding the hydrofluoric acid

and with all possible dispatch." He says further, "in the presence of little ferrous iron, up to, say, 2 centigrams, and 5 to 7 cc. of 40% hydrofluoric acid the color produced by a drop of permanganate lasts some time, but is very evanescent as the ferrous iron, and consequently the manganese salt formed, increases."

In the following pages is outlined a systematic study of various types of agents which suggested themselves as interesting in regard to their effect on the titration of ferrous iron in the presence of fluorides. The effect of each agent is studied under varying conditions of concentration of that agent. Each series of experiments contains the results of a number of titrations with permanganate of measured volumes of standard ferrous sulfate in the presence of measured volumes of hydrofluoric acid and the agent being studied. The total volume in each case was 200 cc. preceding titration unless otherwise designated. Usually, after the end-point reading had been taken and recorded, 0.10 cc. of permanganate was added in excess, the solution then stirred and allowed to stand until the color bleached out. This procedure was adopted as a test on the stability of the end point. Ceresin beakers and hard rubber stirring rods were used.

¹ The iron value of this and other permanganate solutions used in this investigation is the average value obtained by checking against sodium oxalate, ferrous ammonium sulfate and electrolytic iron.

² Approximately 240 g. of $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ were dissolved in water containing 20 cc. of conc. sulfuric acid (sp. gr. 1.84) and diluted to 8 l. This solution was titrated with the permanganate at the time of using and its value computed from the iron value of the permanganate.

Table I shows the effect of varying concentrations of sulfuric acid on this titration in presence of fluorides.

Experiments 6 to 11 inclusive show that ferrous iron can be titrated at room temperature with moderate accuracy in solutions normal in hydrofluoric acid and normal to 5 *N* sulfuric acid. However, considerably less, or more, sulfuric acid lessens the stability of the end point.

Titration in phosphoric acid solution of all concentrations between 0.1 *N* and 0.125 *N* with normal hydrofluoric acid present gives very fugitive end points. The use of solutions of the acid phosphates of the alkalis also gives very fleeting and indefinite end points. Hence phosphoric acid can not be substituted for sulfuric acid in this titration.

The influence of insoluble phosphates was tried to ascertain if they would give prevention of the indefiniteness of the fluoride end point. Phosphates of zinc, calcium,¹ magnesium, iron and aluminum were used. (See Table II.)

Experiments 1, 2, 4, 5, 6, 7, 18, 19 and 20 gave low results because of precipitation of ferrous phosphate, which consequently was not completely

¹ Gage, *Loc. cit.*

² Added solid in excess.

oxidized by the permanganate. In 19 the phosphate was added before the sulfuric acid, in 20 the acid before the phosphate, which accounts for a higher result in 20. Experiments 8, 11 and 22 indicate that good results may be obtained when the proper adjustment is obtained between phosphate of calcium or magnesium and acid. However, with calcium phosphate and phosphoric acid the end points were fleeting and with magnesium phosphate and sulfuric acid the time test of 0.10 cc. of permanganate was not as favorable as when titrating in sulfuric acid solution without the phosphate (Table I). The results with calcium phosphate do not confirm the work of Gage. Ferric, aluminum and zinc phosphates gave poor results, those with the zinc salt being the best, but the end point was extremely fleeting. The phosphates tried seem to have little merit as preventives.

The action of alkali bisulfates is similar to the action of sulfuric acid, but the neutral alkali sulfates have but a slight tendency to prevent the fluoride influence.

The influence of a number of bivalent neutral sulfates was tried, among such being zinc, magnesium, calcium, mercury, cadmium and manganese sulfates. Zinc, cadmium and mercury sulfates give unstable end points which lack reliability. Calcium sulfate added as a solid in excess gives end points which are but slightly more stable. Magnesium sulfate is much more effective. (See Table III.)

When the hydrofluoric acid is added to a solution containing magnesium or vice versa, a very light precipitate forms. The amount of precipitate increases progressively with the concentration of the acid and magnesium. In Experiment 8 the precipitate was very heavy—probably fluoride of magnesium. The prevention of the fluorine influence is very marked, surprisingly so in view of the comparatively poor prevention of zinc sulfate.

The detrimental influence of manganese salts is shown in Table IV.

TABLE IV.—MANGANESE SULFATE AS PREVENTIVE.

Manganese salts are thus seen to vitiate results to an enormous extent; when present in any considerable quantity, they absolutely inhibit a good titration.

The effect of a number of trivalent sulfates was tried, and that of ferric sulfate found to be of most interest (Table V).

TABLE V.—FERRIC SULFATE AS PREVENTIVE.

Ferric sulfate gives good prevention, but with a large amount of hydrofluoric acid a light pink to lavender color is imparted to the solution which is somewhat troublesome (Experiments 4 and 5). When ferric sulfate is added to hydrofluoric acid solutions, the color of ferric salts disappears practically entirely until an excess of ferric iron has been added. Aluminum sulfate gave some preventive effect, but it was not sufficiently satisfactory to be of especial merit. A few experiments using bismuth sulfate were performed. While this salt seemed to improve the end point the improvement was not of sufficient degree to have any value for the purposes of this work. The effect of cerous sulfate was tried and found to be detrimental rather than beneficial.

Cobalt, chromium, nickel and copper sulfates gave colored solutions

when added to hydrofluoric acid solutions and thereby prevented the appearance of good end points.

The effect of a number of oxides was tried to ascertain if they react with the hydrofluoric acid so as to yield undissociated fluorides in solution. Oxides of aluminum, magnesium and zinc are not applicable inasmuch as when added in excess they precipitate hydroxide of iron, thus hindering a good clean-cut reaction. Addition of stannic oxide produced apparently no effect, giving a fleeting end point. The yellow color of tungstic oxide interfered during titration and the end point was not stable.

Table VI gives the tabulated results obtained using molybdic oxide.

TABLE VI.—MOLYBDIC OXIDE AS PREVENTIVE.

Iron and permanganate solutions the same as used in Series V.

Normality.		Solid MoO ₃ in excess.	Iron—Gram.			10 cc. KMnO ₄ lasted. Seconds.

9.....	1.0	solution	0.1534	0.1532 <i>b</i>	0.1534 <i>p</i>	*

* Time not taken, but pink end point was fleeting in each case.

Results designated "b" were obtained by noting the volume of permanganate required to cause disappearance of the blue coloration formed by the reduction of the molybdenum by the ferrous iron. Results designated "p" are those obtained by utilizing the volume of permanganate required to tinge the solution pink.

Columbic and tantalic oxides apparently produced no effect because of the slow solution of these oxides in hydrofluoric acid. If freshly precipitated undoubtedly this action would be faster.

Titanium dioxide gives excellent prevention (Table VII).

TABLE VII.—TITANIUM DIOXIDE AS PREVENTIVE.

Experiments 1, 3 and 6 show that moderately good results can be obtained by using silicic acid as preventive. In Experiment 2 too much silicate was added in proportion to the amount of acid present and some of the ferrous iron was precipitated, hence the low result. Experiments 4 and 5 are included to show the relative values obtained in presence of hydrofluoric acid with sulfuric acid compared with sulfuric acid plus the silicic acid.

Granulated silica, prepared by various chemical manufacturers was tried but it did not work so well. The pink end point of the permanganate was far less stable, giving a tendency toward high results, perhaps owing to the more insoluble nature of the silica, or to slight impurities in the silica, or to both causes.

When boric acid is added to hydrofluoric acid in solution, meta-fluoroboric acid, HBF_4 , is formed, which does not dissociate appreciably to yield hydrofluoric acid in the presence of boric acid. This is illustrated by the fact that a dilute solution of the same will not attack glass.¹

Table IX gives the results of a study of the effect of boric acid in removing the influence of the fluorine when titrating ferrous salts.

TABLE IX.—BORIC ACID AS PREVENTIVE.

6.....	0.50	..	Excess	0.2462	0.2460	—0.0002	80 min.

The six experiments of Table IX indicate a very high degree of efficiency for the boric acid. In Experiment 4 considerable heat was evolved when the boric acid was added. The amount of solid added in each case

¹ See also Moissan, *Traite de Chimie Minerale*, 2, 166 (1904).

depended upon the consumption of the boric acid by the hydrofluoric acid. This is easily regulated, since an excess of reagent does no harm. In fact the excess seems to facilitate obtaining the end point.

Borax was also tried, adding the solid in excess to the sulfate solution containing HF. Its use produced good end points, but not as excellent as with boric acid. A saturated solution of borax was also used with success. Inasmuch as the use of boric acid affords such good titrations a point of interest arises at once in regard to how much effect it will have in offsetting the detrimental influence of manganese salts. This is of especial importance, inasmuch as manganese salts have such a good preventive action when titrating ferrous iron in the presence of chlorides and bromides (Table X).

TABLE X.—BORIC ACID PREVENTION OF THE MANGANESE EFFECT.

15....	1.0	Solid in excess	0.1538	0.1538	120 seconds

In the experiments of Table X the time listed for disappearance of the pink color of the permanganate is only for the disappearance of the deep pink; a lighter shade of pink remained (except in Expts. 11, 13, 14) for a longer period of time than that designated. In Expt. 11 the odor of liberated chlorine was strong. In Expt. 15 after the 0.10 cc. of KMnO_4 added in excess had bleached, 0.10 cc. more of KMnO_4 was added and this addition required 18 minutes to bleach, after which 0.10 cc. more of KMnO_4 retained its pink color for over three hours. This series of experiments shows that the fluorine influence can be removed in the presence of manganous salts very effectively. Hence, in the presence of fluorides, bromides and chlorides the addition of a manganese salt and boric acid allows ferrous iron to be titrated accurately with permanganate.

Inasmuch as hydrofluoric acid solutions of ferrous iron are readily

oxidized by the air, it was decided to study the stability of fluoboric acid solutions of ferrous iron. To measured portions of standard ferrous sulfate were added measured volumes of 10 *N* HF; the solutions were diluted to a definite volume and allowed to stand varying lengths of time after which boric acid was added in excess and the ferrous iron titrated. These results were compared with those obtained by adding an excess of boric acid to the fluoride solution immediately after adding the hydrofluoric acid and allowing to stand an equal time.

TABLE XI.—STABILITY OF FLUOBORIC ACID SOLUTIONS OF FERROUS IRON.

The results confirm the observations of others regarding the ease of oxidation of ferrous salts in the presence of hydrofluoric acid. However, the addition of boric acid makes the solution so much more stable that the oxidation is negligible in a moderate length of time. In Expts. 11 and 12 air was bubbled through the solutions at the rate of about three bubbles a second for an hour. A ceresin bottle was used to hold the solutions and the glass tubes used for conducting the air in and out of the vessel were coated with paraffin. In this case more thorough agitation was accomplished and the solution was kept more nearly saturated with air. Even in this case the theoretical result was obtained when boric acid was added before agitating. However, without the addition of boric acid about 57% of the ferrous iron was oxidized by the air.

Boric acid is the best of all the agents studied, since it removes the fluorine influence in the iron titration so effectually, is so easily prepared in a high degree of purity, is inexpensive, and is sparingly soluble in water so that the addition of the solid can be easily regulated according to the amount of hydrofluoric acid present. A number of silicate analyses have been made and the following method has been found applicable (Table XII).

Analysis of Silicate and Carbonate Rocks.

An appropriate sample (0.5 to 5 g.) in a capacious platinum dish is covered with water and placed on a Cooke water bath¹ in which the water has been previously thoroughly boiled to remove dissolved oxygen. Carbon dioxide is passed for several minutes, or steam allowed to escape for several minutes, or both, to remove any air inside of the glass funnel, after which 5 cc. of 1:1 H_2SO_4 (HCl can be used) is added by pouring down the platinum stirring rod. If carbonates are present care must be exercised to prevent too violent action. Should soluble sulfides be present the acid is likewise added slowly to expel the H_2S as completely as possible. Strong hydrofluoric acid is then added, 5 cc. to 20 cc. depending upon the size of the sample, pouring down the stirring rod. The bath is maintained at an even temperature, a continuous current of steam being expelled through the funnel until the silicate is thoroughly decomposed. If carbon dioxide is allowed to pass through the bath continuously it should be regulated so that its passage is slow, just sufficient to give direction to the current of escaping gases. Occasionally a little previously boiled water is added to the bath to maintain the water level. For this purpose a flask of boiling water should be kept constantly ready for use.

When decomposition is complete the funnel is lifted from its place and cold (previously boiled) distilled water added immediately to the dish to dilute the solution somewhat, followed immediately by an excess of solid boric acid. The solution is stirred, then lifted from the bath. If solid organic matter is present it should be filtered through an asbestos filter using suction (a carbon funnel with a Witte plate is convenient for this purpose) and the filter washed with previously boiled distilled water. The solution is poured into a glass beaker, diluted to a convenient volume, and titrated with standard permanganate. If the solution has been filtered it is titrated in the suction flask. It is well to add some solid boric acid before titrating to give the same color effect as usual at the end point. When hydrochloric acid is used for the decomposition of the sample, some substance should be added to counteract its influence when the ferrous iron is titrated. Since the hydrofluoric acid has been transposed to fluoboric acid any good preventive¹ is applicable. Ten to twenty cc. of the ordinary preventive solution² used in the iron titration (80 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ + 80 cc. H_2SO_4 (sp. gr. 1.84) + 80 cc. H_3PO_4 (sp. gr. 1.7) per liter is effective, or the phosphoric acid may be omitted and 160 cc. of sulfuric acid used instead in preparing this solution.

The above method can be easily adapted to Pratt's³ scheme of decomposing the silicate, which requires less time because of the application

¹ Cooke, *Loc. cit.*

² Barnebey, *Ibid.*

³ Pratt, *Ibid.*

of a higher temperature. The sample is placed in a platinum crucible, carbon dioxide is conducted into the crucible by means of a platinum tube, which is inserted under one edge of the cover, acid is added and heat applied directly to the crucible. As soon as steam is evolved copiously the carbon dioxide is shut off, hydrofluoric acid added and the cover fitted snugly to the crucible. When decomposition is complete dilute somewhat with water, add boric acid and proceed as usual.

Notes on the Method.

1. Scrupulous care must be exercised to exclude the air when decomposing the silicate with hydrofluoric acid in order to prevent oxidation. However, after the addition of the boric acid the ferrous solution becomes quite stable.

2. A carbon dioxide generator, after filling with carbonate (marble) and acid, should be allowed to generate carbon dioxide for a considerable period of time to remove the air as completely as possible. (Heating magnesite would probably be a still better method for obtaining carbon dioxide.) Only recently boiled water should be used in the water bath and only recently boiled distilled water added to the sample.

3. Until accustomed to the method of analysis the analyst should always check his procedure by heating measured volumes of standard ferrous iron solution with hydrofluoric acid, and titrating with the same manipulation as in the analysis in order to ascertain if the air is being excluded effectively.

4. Filtration is desirable when solid organic matter is visible after the sample is thoroughly decomposed. Filtration may not remove all the influence of the organic matter, however. The soluble organic matter naturally still has opportunity to give a reducing effect. If the clear solution is slightly colored by the presence of organic matter it should be largely diluted and titrated to the first distinct pink tinge of the solution. The presence of organic matter makes the end point much less stable than in its absence. Another procedure can be substituted for filtration. The sample can be transferred to a volumetric flask, diluted to the mark and the residue allowed to settle, after which portions can be withdrawn with a pipette and titrated.

5. Instead of adding solid boric acid the fluoride solution can be poured directly into an excess of a saturated solution of boric acid.

6. A convenient strength of permanganate for titrating samples low in ferrous iron content is 1 cc. = 0.001 g. FeO .

Samples 1-5, inclusive (Table XII), contained no organic matter and were free from sulfides. The end points were fleeting in analyses 2a, 3a and 4a, especially the last two. Samples 6-8, inclusive, contained considerable organic matter. In analysis 6a the result is only approximate,

as the end point was very fugitive because of the organic matter present. In 6*b*, 6*c*, 6*d*, 6*e* the solutions were filtered, as also were the samples 7*b* and 7*c* as well as 8*b* and 8*c*. Larger portions could have been used to advantage in Samples 5, 7 and 8. Samples were not analyzed according to procedure "a" for 7 and 8 because of the presence of large amounts of organic matter. Naturally filtration of the hydrofluoric acid solution is not advisable on account of the rapidity of oxidation of ferrous iron in such a solution by the air and also because of the action of the solution on glass.

TABLE XII.—ANALYSES OF SILICATES FOR FERROUS IRON.

8.....	1.0	0.43	0.45

a. Sulfuric and hydrofluoric acids used for decomposition. No boric acid was added.

b. Decomposed like a. Boric acid was added.

c. Hydrofluoric acid used for decomposition. Boric acid was added.

d. Decomposed with hydrochloric and hydrofluoric acids. Manganese sulfate (80 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ per liter) and boric acid were added.

e. Decomposed like d. Manganese solution I and boric acid were added.

The results obtained by decomposition methods "b," "c," "d" and "e" are somewhat lower than those obtained by "a," but they are believed to be more accurate. The author prefers the use of sulfuric acid with hydrofluoric acid for decomposition of a silicate whenever this method of attack is applicable, although hydrochloric acid with hydrofluoric acid or hydrofluoric acid alone can be used satisfactorily. The chlorine influence on the titration must always be removed when hydrochloric acid is utilized.

Naturally, when the above method is applied to the analysis of carbonate rocks, the addition of hydrofluoric acid may be omitted if the sample is thoroughly decomposed by the other acids, or if only the iron existing as carbonate is desired. However, the hydrofluoric acid finds application if considerable siliceous matter is present and the total ferrous iron content of the sample is wanted.

The action of these preventives may be classified as follows: Class (a)

removes most, if not all, of the active hydrofluoric acid by the presence of another acid through the medium of which the oxidation proceeds by virtue of its greater strength as an acid or by mass action. Sulfuric acid by conductivity measurements is stronger than hydrofluoric acid; phosphoric acid is much weaker. Hence sulfuric acid gives fairly good and phosphoric acid poor prevention. The acid salts found to be of worth are valuable mostly for their acidity, *i. e.*, NaHSO_4 , KHSO_4 . (b) Certain salts react with the fluorides present, forming undissociated fluorides and salts of other acids than hydrofluoric, through the medium of which the reaction proceeds. Examples of this class of preventives are ferric and magnesium sulfates. Phosphates are not desirable inasmuch as they yield phosphoric acid by interaction with hydrofluoric acid, and phosphoric acid is to be avoided in the titration unless all the hydrofluoric acid is removed. Of the neutral phosphates only those of the alkalies are soluble in water, hence to add metal phosphates either the solids or the phosphate dissolved in phosphoric acid must be added, thus forming acid phosphates in most instances and again bringing the phosphoric acid into predominance. Still another difficulty arises from the use of phosphates; sufficient acidity must be present to prevent ferrous phosphate from precipitating. If the ratio of phosphate to acid does not give sufficient acidity the titration is worthless, being low. Classes (a) and (b) are so closely related that they could properly be included in one class, but in (a) hydrofluoric acid is present and in (b) a fluoride. (c) Other reagents react with hydrofluoric acid in such a manner as to combine the fluorine in the anion which does not dissociate to yield hydrofluoric acid. Boric and silicic acid are such preventives, forming fluoboric and fluosilicic acids by interaction with hydrofluoric acid.

Of the preventives tried the author prefers boric acid. This acid can be obtained on the market in a high degree of purity and is a cheap commodity. It gives a solution which is clear. The solubility of boric acid in water peculiarly fits it for this purpose, being sufficiently high to allow a rapid reaction with hydrofluoric acid and yet not so high as to cause waste of the chemical when adding the solid in slight excess. The appearance of solid boric acid in excess likewise indicates that sufficient reagent has been added to react with the hydrofluoric acid present. This is a distinct advantage when titrating solutions containing unknown or variable quantities of hydrofluoric acid. Solid boric acid in excess is advantageous rather than detrimental in obtaining the end point. The fluoboric acid solution of ferrous iron oxidizes very slowly in the air, thus removing an undesirable feature of the titration accompanying the usual methods for determining ferrous iron. It gives the best prevention of the hydrofluoric influence during titration.

Summary.

1. This study confirms earlier work which has shown that the permanganate titration of ferrous iron in the presence of fluorides gives an unstable end point, the instability increasing with increased concentrations of iron and hydrofluoric acid.

2. The use of sulfuric acid of normal to 5 *N* concentrations permits a good titration to be made in the presence of normal hydrofluoric acid. Phosphoric acid can not be substituted for sulfuric acid, since the former yields a fugitive end point. Certain acid sulfates accomplish the same result as the free acid.

3. Certain sulfates, *i. e.*, ferric and magnesium sulfates, react with the hydrofluoric acid and check its influence in the titration. Phosphates and acid phosphates are undesirable for prevention of the fluoride influence.

4. Certain oxides also have prevention tendencies, *i. e.*, molybdenum trioxide and titanium dioxide, the titanium dioxide being the better. The hydrofluoric acid may combine with the titanium and molybdenum, forming simple fluorides or fluotitanic and fluomolybdic acids. Boric acid and silicic acid remove the hydrofluoric acid, forming fluoboric and fluosilicic acids. Boric acid is the most effective of all reagents studied.

5. Ferrous iron solutions containing fluoboric acid are quite stable in the presence of air.

6. The prevention of the reagents studied may be classified in three divisions: (1) addition of a stronger acid than hydrofluoric acid for the solution medium, (2) conversion to salts of other acids forming also undissociated or sparingly dissociated fluorides by mass action of the preventer, and (3) conversion of the hydrofluoric acid to a complex acid which when dissociated, gives a complex anion rather than the simple fluorine ion.

7. A modified procedure is given for the analysis of silicate or carbonate rocks for their ferrous iron content, using boric acid to remove the detrimental influence of the hydrofluoric acid.

THE PERMANGANATE AND IODIMETRIC DETERMINATION OF IODIDE IN PRESENCE OF CHLORIDE AND BROMIDE.¹

By O. L. BARNEBEY.

Received February 15, 1915.

The permanganate oxidation of iodide to iodate originated with Pean de Saint Gilles.² A large number of modifications of this method have

¹ Read at the New Orleans meeting of the American Chemical Society.

² Pean de Saint Gilles, *Compt. rend.*, 46, 624 (1858).

been made but they still retain the fundamental idea of conversion of iodide to iodate. Certain authors use other oxidizing agents, such as nickelic oxide,¹ potassium dichromate,² chlorine³ to accomplish the same purpose.

Theoretically this reaction has many points in its favor, the essential one being its application to the estimation of small quantities of iodides. For this purpose the addition of three oxygen atoms to the iodide demands a sufficiently large quantity of oxidizing agent to make the titration quite accurate. The measure of the amount of oxidizing agent required or of the iodate formed gives two means for the quantitative determination of iodides.

Pean de Saint Gilles⁴ determined the quantity of iodide by adding an excess of permanganate to the neutral or alkaline solution, heating a few minutes, adding an excess of ferrous sulfate containing sulfuric acid and then titrating the excess of ferrous iron remaining in the solution. Hence the original method consists of a measure of the oxidation of iodide to iodate from the quantity of permanganate required. Klemp⁵ adds zinc chloride to facilitate precipitation of the manganese and watches for the appearance of the permanganate color in the supernatant liquid. The end point is obscure, however, and continuous heating and cautious addition of permanganate is required to obtain even a moderately good result. Reinige⁶ determined the excess of permanganate with sodium thiosulfate. Sonstadt⁷ precipitates the iodic acid formed by this reaction with barium chloride, transforms the barium iodate with potassium sulfate to potassium iodate and then estimates the amount of iodate "either gravimetrically or iodimetrically." Other investigators have destroyed the excess of permanganate with such agents as alcohol⁸ or hydrogen peroxide,⁹ filtered out the hydrated manganese dioxide and then titrated the iodic acid in the filtrate iodimetrically. Sodium sulfite¹⁰ has been used to reduce the permanganate, later reducing iodic to hydriodic acid and converting to silver iodide. McCullock¹¹ pointed out that the measure

of the available oxygen from the hydrated manganese precipitate gives erroneous results, inasmuch as the precipitate is not pure manganese dioxide, but contains some manganous manganese. This condition of mixed oxides is one that might be anticipated from the general chemistry of the oxides of manganese. The oxide precipitated by the interaction of a reducing agent on permanganate or manganate or by an oxidizing agent on manganous manganese almost, if not invariably, contains part of its manganese in a lower state of oxidation than four.¹ The titration of iodic acid iodimetrically with thiosulfate, after removal of the excess of permanganate by alcohol or similar reducing agent and subsequent removal of the resulting manganese dioxide by filtration, removes the difficulty of an inconstant manganese oxide product of reaction and lessens filtration troubles, inasmuch as a considerable excess of permanganate can be employed and heating continued, if necessary, until the solution is quite easily filtered. The use of hydrogen peroxide² or alkali sulfites³ for the removal of the excess of permanganate would necessitate great care to avoid reduction of an appreciable amount of iodate, as these reducing agents are used to effect quantitative reduction of iodate to iodide.

Investigators using chlorine or hypochlorite have removed the excess of oxidizing agent by means of a current of air,⁴ boiling,⁵ or phenol.⁶ However, the general idea remains the same, conversion of the iodide to iodate and ascertaining the quantity of iodate formed.

The investigation to be outlined in the following pages is divided into two parts: (1) the permanganate titration according to the original and modified method of Pean de Saint Gilles and (2) the iodimetric titration of the iodate formed by the permanganate oxidation of the iodide.

1. The Permanganate Titration of Iodides.

The success or failure of the permanganate method as outlined by Pean de St. Gilles is dependent for the most part on the quantitative oxidation of ferrous to ferric iron by the permanganate in the presence of chloride and bromide. When the titration of ferrous iron with permanganate is attempted in the presence of halides in acid solution free halogen is liberated, the ease with which this liberation occurs increasing in the order hydrochloric, hydrobromic and hydriodic acids. The effect of chlorides

has been studied by a number of investigators¹ and various reagents have been used to prevent the detrimental influence of chlorides. Manganous salts have been found to be particularly effective. The author finds that manganous salts² also prevent the evolution of bromine, the best results being obtained in phosphoric acid solution.

If an alkaline solution containing chloride or bromide and permanganate is treated with ferrous sulfate acidified with sulfuric acid, chlorine (or hypochlorous acid) or bromine is liberated. If the acid ferrous sulfate solution is added in sufficient quantity all at once, thus insuring acidity only when the iron solution can give reduction at the same instant as acidity, then the liberation of halogen is greatly diminished. However, if sufficient manganous sulfate is added to the ferrous sulfate solution, which contains phosphoric acid, before the ferrous iron solution is added to the permanganate solution, then the tendency toward halogen liberation can be completely eliminated. The ferrous iron in the resulting solution can then be titrated accurately with permanganate.

Several series of analyses, in which the time of heating the iodide with permanganate was studied, showed that the heating should be continued a few minutes after the solution reached boiling temperature. Five minutes sufficed in every case. The effect of varying alkalinity was also tried and a low concentration of alkali found to give the best results. In acid solutions free iodine is liberated, which is transposed to iodic acid in part. If the concentration of acid is low, some iodine is liberated, complete conversion to free iodine being effected when the acid attains sufficient strength. In neutral solution the transposition is complete to iodic acid, but more time is required than in alkaline solution. Inasmuch as strong alkaline solutions of permanganate on heating decompose to a greater or less extent, liberating oxygen, a 0.01 *N* solution of sodium hydroxide was chosen for this work, 1 cc. of normal alkali being added for each 100 cc. of solution present. Heating just below boiling for five minutes a 0.01 *N* sodium hydroxide solution containing a moderate amount of permanganate (10–20 cc. of 0.1 *N* solution) causes a loss of oxygen which is so small as to be negligible. In fact such solutions give very little loss when heated for sixty minutes.

When a considerable quantity of iodic acid is treated with a large excess of ferrous iron in acid solution more or less reduction of the iodate occurs, simultaneously oxidizing the iron and liberating free iodine. To ascertain the extent of the reducing effect of ferrous iron on iodic acid in the presence of varying concentrations of sulfuric and phosphoric acids, a series of experiments was performed (Table I). In this series the quantity of potassium iodate was kept constant throughout and the other

¹ See Barnebey, *THIS JOURNAL*, 36, 1429 (1914).

factors varied in a systematic manner. Each experiment was performed at room temperature. Each solution was allowed to stand 5 minutes after mixing the reagents. The volume before titration was 200 cc. in each case.

All the low results of this series were caused by a partial oxidation of ferrous iron by the iodic acid, more or less iodine being visible at the end of the five-minute period preceding titration. In no case was iodine liberated at once. These results indicate that the solution should not have an acidity with sulfuric or phosphoric acid greater than normal and that not more than 0.1 g. of ferrous iron should be added in excess, if five minutes are to be allowed to intervene between the time of adding the excess of iron salt and titration of that excess with permanganate. However, much larger quantities of both ferrous iron and sulfuric or phosphoric acids can be present if the excess of ferrous iron is titrated immediately.

Table II gives the results of actual analyses of known amounts of potassium iodide, thus showing the combined effect of manganese dioxide and potassium iodate on the decomposition of potassium permanganate and also obtaining a further check on the reduction of iodic acid by ferrous iron. The potassium iodide was measured into an Erlenmeyer flask, and 1 cc. of N NaOH added, followed by the permanganate. The solution was heated to boiling and kept just below ebullition for the time designated. After cooling in running water the mixed solution of 50 cc. of

¹ Computed on the basis of three replaceable H atoms.

ferrous sulfate (1 cc. = 0.802 cc. KMnO_4) plus 25 cc. of manganese preventive solution (60 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ and 250 cc. H_3PO_4 of sp. gr. 1.70 per liter) was added. The time interval of standing previous to titration was about ten minutes in each experiment. No iodine was visible before titration, which showed that no reduction of iodic acid had taken place.

TABLE II.—PERMANGANATE DETERMINATION OF IODIDE IN PURE POTASSIUM IODIDE.

1 cc. KMnO_4 = 0.005648 g. Fe = 0.002798 g. KI.

4.....	50	60	60	9.64	40.10	29.54	0.0830	0.0827

The two preceding tables of results allow at least three conclusions: (a) the loss due to heating of the alkaline solution is negligible, (b) the reducing action of ferrous iron on the iodic acid can be made inappreciable, and (c) accurate determinations of iodide can be made by using the mixed solution containing some manganese salt and ferrous sulfate to remove the excess of permanganate as well as the hydrated manganese dioxide, the excess of ferrous iron being subsequently titrated with permanganate.

14.....	50	50	10	15	0.0415	0.0414	—0.0001
15.....	50	50	10	15	0.0830	0.0827	—0.0003

In Series III 50 cc. portions of 0.01 *N* potassium iodide solution were treated in an Erlenmeyer flask with permanganate in excess in the presence of bromides and chlorides, added in the form of 0.1 *N* potassium bromide and 0.2 *N* sodium chloride, or of the solids. One cc. of *N* sodium hydroxide was added, the solution heated and potassium permanganate added until there was about 10 cc. excess, then the solution was heated for about five minutes. The solution was cooled, and the ferrous sulfate solution (containing 250 g. per liter of manganous sulfate) was added in sufficient quantity to be about 10 cc. in excess. After complete solution of the manganese dioxide, phosphoric acid (1:3) was added. The excess of ferrous iron was then titrated with the permanganate.

In sample 6 the end point was blurred because of liberation of free bromine, the odor of which was distinct. MnSO_4 was not present in sufficient amount to take care of the large amount of KBr added originally. In other titrations concordant results were obtained.

In Series IV, 0.001 *N* potassium iodide was used with 0.001 *N* permanganate and 0.001 *N* ferrous sulfate. The method of procedure was the same as with 0.01 *N* potassium iodide. 1 cc. of *N* sodium hydroxide and 5 cc. of preventive solution (200 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ and 350 cc. H_3PO_4 of sp. gr. 1.7 per liter) were employed in each case. The total volume was 100 cc. for each titration. Considerable care was found to be necessary to exclude foreign impurities when dealing with such weak solutions of permanganate. Only recently boiled water, previously distilled from alkaline permanganate, was employed. The titrations were continued carefully to the first definite pink color and the amount of permanganate necessary to give the same pink color in a blank experiment was subtracted.

5.....	5	5	0.00083	0.00082	—0.00001

Correct results are thus seen to be possible with very small quantities of iodides.

2. The Iodimetric Titration of Iodate formed by the Permanganate Oxidation.

During the study of the permanganate titration of iodides, potassium iodide was added in a number of instances to the solution after the final titration of the excess of ferrous sulfate with permanganate and the resulting iodine titrated with standard thiosulfate. The results obtained

were surprisingly accurate. Consequently the author decided to study the factors influencing this titration.

The first point of interest is naturally the effect of ferric iron on potassium iodide in the acid medium necessary for the liberation of iodine by the interaction of iodic and hydriodic acids.

Tenth-normal potassium iodate (3.5678 g. pure KIO_3 per liter), ferric chloride (1 cc. = 0.006374 g. Fe) slightly acid with hydrochloric acid, ferrous sulfate solution (1 cc. = 0.004528 g. Fe), slightly acid with sulfuric acid, 5 *N* hydrochloric acid, 10 *N* sulfuric acid, 10 *N* phosphoric acid (computed on basis of 3 replaceable hydrogen atoms), manganese preventive solution containing 200 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ and 340 cc. H_3PO_4 (sp. gr. 1.7) per liter, *N* potassium iodide, and 0.1055 *N* sodium thiosulfate were used in the experiments of Table V. The letter *s* designates

¹ At end of 20 minutes starch solution was added and a drop of thiosulfate (0.04 cc.) and the remainder of the time was required for a very faint blue color to reappear.

² Oxidized with permanganate, then 1 cc. of ferrous sulfate was added in excess.

the experiments in which starch was used as indicator. When starch was not used, the bleaching of the iodine color of the solution was taken as the end point.

This series (Experiment 2) shows that normal phosphoric acid is capable of decreasing the speed of reaction between over a tenth of a gram of ferric iron and 0.05 *N* potassium iodide in a volume of 100 cc. at room temperature (21°) to such an extent that it becomes negligible for one or two minutes, only amounting to 0.04 cc. of 0.1 *N* thiosulfate in ten minutes. A considerable increase of the concentration of phosphoric acid, even to 4 *N*, does not change the speed of reaction sufficiently to give a measurable difference of volume of thiosulfate required by the method employed. Dilution of the normal solution to 400 cc. (Experiment 8), thus diminishing the concentration of all the reagents involved, causes a still slower rate of reaction. Sulfuric acid (Experiments 9 and 10) can not be substituted for phosphoric acid, since its action toward decreasing the rate of reaction is not commensurate with the latter. The preventive solution containing phosphoric acid (Experiments 11-15) employed in the permanganate determination of iodides exerts the same influence as phosphoric acid itself. Experiment 16 shows that ferrous iron is without effect. Experiments 18 to 22 show that iodic acid can be titrated quantitatively in the presence of the phosphoric acid or preventive solution, and Experiments 23 and 24 show that the ferric chloride has no influence on the titration of iodic acid, if the titration is performed immediately after adding the potassium iodide.

Definite samples of potassium iodide were taken in the Series VI and varied quantities of potassium bromide and sodium chloride added to each, after which the sample was analyzed for iodine by the permanganate method as previously outlined and the result recorded. Ferrous sulfate solution was then added in slight excess, followed by 5 cc. of *N* KI, and the free iodine titrated immediately with standard thiosulfate adding 1 cc. of 1% starch solution when the solution became very faintly yellow in order to get the sharp iodine-starch end point. The permanganate, ferrous sulfate and thiosulfate solutions used in this series were tenth-normal and the potassium iodide was hundredth-normal.

Table VII includes results obtained using 0.001 *N* solutions. The 0.001 *N* KMnO_4 is thousandth-normal compared with KI as standard. Reacting with iron in acid solution this permanganate would be 0.01 *N* inasmuch as 2KMnO_4 or $\text{K}_2\text{Mn}_2\text{O}_8$ will react with 10 Fe in acid solution but will only oxidize one molecule of KI to KIO_3 in alkaline solution. Hence the permanganate contains 0.316 g. of potassium permanganate per liter. The same relative strength obtains for the ferrous sulfate solution used in this series. The thiosulfate solutions used in this work were standardized against pure potassium iodate, referring the normality

strength of the thiosulfate (0.001 *N*) to potassium iodide as a basis rather than to the iodate. The same precautions used in Series IV are necessary here to avoid any slight impurities of oxidizing or reducing character in the permanganate determination. The manganese solution used in these two series contained 200 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ + 350 cc. of H_3PO_4 (sp. gr. 1.7). In Table VI 15 cc. and in Table VII 5 cc. of this solution were added in each experiment.

These two series show that the iodimetric titration of the iodate in the residual solution from the permanganate method is accurate if the solution contains sufficient phosphoric acid to prevent the action of ferric iron on potassium iodide. Naturally if the permanganate data are not desired they can be neglected and only the thiosulfate titration computed. The iodimetric method is to be preferred when titrating such small amounts of iodine as the samples of Series VII contained, essentially because of the sharpness of the starch iodine end point contrasted with that of permanganate and of the lesser effect of slight impurities such as oxygen in water on the final titration with the thiosulfate.

The following procedure is well adapted to the analysis of a halogen mixture for its iodine content. One-twentieth to five grams of sample,¹

¹ If as small a sample as 0.05 g. is desired a larger portion should be weighed out and an aliquot analyzed, for example, 0.5 g. diluted to 500 cc. and a 50 cc. portion used in the analysis.

depending upon the amount of iodine present, is dissolved in 100 cc. of recently boiled distilled water in an Erlenmeyer flask, 1 cc. of *N* sodium hydroxide added, the solution is heated to boiling and standard permanganate added, 5–10 cc. at a time with continuous shaking, allowing several seconds between each addition before observing the color of the solution. If the solution becomes cooled it is reheated and the additions are continued until a distinct color (red or green) is imparted to the solution. The flask is covered with a small watch glass and the liquid then heated just below boiling for about five minutes. If the color disappears, more permanganate is added and the solution reheated. It is then cooled in running water and to it is added, all at once, with agitation of the solution, a mixture of 15 cc. of manganese preventive solution (200 g. $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ + 350 cc. H_3PO_4 , of sp. gr. 1.7, per liter) and sufficient standard ferrous sulfate to react with all the manganese dioxide and excess of permanganate and have an excess of ten to fifteen cubic centimeters. As soon as the manganese dioxide has dissolved completely the solution is diluted to 300–400 cc. and titrated with the permanganate¹ to the first appearance of a faint pink color. A smaller amount of preventive solution can be added and a smaller volume used with small quantities of iodine involved. The percentage of iodine is calculated from the amount of permanganate required to oxidize the iodide to iodate.

For the iodimetric titration a few drops of ferrous sulfate are added to bleach out any excess of permanganate, followed by 5 cc. of *N* KI solution (free from iodine) or 1 g. of solid,¹ after which the iodine is titrated immediately with standard thiosulfate. The percentage of iodine or iodide is then computed from the amount of thiosulfate required to react with the iodine produced by the reduction of the iodate to iodide.

The two methods have about equal merit, except when applied to extremely small quantities of iodides, when the iodimetric method is preferable. If the iodimetric method only is to be followed, naturally the strength of the permanganate and ferrous sulfate solutions need not be known exactly.

Summary.

1. In the original method of Pean de St. Gilles for titrating iodide, in the presence of bromide and chloride with permanganate the results are erroneous because of the formation of free bromine, chlorine or hypochlorous acid.

¹ No iodine color should be visible before titration with permanganate or before the addition of potassium iodide prior to the thiosulfate titration. If such a color develops, the proper adjustment has not been made between an exceptionally high concentration of ferric iron and phosphoric acid or too long a time has intervened between the time of finishing the permanganate and starting the thiosulfate titration, in which case another sample must be analyzed, using a greater dilution and correspondingly more preventive solution or phosphoric acid.

2. The presence of manganese sulfate and phosphoric acid in the ferrous solution allows the removal of the excess of permanganate and manganese dioxide without liberation of bromine or chlorine from the halides. Likewise the manganese and phosphoric acid insure a correct permanganate titration of the ferrous iron excess.

3. Iodide can also be determined in the presence of bromide and chloride by addition of potassium iodide to the final solution obtained as in 2 and titration of the liberated iodine with thiosulfate.

4. Both titrations can be made on a single sample, using the residual solution from the permanganate titration for the iodimetric determination.

Very small amounts of iodine are best determined by the iodimetric method. With moderate quantities of iodine both methods outlined are easy of manipulation, rapid in execution and accurate.

THE PRECIPITATION OF PHOSPHORUS AS AMMONIUM PHOSPHOMOLYBDATE IN THE PRESENCE OF SULFURIC ACID.

BY K. GEORGE FALK AND KANEMATSU SUGIURA.

Received March 20, 1915.

The Neumann method for the determination of phosphorus in organic matter is based upon the oxidation of the material by a mixture of concentrated sulfuric and nitric acids, precipitation of the phosphorus as ammonium phosphomolybdate, and titration of the latter, after removal of ammonia, with standard sodium hydroxide solution. The formula of the phosphomolybdate precipitate has been taken to be essentially $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3 \cdot 2\text{HNO}_3$ under the conditions described by Neumann,¹ Gregerson,² and others. A substance possessing this formula, after the removal of ammonia either by boiling in alkaline solution or by combination with formaldehyde,³ would require 56 equivalents of sodium hydroxide per gram molecule of P_2O_5 to be neutral toward phenolphthalein. If the precipitate is titrated with 0.5 *N* NaOH solution, one cc. would be equivalent to 1.268 mg. P_2O_5 or 0.553 mg. P; on the other hand, if it is dried at 110–120° before titrating, the nitric acid would be driven off and then one cc. would be equivalent to 1.365 mg. P_2O_5 .

The possibility of the composition of the precipitate varying under different conditions has been indicated a number of times,⁴ but the good

⁴ Recently by Hibbard, *J. Ind. Eng. Chem.*, **5**, 998 (1913), who also gives a very complete bibliography. Cf. also A. E. Taylor and C. W. Miller, *J. Biol. Chem.*, **18**, 215 (1914).

results obtained in practice with the factor given by Neumann appeared to substantiate the formula ascribed. Recently; however, Heubner¹ found this factor to be too small and adopted the value 0.57 mg. in place of 0.553 mg. for the quantity of phosphorus equivalent to one cc. 0.5 *N* NaOH solution.

The work described in this paper developed from the study of the phosphorus determinations made in connection with enzyme investigations in this laboratory, and deals especially with the part played by sulfuric acid in the precipitation of the phosphomolybdate.

A number of different standard phosphate solutions were used. The experiments to be described were made with sodium ammonium phosphate 10.88 g. of $\text{NaNH}_4\text{HPO}_4 \cdot 4\text{H}_2\text{O}$ (Kahlbaum's "zur Analyse") were dissolved in water and diluted to two liters. Two different solutions, designated I and II were made up at different times. The methods of analysis used will first be given.

A. Molybdate Method, no Sulfuric Acid Present.²—To the phosphate solution (generally 25 cc.) 12 cc. ammonium nitrate solution (750 g. NH_4NO_3 dissolved and diluted to 1 liter) and 50 cc. molybdate solution (60 g. MoO_3 , 440 cc. H_2O , 60 cc. NH_4OH , sp. gr. 0.90, poured into a mixture of 250 cc. H_2O and 250 cc. HNO_3 , sp. gr. 1.40, filtered after standing several days) were added, the mixture heated at 80° on a water bath for 10 minutes, cooled, and allowed to stand over night. It was then filtered on asbestos in a Gooch crucible, washed 5–6 times with an NH_4NO_3 solution (containing 50 g. of the salt and 10 cc. conc. HNO_3 in 1 liter), once with 1% HNO_3 solution, dried in an air oven at 120° and weighed as $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3$.

B. Magnesium Ammonium Phosphate.—To 25 cc. of the phosphate solution, 10 cc. magnesia mixture (containing 55 g. cryst. magnesium chloride, 70 g. NH_4Cl , and 300 cc. NH_4OH , sp. gr. 0.96, diluted to 1 liter and filtered) were added, the mixture heated to boiling and 5 cc. 3 *N* NH_4OH solution added drop by drop; stirred, allowed to stand over night and filtered through a Gooch crucible with asbestos (or through an ashless paper). The precipitate was washed with 2.5% ammonia solution, dried, ignited to constant weight (after addition of conc. HNO_3) over a Meker burner, and weighed as $\text{Mg}_3\text{P}_2\text{O}_7$.

C. Ignition Method.—50 cc. of the solution were evaporated to dryness in a platinum dish at 100° in an air oven; the residue was then ignited to constant weight over a Meker burner and weighed as NaPO_3 .

D. Neumann Method.—To the phosphate solution were added the stated amounts of conc. H_2SO_4 , sp. gr. 1.84, water, and 50% NH_4NO_3 solution, the mixture heated to 75° and the stated quantity of a 10%

¹ *Biochem. Z.*, 64, 393 (1914).

² Cf. for instance, Olsen, "Quantitative Chemical Analysis" 1910, p. 119.

ammonium molybdate solution (from Merck's product, highest purity) added with stirring. After 15 minutes, the mixture was cooled and either filtered at once or allowed to stand over night and then filtered.

DI. Weighing the Precipitate.—The precipitate was filtered on a Gooch crucible (asbestos), washed 7 times (unless otherwise stated) with 5–10 cc. ice-cold water each time, and dried at 120° in an air oven.

DII. Titrating the Precipitate.—The phosphomolybdate precipitate obtained as described in Method D was filtered on a Gooch crucible or on paper, washed with ice-cold water as described in DI, then the paper or the Gooch crucible containing the wet precipitate was returned to the beaker in which the precipitation had been made. If the phosphomolybdate precipitate had been dried and weighed as in Method DI, the Gooch crucible with the precipitate was placed in a beaker. The subsequent treatment of the wet or dry precipitate was the same, namely, 30 cc. water were added, then 45 cc. 0.5 *N* NaOH solution with stirring until all had dissolved; the solution was then either boiled for at least 30 minutes until litmus paper showed no further evolution of ammonia, cooled, made acid with 0.5 *N* H_2SO_4 solution, and titrated with 0.5 *N* NaOH solution using phenolphthalein as indicator; or, 50 cc. 30% formaldehyde solution, neutralized toward phenolphthalein, were added, the mixture allowed to stand 5 minutes, 7 cc. (or other suitable amount) 0.5 *N* H_2SO_4 solution added, and the solution titrated to alkaline reaction with 0.5 *N* NaOH solution.

E. Reprecipitation as Phosphomolybdate.—The weighed precipitate (from A or D, DI) was treated in a beaker with 50 cc. H_2O and 3 cc. conc. ammonia solution, warmed, filtered through paper, and washed successively with 2.5% ammonia solution and water. To the filtrate were added 20 cc. 50% NH_4NO_3 solution, and 1 cc. 10% ammonium molybdate solution. The mixture was heated on an electric stove until bubbles began to rise, and 20 cc. warm nitric acid (3 parts conc. to 1 part water) added drop by drop with stirring. It was then cooled, and after standing over night treated as in Method A.

F. Reprecipitation as Magnesium-Ammonium Phosphate.—The phosphomolybdate precipitate was transferred to a beaker, dissolved in ammonia (Method E), acidified with conc. HCl, and made slightly alkaline with ammonia; 10 cc. of the magnesia mixture (Method B) were then added, the mixture heated to boiling, cooled, and 20 cc. conc. ammonia solution added. After standing over night, the precipitate was filtered, etc., as in Method B.

G. Lead Molybdate.¹—The phosphomolybdate precipitate was dissolved in ammonia (Method E), diluted to 100 cc. and 25 cc. portions taken for analysis. Each portion was diluted with 50 cc. H_2O , and 22 cc.

¹ Raper, *Biochem. J.*, 8, 649 (1914).

conc. HCl, followed by 20 cc. of 4% lead acetate solution and 200 cc. of a mixture of equal parts of 50% ammonium chloride and 50% ammonium acetate solutions added. After standing over night, the precipitate was filtered on a Gooch crucible (asbestos), washed with hot water 10 times (the wash water was somewhat turbid up to the sixth washing), then dried, ignited over a Meker burner, and weighed as PbMoO_4 .

The results will be given as mg. P_2O_5 in 25 cc. solution, since this was the quantity used in the analyses. The phosphate contents of the two solutions were first determined by the standard methods. Four analyses of 25 cc. portions of Solution I by Method A gave 1.2338–1.2394 g. phosphomolybdate when dried at 120° , or a mean content of 46.8 mg. P_2O_5 . Two of these precipitates, titrated by Method DII (formaldehyde), gave the same value (factor 1.365). Four analyses by Method B, filtered on a Gooch crucible, gave 0.0730–0.0742 g. $\text{Mg}_2\text{P}_2\text{O}_7$, or 46.8 mg. P_2O_5 as mean, and two analyses, filtered on paper, 0.0715–0.0728 g. $\text{Mg}_2\text{P}_2\text{O}_7$, or 46.0 mg. P_2O_5 . By Method C, 50 cc. portions gave 0.1336 and 0.1337 g. NaPO_3 , or 46.5 mg. P_2O_5 per 25 cc. Solution I contained, therefore, as the mean, very nearly 46.8 mg. P_2O_5 per 25 cc., taking into account the number of the determinations by each method, and the separate deviations. Four 25 cc. portions of Solution II by Method A gave 1.2350–1.2401 g. phosphomolybdate, mean P_2O_5 content 46.8 mg.; two portions precipitated by Method A, then dissolved without drying and reprecipitated by Method E, gave 1.2455 and 1.2469 g. phosphomolybdate, mean 47.1 mg. P_2O_5 . These last two precipitates titrated by Method DII (formaldehyde) required 34.91 and 34.92 cc. 0.5 N NaOH solution, or 47.7 mg. P_2O_5 as mean. Solution II may, therefore, be taken as containing very nearly 47.1 mg. P_2O_5 per 25 cc.

A number of experiments which will not be given in detail showed that the titration of the phosphomolybdate precipitate by Method DII gave the same results whether the ammonia was removed by boiling or was combined with formaldehyde. The same results were also obtained whether the precipitates were filtered on paper or on asbestos in a Gooch crucible.

Four 25 cc. portions of Solution I by Methods D and DII, with 5 cc. conc. sulfuric acid, 8 cc. NH_4NO_3 solution, and 40 cc. molybdate solution required 37.33–37.51 cc. 0.5 N NaOH solution. Assuming the formula $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3 \cdot 2\text{HNO}_3$ and the factor 1.268, this corresponds to an average of 47.6 mg. P_2O_5 . One portion of the same mixture by Methods D and DI gave 1.3565 g. phosphomolybdate, which, when titrated by Method DII required 37.36 cc. 0.5 N NaOH solution. Assuming no HNO_3 in the dried precipitate, these values correspond to 51.3 and 51.0 mg. P_2O_5 , respectively. It will be noted, however, that the titration values are the same, whether or not the phosphomolybdate precipitate

was dried before titrating. This was observed in every case. With mixtures containing 5 cc. sulfuric acid, 20 cc. ammonium nitrate solution, and 40 cc. molybdate solution, Methods D and DII, direct titration of the undried precipitate, gave 36.12 and 36.14 cc. 0.5 *N* NaOH solution, corresponding to 45.9 mg. P_2O_5 (1.268 factor). The same mixture by Methods D and DI, after drying and weighing the phosphomolybdate precipitate, gave 49.5 mg. P_2O_5 , and titrating this dried precipitate 36.16 cc. With 50 cc. NH_4NO_3 solution, 70 cc. H_2O and the rest of the mixture the same, 35.80–35.88 cc. 0.5 *N* NaOH solution were required for the undried precipitates, or 45.5 mg. P_2O_5 , assuming HNO_3 to be present. This value is considerably lower than the standard value (46.8), but, assuming no nitric acid to be present in the precipitate, would give 48.9 mg. P_2O_5 , a value much too large. The filtrates from these last precipitates, on being neutralized with ammonia, acidified with nitric acid, and 15 cc. conc. nitric acid in excess added, gave no further precipitate. The results with 5 cc. conc. sulfuric acid showed that drying the precipitate had no effect on the titration, and that the results were either too large or too small, depending upon the amount of ammonium nitrate added. In the ordinary Neumann wet combustion method, often more than 5 cc. conc. sulfuric acid are present. A number of experiments were, therefore, made with the following mixture: 25 cc. Solution I, 10 cc. conc. sulfuric acid, 65 cc. H_2O , 50 cc. ammonium nitrate solution, and 40 cc. molybdate solution. Eight determinations by Methods D and DII required 35.55 to 36.02 cc. 0.5 *N* NaOH solution, giving a mean value 45.5 mg. P_2O_5 (factor 1.268). Assuming no nitric acid present in the precipitate, the value 48.9 mg. P_2O_5 (factor 1.365) is obtained. Four portions of the same mixture by Methods D and DI gave 1.2985 to 1.3047 g. phosphomolybdate precipitate, or 49.2 mg. P_2O_5 (for the formula $(NH_4)_3PO_4 \cdot 12MoO_3$). These precipitates when titrated by Method DII required 35.83 to 36.03 cc. 0.5 *N* NaOH solution, or very nearly the amounts required by the undried precipitates. With the factor 1.268 this corresponds to 45.5 mg. P_2O_5 ; with the factor 1.365 to 49.0 mg. P_2O_5 . The filtrates from these precipitates, neutralized with ammonia, acidified with nitric acid and 15 cc. conc. nitric acid in excess added, gave no further precipitate on standing. A few experiments in which more sulfuric acid was present, were made. Using 12.5 cc. conc. sulfuric acid in place of 10 cc., determinations by Methods D and DII required 34.81 and 35.29 cc. 0.5 *N* NaOH solution, while the filtrates, treated as described above, gave additional precipitates after standing over night, requiring 0.89 and 0.34 cc. The average total titration was 35.67 cc. With 15 cc. conc. sulfuric acid in place of 10 cc. the first precipitates required 28.83 and 30.13 cc., while from the filtrates were obtained precipitates requiring 7.70 and 6.53 cc. The average total titration was 36.60 cc., of which 15–20%

was obtained with the second precipitates. The total titrations with different amounts of sulfuric acid present were not in accord. This would appear to indicate a varying composition of the precipitates. With more than 10 cc. conc. sulfuric acid present, the precipitation was not complete. 50 cc. of the 50% NH_4NO_3 solution present in 190–195 cc. total solution is slightly more than the quantity recommended by Neumann, and somewhat less, 13% instead of 15%, than that recommended by Gregerson.

The experiments with Solution II were carried out with different ends in view, and the results obtained indicate some of the reasons for the irregularities observed by different workers. 25 cc. of this solution contained 47.1 mg. P_2O_5 as indicated before. The mixture used in all of the following work with this solution was made up of 25 cc. Solution II, 10 cc. conc. sulfuric acid, 50 cc. NH_4NO_3 solution, 65 cc. water, and 40 cc. molybdate solution.

The phosphomolybdate precipitate in the Neumann method must be washed with ice-cold water until the wash water is no longer acid. Two sets of two portions each, precipitated by Method D, then treated by Method DI, the first set washed four times with ice-cold water, the second seven times, gave 1.3079–1.3089 g. and 1.3042–1.3047 g. phosphomolybdate precipitate, respectively, corresponding to 49.5 and 49.3 mg. P_2O_5 . Two other sets of three portions each by Methods D and DII, washed four times and seven times, respectively, required 36.43–36.72 cc. and 36.11–36.27 cc. 0.5 *N* NaOH solution, respectively, corresponding to 46.3 and 46.0 mg. P_2O_5 with the factor 1.268, or 49.9 and 49.4 mg. P_2O_5 with the factor 1.365. The fourth washings required 2.44 cc. 0.5 *N* NaOH, the 7th 0.12 cc. 0.5 *N* NaOH. The washings tested for sulfuric acid gave, in a series of similar experiments, for the sixth washing a test equivalent to 0.2–0.3 cc. 0.1 *N* H_2SO_4 , and for the eighth washing a test equivalent to 0.02–0.05 cc. 0.1 *N* H_2SO_4 . After the sixth washing the phosphomolybdate precipitate began to run through the filter, as shown by the turbidity. Practically all the free acid was, therefore, removed by seven washings, but not by four. No volatile substance, such as nitric acid, is present in the precipitates, as shown by the agreement between the dried and undried precipitates.

A number of experiments involving solution of the phosphomolybdate and reprecipitation were made. Three portions by Methods D and DI gave 1.3087–1.3116 g. phosphomolybdate precipitate, corresponding to a mean P_2O_5 content of 49.5 mg. These precipitates dissolved and treated by Method F gave 0.0728–0.0732 g. $\text{Mg}_2\text{P}_2\text{O}_7$, corresponding to 46.6 mg. P_2O_5 . Another set of three by Methods D and DI gave 1.3137–1.3138 g. precipitate, corresponding to 49.7 mg. P_2O_5 ; these precipitates dissolved and reprecipitated by Method E gave 1.2561–1.2564 phosphomolybdate

precipitate, corresponding to 47.5 mg. P_2O_5 ; these dissolved and reprecipitated by Method F gave 0.0728–0.0732 g. $Mg_2P_2O_7$ or 46.5 mg. P_2O_5 .

These experiments show that the first precipitate of the phosphorus as phosphomolybdate from the solution containing sulfuric acid possesses a different composition from that of the precipitate obtained if little or no sulfuric acid is present. That no nitric acid is contained in the precipitate formed with sulfuric acid present in the solution is shown also by the fact that the same results were obtained whether or not the precipitates were dried at 120° . An attempt was, therefore, made to study the composition of these precipitates. The amount of sulfate in the precipitates was accordingly determined. Four portions of Solution II, with the same mixture as before, were treated by Methods D and DI. The precipitates were dissolved and reprecipitated by Method E; the mother liquors from these reprecipitations were evaporated to dryness on the water bath after the addition of one cc. conc. hydrochloric acid, 25 cc. water added, and the mixture filtered, the filtrates diluted to 100 cc. and 5 cc. concentrated hydrochloric acid and 5 cc. 10% $BaCl_2$ solution added while boiling. After the customary treatment, 0.0179–0.0214 g. $BaSO_4$ were obtained, equivalent to a mean value of 0.0080 g. H_2SO_4 . Similar treatment of Solution II without added sulfuric acid, by Methods A and E, gave 0.0001 and 0.0004 g. $BaSO_4$. These results appear to show that sulfuric acid is an essential part of the precipitate formed under the given conditions.

Based upon the amounts of phosphate and sulfate present, and upon a number of nitrogen and molybdenum determinations, the composition of the precipitate was calculated to be $4[(NH_4)_3PO_4 \cdot 12MoO_3] + (NH_4)_2SO_4 \cdot 5MoO_3$. The mean of four closely agreeing nitrogen determinations by the Kjeldahl method¹ of the precipitates obtained from Solution II by Methods D and DI was 2.23%; calculated for the above formula, 2.35% N. Several determinations of the molybdenum in these precipitates by Method G gave, for 25 cc. portions of the phosphomolybdate precipitate dissolved in 100 cc., 0.7627 and 0.7496 g. $PbMoO_4$, corresponding to an average of 90.6% MoO_3 . The calculated MoO_3 content for a substance of the above formula is 91.3%; for a substance of the formula $(NH_4)_3PO_4 \cdot 12MoO_3$, 92.1%. To check up the method, similar portions of the phosphomolybdate precipitate from Solution II by Method A without the addition of sulfuric acid, gave 0.7216 and 0.7326 g. $PbMoO_4$, or a mean MoO_3 content of 92.6%.

The precipitate is probably present as a complex compound and not as a mixture, since similar solutions containing no phosphoric acid gave no precipitate of sulfomolybdate. The formula found, as given above,

¹ Sherman, "Methods of Organic Analysis," 1912, p. 294.

naturally holds only for the precipitate formed under the given conditions. Under different conditions different proportions of sulfuric acid and molybdic oxide might be carried down, but the general relations would probably be similar. Thus, the carrying down of molybdic acid in excess of the 24 MoO_3 to one P_2O_5 has been observed at different times, recently by H. S. Halcro Wardlaw in a paper on the "Accuracy of Neumann's Method for the Estimation of Phosphorus."¹ That sulfate may be present in the precipitate has also been indicated at various times, but it was considered to replace the nitric acid which ordinarily forms part of the precipitate. The composition of the precipitates described in this paper have been given in the above form, because when no sulfuric acid was present, each P_2O_5 was combined with 24 MoO_3 . The sulfuric acid which was precipitated was, therefore, assumed to carry down the further portion of MoO_3 which was found.

If the precipitate, whose complete formula may be written $(\text{NH}_4)_{14}(\text{PO}_4)_4\text{SO}_4 \cdot 53\text{MoO}_3$ is titrated with alkali after removal of the ammonia, each gram molecule of P_2O_5 would require 58 equivalents of NaOH , instead of the 56 required by two molecules of the precipitate $(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3 \cdot 2\text{HNO}_3$. From a consideration of the phosphosulfomolybdate precipitate, it is evident that the proportion of sulfate, phosphate, and molybdenum in the complex may well be subject to considerable variation. If the same ratio for MoO_3 to sulfate precipitated with the phosphomolybdate holds, a smaller concentration of sulfuric acid in the solution would be expected to result in titration values six times smaller than if the amount of sulfate in the precipitate alone varied. This may account for the entirely different factor, corresponding to less than 56 equivalents NaOH per gram molecule P_2O_5 , found by Heubner, who worked with smaller amounts of phosphorus and sulfuric acid. Between these two sets of results lie those obtained by Neumann, Gregerson, and more recently by Greenwald.² These workers found the relation, 56 equivalents NaOH per gram molecule P_2O_5 , to hold for the P_2O_5 content of the phosphomolybdate precipitate for the conditions of precipitation chosen by them.

In the course of this investigation a number of other phosphate solutions, and also solutions containing widely different amounts of phosphate, were used. The results obtained bear out, in general, the conclusions given, but not enough work was done to determine the variation of the composition of the precipitate with different amounts of phosphate and sulfuric acid. Finally, it may be stated that the titration of the phosphomolybdate precipitate gives satisfactory results only if the conditions of precipitation have been worked out with known amounts of phosphate

¹ *J. Roy. Soc. New South Wales*, 48, 73 (1914).

² *J. Biol. Chem.*, 14, 369 (1913).

and an empirical factor determined. Otherwise, solution and reprecipitation of the phosphomolybdate precipitate are essential.¹

Conclusions.

The precipitate of ammonium phosphomolybdate formed in the presence of sulfuric acid (as in Neumann's method) contains sulfate apparently as an essential part of the molecule, together with an excess of molybdic oxide, and no nitric acid. The composition of this phosphosulfomolybdate precipitate may vary with the concentration of the different constituents in the solution. These variations explain the different factors found for the titration of the precipitate with alkali. The composition of the precipitate for a certain set of conditions was found to be $4[(\text{NH}_4)_3\text{PO}_4 \cdot 12\text{MoO}_3] + (\text{NH}_4)_2\text{SO}_4 \cdot 5\text{MoO}_3$.

FLUOBORIC AND FLUOSILICIC ACIDS IN THE QUALITATIVE ANALYSIS OF SODIUM.

By F. C. MATHERS, C. O. STEWART, H. V. HOUSEMANN AND I. E. LEE.

Received April 10, 1915.

The scheme for the detection of sodium is the only unsatisfactory test in the qualitative analysis of the soluble or alkali group of bases. The flame or spectrum test is so delicate that the quantity of sodium normally present in all reagents always distinctly gives it. This is confusing to inexperienced students. The pyroantimonate method has never given accurate results in this laboratory in the hands of beginning students. The following method is the final result of experiments which have been conducted by the authors for a number of years in an effort to devise a quick and accurate test for sodium.

Method of Analysis.—The filtrate containing the potassium, sodium, ammonium and magnesium (after the other metals have been removed in the ordinary way) is evaporated to dryness and ignited to remove the ammonium. The residue is dissolved in 10 cc. of water² by warming. A small portion of the solution (a few drops) is removed and tested for potassium with sodium cobaltic nitrite. The remainder of the solution is treated with an equal volume of alcohol and an excess of fluoboric acid in 50% alcohol. The potassium is completely precipitated as potassium fluoborate, a flocculent, easily filtered precipitate. Sodium and magnesium remain in solution. The sodium in the filtrate may then be precipitated with fluosilicic acid as sodium fluosilicate, a gelatinous, semi-transparent precipitate which settles slowly, consequently careful observation is necessary to detect it when only small quantities of sodium are present.

¹ Cf. Hibbard, Raper, and others.

² Ten cc. of water should be used for each gram of sodium and potassium chloride present.

Magnesium fluosilicate, a very soluble salt, does not precipitate, but potassium fluosilicate and sometimes ammonium fluosilicate are precipitated if the potassium and ammonium have not been previously removed. In the absence of sodium, a precipitate sometimes forms on long standing as a result of the action of hydrofluoric acid upon the glass, if any free hydrofluoric acid was present in the reagents.

Lithium does not interfere with the test for sodium, probably on account of slow precipitation or colloidal solution of the lithium fluosilicate of which only 4 parts dissolve in 100 of 46% alcohol (Comey). In some test solutions rich in lithium, a gel formed after 48 hours.

Preparation of Reagents.—Fluoboric acid is very easily made by adding an excess of boric acid to hydrofluoric acid in a lead or platinum dish. Thirty-five grams of boric acid to 100 g. of 48% hydrofluoric acid is generally sufficient, but boric acid should always be added until a test portion does not precipitate a lead nitrate solution. The solution, after cooling, is treated with an equal volume of alcohol and enough fluosilicic acid to precipitate any sodium which may have been introduced as an impurity in the boric acid. A large excess of the fluosilicic acid must be avoided.

Fluosilicic acid may be easily prepared by pouring hydrofluoric acid upon sand until the latter is barely covered. A wax bottle may be used because the heat of reaction is not great. The reaction is complete in a few hours but the solution should always be tested for free hydrofluoric acid. An equal volume of alcohol should be added before using.

The reagents must be kept in wax, rubber, lead or paraffin bottles or beakers. In the ordinary course of analysis, these reagents when properly made, do not noticeably etch the test tubes.

These reagents work just as satisfactorily when made from commercial as from pure hydrofluoric acid. The only difficulty is in the preparation where the impurities, *e. g.*, sulfates, interfere with the test for fluoride in determining the completeness of the change into fluoboric and fluosilicic acids.

Delicacy of Tests.—One milligram of sodium in 5 cc. of 50% alcohol gives a good test with fluosilicic acid. In the detection of smaller amounts of sodium, a smaller volume of solution must be used. If large amounts of potassium and only small amounts of sodium are present, the filtrate after the precipitation of the potassium with fluoboric acid, should be evaporated to dryness and ignited for an instant at a dull red heat. The residue should be dissolved in 50% alcohol (2–3 cc.), filtered and tested for sodium with the fluosilicic acid. In this way 2 mg. of sodium in 0.5 g. of potassium chloride was easily detected. Addition of 1 g. magnesium chloride in no way interfered with the test for the sodium. Correspond-

ing solutions containing no sodium gave no precipitate with the fluosilicic acid.

One mg. of sodium in 5 cc. of 50% alcohol was easily detected in a solution containing 0.1 g. of lithium as chloride and also in a solution containing 0.1 g. of lithium as chloride and 0.2 g. of potassium chloride. A blank, containing only lithium, gave no precipitate.

Pure fluoboric acid in 50% alcohol solution may be used as a test for potassium in place of sodium cobaltic nitrite or perchloric acid. Two milligrams of potassium in 5 cc. of 50% alcohol may be easily detected. The only objection to this test is that impure fluoboric acid, *e. g.*, when made from commercial hydrofluoric acid, sometimes gives a precipitate when potassium is absent; the cause of this was not investigated. The advantage of this test is that it is not interfered with by sodium and magnesium nor by ammonium and cyanides which interfere with the sodium cobaltic nitrite test. However, owing to the trouble of making pure fluoboric acid, the test for potassium with sodium cobaltic nitrite seems best wherever it can be used.

Use of Other Reagents.—Perchloric acid¹ is preferable to the fluoboric acid in this method but the latter is recommended because it is so much easier to prepare.

Oxalic acid in 50% alcohol solution gives a delicate test for sodium, but no rapid method was found of removing the interfering potassium, without introducing free acid which prevents the precipitation of the acid sodium oxalate.

Potassium fluozirconate in 50% alcohol solution, is a delicate reagent for sodium, but potassium solutions also precipitate it.

Tartaric acid in 50% alcohol solution does not completely precipitate the potassium in potassium chloride because of the free mineral acid that is simultaneously formed, hence tartaric acid cannot be used in place of the fluoboric acid.

The advantages of this new method are:

1. Tests may be made in the presence of magnesium, the removal of which, generally a long difficult task, is necessary if the potassium pyro-antimonate method is to be used.

2. The reagents are comparatively cheap and are very easy to prepare.

3. The reactions and equations are simple and easily understood, and only a short time is required to make an analysis.

4. The test is decisive, and the student has confidence in his work. A large class of inexperienced students obtained very accurate results in a trial of the method lasting two terms.

NOTES.

A Laboratory Stool.—The laboratory stool pictured herewith is an ordinary camp stool of strong construction, so made as to serve as a device for locking the drawers and doors of the student's compartment. For a laboratory table 33 inches high the dimensions shown on the sketch will be found convenient.

Two holes, A, A, are so placed as to fall together when the stool is closed. A large staple is attached to the wooden strip that separates the drawer from the locker-doors of the ordinary laboratory table. At the end of the laboratory period the student closes his stool, hangs it under the edge of his table, the staple being passed through the holes A, A, in the stool, and snaps a padlock on the outside. It is then impossible to open the locker, since both drawers and locker-doors are blocked by the stool. A single padlock is thus made to do service for from two to four locks.

The stool can easily be carried about the laboratory to suit the convenience of the student, or may even be taken into another room, but must be returned to its place beneath the edge of the laboratory desk before its owner will be able to lock his compartment. If each stool be numbered on both sides with a number corresponding to the locker to which it belongs, there will be little temptation for the lazy student to take his neighbor's stool when he is ready to lock his desk and leave the laboratory.

If one end of the laboratory be provided with a blackboard, and the nearest desk raised six inches above the level of the others, it will be possible for the students in a fairly large laboratory to get near enough to permit lectures being given there, if movable stools of this kind be provided. Of course if this be done it will be necessary to dispense with the shelving and other superstructure commonly found on laboratory tables, in order that the view may not be obstructed. As a matter of fact the student's reagent-bottles should not be kept on shelves, but in a small tray that may

be put inside his desk; for in this way the reagents are kept cleaner, and the work of the janitor is made much easier.

HORACE GROVE DEMING.

Los Baños, P. I.

Note on a New Analytical Suction Filter.—The description of the following apparatus which I have invented is not of particular interest simply because it contains certain new features, or even old features combined in a new way, but because it is an apparatus whose value can be measured by its usefulness.

Probably every chemist at some time in his course of study has done a certain amount of quantitative analysis, and in the analysis of more complicated substances, such as dolomite or talc, has felt a desire that he might use a Gooch crucible and a suction filter, in one of the first stages of analysis, owing perhaps to the quickness of the filtration and the simplification by eliminating the necessity of burning the filter paper and many other details which tend to lengthen and make tedious some of these analyses. But the style of the present suction filter makes its use at this stage practically prohibitive, because the next stage of analysis could not be carried on in this vessel, nor could the contents be readily taken out, owing to the awkwardness of its shape.

It is often necessary to operate with very small quantities of liquid and it is important in such cases to avoid possible loss of liquid through adherence to the surface of the receptacles employed in making the analysis. At the same time it is desirable to avoid the necessity of carrying in stock various sizes of filter apparatus. It is also necessary to employ for filtering purposes an apparatus which can be easily and conveniently handled and cleansed. It is exceedingly desirable to employ apparatus so constructed as to utilize suction action in effecting the filtering.

So it is the purpose of my filter to provide an apparatus which accomplishes these various desirable results. A description of the apparatus is as follows:

The apparatus is very simple and consists of three parts. The main body of the apparatus somewhat resembles Witts filter, and consists of a cylindrical glass jar, $6\frac{1}{2}$ inches deep and $5\frac{1}{2}$ inches in diameter, with a suction outlet near the top fitted with a ground glass stopcock. The top rim has a pouring lip in the side opposite the suction outlet and the entire upper surface is ground. Half way up from the bottom on the inside surface are three glass protrusions at equal distances apart for supporting a perforated shelf, which is the second part. The third part is the cover having a ground glass rim to fit the upper surface of the jar and having an extra large stopper opening of one and three-quarter inches in diameter.

Now, where small quantities are to be filtered, the shelf is inserted and

a small beaker or crucible is placed thereon to catch the filtrate. After the filtration, whether with a Gooch or ordinary filter, we find the filtrate is in the desired vessel ready for the next operation. If large quantities

are to be filtered the shelf is removed and a large beaker inserted; or the jar itself may be used very conveniently, the three small protrusions interfering but little in washing, and the pouring lip facilitating the emptying of the jar.

There are, indeed, many suction filters which in certain respects resemble my filter, but owing to their lacking in certain features have not rendered themselves very popular. My filter I find the most simple and natural, and at the same time most convenient for speed, neatness and accuracy, and for that reason have called attention to it and have named it the Takamine Analytical Filter (for which the patent is pending).

JOKICHI TAKAMINE, JR.

NEW YORK.

An Alternating Current Thermoregulator.—The electromagnetic thermostat regulator is a well-known convenient instrument. The principle of operation is that the expansion or contraction of mercury in a large open mercury thermometer makes or breaks a contact which throws on or off a current through an electromagnet.

Regarding these regulators Ostwald¹ says: "The great drawback I find with such instruments is that the current always remains closed for a considerable length of time. This causes a rapid running down of the battery which in turn easily occasions the regulator to fail in its action."

It was suggested by Professor J. W. Dorsey of the electrical engineering department of the University of Manitoba that alternating current from the city mains might be used to run the electromagnet and accordingly

¹ "Physico Chemical Measurements," 1894, p. 62.

an arrangement was constructed as shown in the diagram. It may be a surprise to many chemists to know that an electromagnet can be run by alternating current, but with a current of 60 cycles the pull on the armature is quite appreciable.

The electromagnet had the following construction: The soft iron coil A was 4.5 cm. long and 0.9 cm. in diameter.

The winding consisted of about 350 turns of No. 20 insulated copper wire wound directly on the coil and well protected at the ends by two hard rubber disks.

The soft iron armature B was sawed from a circular bar. It was 0.8 cm. in diameter and 0.2 cm. thick. It was soldered to a piece of No. 19 copper wire as shown in the diagram. The position shown there was chosen

for the armature because then only a small surface came in contact with the core and also the pull of the electromagnet seemed to be stronger than in any other position of the armature.

The electromagnet and lamp resistance were fastened permanently on the wall beside the thermostat in such a position that when no current is flowing through the electromagnet the armature falls down and the circuit through the thermostat heater is completed at C. An excessive temperature in the thermostat causes the mercury in the regulator to rise and completes the other circuit at D. The electromagnet then draws up and retains the armature, breaking the heating circuit at C. The wires at C must be fairly stout to prevent overheating and sticking due to sparking. The vibration of the armature also tends to prevent sticking of the contacts.

The amount of electric power used in the electromagnet coil and in the lamp resistance is small. This apparatus has been in use for two months and has given satisfaction.

HAROLD S. DAVIS.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY.]

A STUDY OF THE REACTIONS OF SODIUM MALONIC ESTER.¹

[FIRST PAPER.]

By C. LORING JACKSON AND F. C. WHITMORE.

Received March 17, 1915.

This paper contains a proof that the first step in the reaction of sodium malonic ester and an organic halogen derivative consists in the union of the two reagents to form an addition compound. It therefore places on a firm experimental basis that part of the theory proposed recently by Bigelow and one of us to explain these reactions; but it has also a wider interest, since it increases by one the meagre list of such intermediate compounds, and thus adds weight to the common theory that substitution is preceded by addition.

In 1888 W. S. Robinson and one of us² found that when sodium malonic ester reacted with tribromodinitrobenzene one of the atoms of bromine was replaced by hydrogen and one by the malonic ester residue, while the third remained unaltered, giving bromodinitrophenylmalonic ester. Further work in this laboratory led to the discovery of other cases of this strange replacement of a halogen by hydrogen, but no progress was made toward explaining the reaction until 1911, when H. E. Bigelow and one of us³ found that bromotriiododinitrobenzene was converted by sodium malonic ester in the cold into bromodiiododinitrobenzene, but, if the reagents were heated, that bromoiododinitrophenylmalonic ester was formed. These experiments showed that the replacement of halogen by hydrogen preceded that by the malonic ester radical, and led to the following explanation³ of the reactions with sodium malonic ester: When an organic substance containing a halogen reacts with sodium malonic ester, the first step consists in the addition of the halogen and the organic radical to the (enol) sodium malonic ester. Owing to the attraction of the sodium, the more negative part of the compound will be added to the carbon atom carrying the NaO. As a rule this would be the halogen

¹ The work described in this paper formed part of a thesis presented to the Faculty of Arts and Sciences of Harvard University for the degree of Doctor of Philosophy by Frank Clifford Whitmore.

² *Am. Chem. J.*, 11, 93 (1889).

³ *Ibid.*, 46, 549 (1911).

Donald.¹ Von Findeisen, however, did not attempt to make a more general application of the theory, or to test it by further experiment.

We have found only two different explanations of the reactions of sodium malonic ester, both of which were advanced by Nef. The first² explains the usual reactions by supposing that the alkyl halide dissociates into the halogen acid and a methylene compound, to which malonic ester is then added.

It seems to us that a fatal objection to this theory is found in the fact that it does not explain such reactions as the formation of benzoylmalonic ester from benzoylchloride, or the conversion of trichlorotrinitrobenzene into dichlorotrinitrophenylacetic ester³ (a product of the decomposition of the original malonic ester).

Nef's second theory⁴ deals with the less usual reactions, in which hydrogen takes the place of a halogen. Here he assumes an addition of malonic ester to the halogen,

and that the addition compound at once falls into the hydrogen derivative and the substituted malonic ester.

Among the objections to this theory, which have occurred to us, the following seem of especial weight: The work described in this paper shows that the addition compound is not made up of *free* malonic ester and the other reagent, as maintained by Nef, but contains sodium; and while such a product might be expected with iodine because of the analogy between $\text{K} - \text{I} = \text{I}_2$ and Nef's compound, $\text{Na} - \text{I} = (\text{CH}(\text{COOR})_2)\text{R}'$ (in which R' is a negative radical), it is much less likely that it would be formed with bromine, for which we can find little analogy; and what we know of chlorine makes it very improbable that such a compound could be derived from it. In fact Nef emphasizes this point to explain the difference in behavior of the bromo and iodophenylacetylenes on one side and the chloro compound on the other. Later, however, Willcox,⁵ in a paper from Nef's laboratory, showed that the behavior of the ethylsulfuric chloride made it necessary to extend the theory to the chlorine compounds in the face of this acknowledged objection.

¹ *Am. Chem. J.*, 22, 228 (1899).

² *Ann.*, 298, 263 (1897).

³ Jackson and Smith, *Am. Chem. J.*, 32, 174 (1904).

⁴ *Ann.*, 308, 306 (1899). In this paper he says that C. L. Jackson and his scholars have never detected the ethanetetracarboxylic ester as the other product of these reactions. This is a mistake, as its presence was reported in 1890, Jackson and Moore, *Am. Chem. J.*, 12, 7, and Jackson and Dunlap, *Ibid.*, 18, 117 (1896), while tartronic acid was detected even earlier, Jackson and Robinson, *Ibid.*, 11, 541 (1889).

⁵ *Am. Chem. J.*, 32, 449 (1904).

Nef's addition compound contains the halogen already combined with sodium, and his theory assumes that in decomposing the halogen breaks away from the sodium to combine with the carbon of the malonic ester, but certainly such a startling hypothesis cannot be accepted, until it has been supported by most convincing evidence.

According to Nef's theories the formation of substituted malonic esters and the replacement of halogen by hydrogen are brought about in entirely different ways, so, for instance, to explain the formation of bromotritrophenylmalonic ester from tribromotritrobenzene¹ one of the atoms of bromine must have taken up sodium and the malonic ester residue, and another have been split off as hydrobromic acid, if this were possible, but no reason is given to explain why these two atoms of bromine should react entirely differently. Until these objections are removed, it seems to us that our theory should be preferred to those of Nef, as it explains all these observations in a satisfactory manner, as will be shown in our second paper.

In continuing the study of our theory we have tried to submit it to the test of experiment in two ways: First, by isolating the addition compound predicted by it, with results described in this paper; and, second, by studying the effect on the course of reaction of the relative attraction for sodium of the two radicals added, which will be described in a second paper.

Before discussing our quantitative experiments on the addition compound the proofs of its formation may be given. When the pale yellow bromotriiododinitrobenzene is treated with colorless sodium malonic ester in the cold, the mixture turns dark blood red, and if this solution is acidified, the color is discharged, owing to the formation of bromodiiododinitrobenzene and ethanetetra-carboxylic ester (or iodomalonic ester), which are colorless, or nearly so. These changes of color, therefore, can be due only to the formation and destruction of a new compound under the conditions predicted by our theory; and the only compounds we can find, which could be formed under these conditions, are our addition compound, or one of the strongly colored salts of a quinol nitro acid;² but the latter substance on acidification would give the original triiodo-compound, and certainly could not form the iodomalonic ester and bromodiiododinitrobenzene actually obtained, so this alternative must be rejected, and there is left as the only cause of this red color the formation of the addition compound required by our theory. The similar observations when 1,3,5-triiododinitrobenzene was treated with sodium malonic ester³ furnishes us with another undoubted case of a colored addition

compound; and we may have observed many others, as a marked change of color was observed in every one of the 83 reactions studied in this laboratory, in which a nitrohalogen aromatic compound was treated with sodium malonic ester, sodium acetacetic ester, or a sodium alcoholate, but, although some of these colors may have been caused by one of our addition compounds, we can prove this to be the case only in the two reactions already given, as in each of the others it was possible a quinol nitro salt was formed and frequently also a colored salt of one of the reaction products.

The second proof of the formation of our addition compound is furnished by its solubility, as 10 cc. of absolute alcohol dissolve over 10 g. of the red product, but only 1.5 g. of sodium malonic ester and 0.043 g. of bromotriiododinitrobenzene, so there was in solution more than 6 times the weight of solid, which would have been dissolved, if there had been only a mixture of the two components.

This red compound made from bromotriiododinitrobenzene and sodium malonic ester is particularly well adapted for study, because it is very stable, keeping unaltered for nearly a year, is formed almost quantitatively, and the main reaction is not embarrassed by parallel or subsequent reactions. Most of the other addition compounds we have considered are inferior to this in at least one, or, sometimes in all three, of these respects.

After preliminary experiments had established the comparative stability of this compound in the cold, and had shown that it could be obtained from its solutions only by evaporation, we were confronted with the problem of determining the composition of a very soluble amorphous substance, for, although in one experiment we had obtained crystals, which seemed to be the addition compound, in a year and a half of attempts to prepare them again, we never observed the least sign of crystallization. Owing to the difficulty in purifying such a substance, we first made a set of analyses of specimens containing the addition compound mixed with a known quantity of one or the other reagent.

As the bromotriiododinitrobenzene is only slightly soluble in absolute alcohol, preparations were made with a sufficient excess of this reagent to saturate the alcohol used, and leave a small quantity of the solid. After the reaction with sodium malonic ester had taken place, the solution was filtered off, a portion evaporated *in vacuo* (it decomposed, if warmed), and the amount of sodium in the residue determined. The weight of bromotriiododinitrobenzene which dissolved in the volume of alcohol used, was determined by a parallel experiment, and on subtracting this from the weight of the residue there was left the weight of the addition compound containing the sodium. Possible weak points in this method of attack were that the reaction might not run to an end, and that the presence of the addition compound might change the solubility of

the substituted benzene. The first of these difficulties evidently did not exist, however, since the percentages of sodium agreed within 0.2% with that calculated for $(C_6BrI_3(NO_2)_2)(CH(CONaOC_2H_5)(COOC_2H_5))$, and the absence of the second was proved by the fact that solutions containing much of the addition compound gave the same analytical results as the more dilute, which would have been impossible, if the size of the correction had been affected by the presence of this substance. Similar experiments were tried with a known excess of sodium malonic ester, the solvent being a mixture of benzene and alcohol, which takes up but little of this substance. Applying the correction in this case for the amount of sodium malonic ester dissolved, the percentage of halogens in the residues differed from that calculated for the addition compound by only 1.25% in the worst case. Here, again, the agreement is better than we expected, as this correction would be seriously affected by the moisture and carbon dioxide of the air forming malonic ester, which would add to the weight of the substance analyzed. Exposure to the air was avoided as completely as possible, and evidently with good success, as the error is little, if at all, greater than would be expected from the larger size of the correction than in the preceding case.

These determinations do not *prove* the existence of the addition compound, as they were made with unpurified residues, which did not crystallize or show any other criterion of their freedom from impurities beside the known excess of one of the reagents, but they certainly furnish a strong argument in favor of its existence, as the first series proves that a given volume of alcohol in presence of sodium malonic ester takes up more bromotriiododinitrobenzene than it can alone, and this additional amount dissolved is just sufficient to form a compound made up of one molecule of each reagent. This amount is considerable, for instance in one determination the alcohol, which would normally have taken up only 0.0622 g., with the sodium malonic ester dissolved 0.2397 g. In the second series the bromotriiododinitrobenzene caused the benzene and alcohol to dissolve an amount of sodium malonic ester in addition to that, which would be taken up by the solvent alone, exactly enough to form this same compound.

We tried next to obtain a pure specimen of the red addition compound, using the constituents in molecular proportions in a mixture of benzene and absolute alcohol. The resulting solution, after it had stood several days, was evaporated *in vacuo* till sufficient solid had deposited, and, after this had been filtered out, a second solid red fraction was obtained from the filtrate, but the filtrate from this yielded a dark red liquid. Analyses showed that the least soluble fraction contained bromotriiododinitrobenzene, the most soluble fraction malonic ester, or its sodium salt, while the intermediate fraction gave a percentage of halogens agree-

ing with that for the addition compound. These experiments therefore showed that the substance could be purified by this fractional evaporation. It is to be observed that with equal molecules of the two reagents the action does not run to an end, whereas our previous series of experiments indicated that with a large excess of one of the reagents the other was completely used up.

The way had now been cleared for the study of the homogeneity of the addition compound. A large amount of it was made, as in the second series of experiments, and submitted to an elaborate systematic fractionation, in which 29 solid fractions were obtained. This work was tedious in the extreme, as it was necessary to carry on all the evaporations at ordinary temperatures. Analyses of the most and least soluble fractions showed that the unaltered portions of the two reagents accumulated in these as in the second series, and, after these had been rejected, a considerable amount of intermediate material was left, which was divided into 4 fractions according to solubility, when analyses showed that the percentage of halogens in the least soluble fraction agreed absolutely with that in the most soluble. It seems to us that this proves the red addition product is a definite compound with the composition

We also describe in this paper some improvements in the preparation of triiodoaniline, which make it possible to obtain this substance in a state of purity with tolerable certainty.

Experimental.

Preparation of Triiodoaniline (Monochloride of Iodine).—Success in this preparation depends in great measure on the purity of the monochloride of iodine used, since a slight excess of free iodine, or, worse still, of trichloride of iodine, gives a black product, which produces distressing results, when submitted to the diazo reaction. Our predecessors tried to avoid this difficulty by continuing the action of the chlorine on the iodine until a few yellow crystals of the trichloride appeared, when the attempt was made to remove this impurity either by heat or the addition of iodine.¹ These methods proved unsatisfactory, partly because the amount of impurity was considerable, since much of the trichloride was needed to saturate the monochloride, before the crystals appeared, and partly because the action of heat in removing it was incomplete without too great a loss of the monochloride, or the action of iodine on the trichloride was exceedingly sluggish. We have accordingly substituted for them a process, in which the monochloride is prepared with little more than a trace of free iodine, and the temperature, at which it is driven over into the aniline hydrochloride, is kept so low that most of this iodine is left

¹ *Am. Chem. J.*, 26, 55 (1901); 46, 557 (1911).

behind. Our process is based on Stortenbeker's¹ work on the equilibria in the system iodine-chlorine. Out of 12 preparations we obtained with it white, or nearly white, triiodoaniline in 11, the twelfth being only pale brown, whereas a white product was the exception rather than the rule with the older processes.

A rapid stream of chlorine, dried by several spiral washing tubes of strong sulfuric acid, was passed over 42 g. of cold iodine (the amount for 10 g. of aniline) in a flask. The point at which the process should be stopped was determined by watching carefully the appearance of the product after all the crystals of iodine had disappeared. If some of the liquid was shaken up on the side of the flask at this point, it left a sticky opaque coating, but, as more chlorine was added with constant shaking, the liquid flowed from the side of the flask without wetting it; which in turn was followed by a more perfect liquefaction, so that the side of the flask was wet once more, leaving a slightly streaked layer red and transparent, when held to an electric light. The action of the chlorine was stopped when this streakiness had almost, but not quite, disappeared. It seemed to be caused by free iodine, which in this way was reduced to a minimum with no danger of forming any of the much more injurious trichloride of iodine. If the action of the chlorine was carried too far, the red transparent film on the side of the flask was entirely uniform. Such a preparation solidified on cooling to a mass of long, dark red needles, but gave an impure triiodoaniline as the rapid crystallization was brought about by a little trichloride of iodine. A specimen prepared by stopping the chlorine at the right point did not solidify even after standing for several days at 0°, probably because the slight excess of iodine prevented the crystallization. This was left behind in the flask, after the monochloride had been drawn over into the solution of aniline hydrochloride.

To prepare the triiodoaniline 10 g. of freshly distilled aniline were dissolved in 1 liter of strong hydrochloric acid, twice the quantity used by our predecessors, which, although it slightly lowered the yield, gave a purer product. The solution was then diluted to 7-8 liters and a rapid stream of air sucked through it, which had previously passed through the weighed flask containing the monochloride of iodine heated to 20-30° in a water bath. This very low temperature reduced any decomposition of the monochloride to a minimum, and also kept back most of the free iodine. After the calculated amount of the monochloride had volatilized, the solution with the flocculent precipitate was allowed to stand over night, filtered through a large cloth bag, as suction rendered the precipitate unmanageable, washed free from hydrochloric acid, and dried on a steam radiator. The yield of crude triiodoaniline amounted in 11 experiments to 480 g. from 568 g. of the monochloride of iodine, that is 85% of the

¹ *Z. physik. Chem.*, 3, 11.

theory. The products varied from light gray melting $165-172^{\circ}$ (uncorr.) to pure white melting as high as 178° (uncorr.). Pure triiodoaniline melts at 185.5° . If the monochloride of iodine was a bad preparation, or the triiodoaniline was black, it saved time to throw it away, rather than to try to get a pure substance from it.

The crude triiodoaniline was extracted several times with small quantities of boiling alcohol, which left a residue of the pure substance melting at 185° (uncorr.) instead of 185.5° . The first of these alcoholic extracts were very dark, even when the crude triiodoaniline was nearly white. From them two substances were obtained. The first by cooling the mother liquors from a specially impure triiodoaniline, after they had been evaporated to small volume. The substance thus obtained proved after several recrystallizations from alcohol to have the constant melting point 95° (uncorr.), and is therefore diiodoaniline, which melts according to Rudolph and Michael and Norton¹ at $95-96^{\circ}$. This inference was confirmed by the analysis of a slightly impure specimen.

Diiodoaniline Hydrochloride.—The second compound was obtained in quantity from a specimen of the triiodoaniline, which had been dried without washing it free from hydrochloric acid, but small amounts of this and the free diiodoaniline were formed in every preparation of triiodoaniline. The alcoholic extract from the specimen first mentioned deposited it in silvery white plates melting near 200° . As it was found impossible to purify it by crystallization, which, on the contrary, rendered it more impure, the original crystals were dried *in vacuo* and analyzed I. Another sample was made by dissolving diiodoaniline in dry benzene and treating it with dry hydrochloric acid gas. The white precipitate was dried *in vacuo*. II.

I, Subst. 0.1854, II, 0.2286, 2090; $\text{AgCl} + \text{AgI}$, 0.2973, 0.3676, 0.3379. Calculated for $\text{C}_6\text{H}_4\text{I}_2\text{NH}_2\text{HCl}$: $\text{Cl} + \text{I}$, 75.88; found: 75.73, 75.95, 76.37.

The two preparations showed the same properties. Silver white plates blackening slightly at 185° and melting with decomposition at 207° (uncorr.). Water does not act on it in the cold but when hot decomposes it into diiodoaniline and hydrochloric acid, as would be expected from the fact that the triiodoaniline hydrochloride has not been prepared.

Preparation of Bromotriiododinitrobenzene.—Ten grams of the triiodoaniline prepared and purified as described above were mixed in a heavy walled Erlenmeyer flask with 120 cc. of glacial acetic acid and 50 cc. of fuming hydrobromic acid, and 3 g. of powdered sodium nitrite added so slowly that an entire day was occupied by the addition, the flasks being kept stoppered during the reaction, which seemed to succeed better under this slight pressure. After standing over night the diazo compound was decomposed by warming, and the solid product extracted

¹ Ber., 11, 78, 109 (1878).

with small quantities of alcohol, till the residue melted at 142° (instead of 146°). It was found not worth while to use the crystals obtained from the extracts. This process differs in several particulars from that given by Bigelow and one of us,¹ the most important being the use of fuming hydrobromic acid instead of the constant boiling acid. This was obtained by passing hydrobromic acid gas into a constant boiling specimen made from sulfuretted hydrogen, bromine and water. The bromotriiodobenzene was sometimes gray instead of yellow, but gave the dinitro compound without difficulty.

The bromotriiodobenzene melting not below 142° was boiled for 4 hours with nitric acid of sp. gr. 1.51 in a flask fitted to a return condenser by a ground joint, and instead of allowing the mixture to cool the hot acid was decanted from the crystals, which were then washed by decantation with water. These white, feathery crystals always melted above 280° and sometimes at 290° (instead of 292°). The yield was nearly 50%. The hot acid contained only material so impure and in such small amount that it was not worth while to purify it. The improvements introduced by us into these preparations remove the necessity of the tedious crystallizations, which were a feature of the earlier work.

The Addition Product of Bromotriiododinitrobenzene and Sodium Malonic Ester.—When these two substances are mixed in absolute alcohol, or benzene solution, a dark blood-red color appears, which is destroyed by acidification with the formation of bromodiiiododinitrobenzene and ethanetetra-carboxylic ester as the principal products. The red substance formed in this way shows considerable stability, if protected from water and acids. A specimen of the solution made with equal molecules of the components did not lose its color, or form any precipitate even after standing over two years in a sealed tube. In order to test its stability under more exacting conditions we made a preparation in benzene and alcohol with 4 molecules of the ester to one of the benzene compound, as we thought at that time this excess would favor the decomposition of the addition compound, but after standing 3 weeks no test for a sodium halide was obtained in the white precipitate, which had come down, and this was therefore only sodium malonic ester precipitated slowly by the benzene. To meet the objection that sodium iodide might have been formed but retained in colloid solution in the benzene,² the experiment was repeated with exactly the same result in absolute alcohol, where there is little chance of the formation of a colloidal solution. A fuller study led us to believe that varying the proportion of sodium malonic ester from 1 to 5 molecules had no effect upon the reaction, except that an excess made the red color appear sooner in benzene and alcohol, and the bromotriiododinitro-

¹ *Am. Chem. J.*, 46, 549 (1911).

² Compare Paal and Kuhn, *Ber.*, 39, 2859 (1906).

benzene dissolve more rapidly in alcohol, than when the reagents were used in equivalent amounts. Although the red solution was so stable in the cold, it decomposed, when heated for 2 hours, forming a considerable precipitate of sodium iodide whether in alcohol or in alcohol and benzene. It was necessary, therefore, to carry on all the evaporations in our experiments at ordinary temperatures, which greatly increased the tediousness of the work.

In our attempts to isolate the red addition compound we tried first to precipitate it from its benzene solution by the addition of other solvents, but without success, for although ligroin precipitated a red oil, this seemed less manageable than the residues left after evaporating off the benzene; and no other solvent produced any effect, if it was dry and free from acid. As it is a sodium salt we next tried to replace the sodium by some other metal in the hope of getting an insoluble product. For this purpose the red alcoholic solution was treated with silver nitrate, calcium chloride, ferric chloride, or mercuric chloride dissolved in absolute alcohol, but in no case was a precipitate formed.

The negative results of these experiments reduced as to obtaining the substance by evaporation, which was carried on to best advantage in a Hempel *vacuum* desiccator charged with fused potassium hydroxide. With this 175 cc. of a mixed benzene and alcohol solution were reduced to 15 cc. in about 20 hrs. instead of taking 3 days or more, as was the case when a common *vacuum* desiccator with sulfuric acid was used. We tried also passing a stream of air through the liquid from a capillary tube, while a *vacuum* was maintained, as in distillation under diminished pressure, but this worked no more rapidly than the Hempel desiccator, and was more apt to lead to decomposition because of the difficulty in removing all traces of moisture and carbon dioxide from so large a volume of air. The residues at first were red oils, or tars, which, after all the solvent had gone, were converted into amorphous viscous solids of a dark red color. If the process had succeeded, these showed no signs of crystallization; if it had not, white crystals were deposited in small amount, which were either unaltered bromotriiododinitrobenzene, or ethane-tetracarboxylic ester formed by carbon dioxide from the air. Such specimens were rejected. The result was the same, whether the reaction took place in benzene and alcohol, or in absolute alcohol alone.

After working on this substance for half a year one preparation containing a large excess of malonic ester deposited a few minute clusters of crystals, which looked black to the naked eye, but under the microscope appeared as red plates. As they looked not unlike iodine, they were carefully tested for this substance with negative results. They dissolved easily in alcohol with a red color, and kept between two sealed watch glasses apparently unaltered for nearly a year, after which they became

tarry. The quantity was too small for decisive study, but the appearance and properties justify the surmise that they were crystals of the addition compound. For a year and a half we tried by every modification of the process we could devise to get such crystals again, but have not even caught a glimpse of them. Substituting malonic methyl ester for the ethyl compound gave no better result in spite of the greater tendency of methyl compounds to crystallize.

Sodium Determinations Made with the Impure Addition Compound.—

As at first there seemed little chance of obtaining a pure specimen of the addition compound, we determined the amount of sodium in a preparation containing a known amount of the bromotriiododinitrobenzene. The results were even better than we had hoped.

The specimens were prepared in absolute alcohol, in which the red product is very soluble, whereas a series of determinations showed that 100 cc. of absolute alcohol dissolve of the bromotriiododinitrobenzene only 0.416 g. at 15°, 0.420 g. at 16°, 0.432 g. at 20°, and 0.440 g. at 21°. We proceeded as follows:

The clean sodium was weighed to milligrams in a weighing bottle under kerosene oil, and after drying quickly with filter paper was dropped into absolute alcohol, which, like all used in this work, had been distilled after treatment with a little sodium to remove the last trace of water. The malonic ester corresponding to the sodium was then weighed to centigrams, and also an amount of bromotriiododinitrobenzene, which gave one molecule of this substance for each molecule of the ester, and an excess more than enough to form a saturated solution with the amount of absolute alcohol used. The substituted benzene was first boiled with absolute alcohol, which dissolved only a small part of it, and after it had been cooled, the malonic ester was added, and finally the cool sodium ethylate solution. A dark red color appeared instantly, and after 5 minutes most of the solid had gone into solution. The flask was allowed to stand at about 20° for 2 or 3 days with occasional shaking to complete the reaction. Another flask was prepared with portions of the same specimens of bromotriiododinitrobenzene and absolute alcohol, and exposed to exactly the same conditions to determine the amount dissolved. At first very dilute solutions of the red compound were used, so that its presence might not change the solubility of the bromotriiododinitrobenzene. Later, stronger solutions were used, in which the correction for the dissolved bromine compound was much smaller in proportion to the amount of red product. As the two sets of corrected results agree with each other, the method of correcting for the presence of the dissolved benzene compound must be at least approximately accurate.

After the two flasks had stood for at least 3 days, the temperatures were taken, the contents filtered to remove undissolved bromotriiododinitrobenzene, and the filtrates kept in well-stoppered bottles, which as a further precaution were sealed with hard paraffin. 25 cc. of the filtrate were transferred to a platinum crucible and the solvent evaporated in a vacuum desiccator over sulfuric acid and a trace of potassium dichromate, as experiment had shown that evaporation on the steam bath decomposed the red substance. After most of the solvent had evaporated, a fresh portion of 25 cc. of the filtrate was added, and the process continued until a sufficient amount of residue had been obtained. The residue was brought to constant weight *in vacuo*—a very tedious process, as the viscous solid retained traces of the solvent obstinately. It was found later that the work would have gone less slowly with a potassium hydroxide

Hempel desiccator; as it was, the shortest of these determinations lasted 10 days. The weighed product was then treated with a little strong nitric acid and strong sulfuric acid in the cold. This must be done with great caution to avoid spattering, as the decomposition was attended with a vigorous effervescence. The sodium was then determined in the ordinary way. Before calculating the analyses the weight of substance was corrected by subtracting from it the weight of bromotriiododinitrobenzene contained in the same volume of the solvent, which had been submitted to the same conditions in the blank experiment.

Residue, 0.3725, 1.6648, 2.4136. Correction, 0.0622, 0.4662, 0.5080. Subst., 0.3103, 1.1986, 1.9056; Na_2SO_4 , 0.0284, 0.1016, 0.1653. Calculated for $\text{C}_6\text{BrI}_3(\text{NO}_2)_2\text{CHCO-NaOC}_2\text{H}_5\text{COOC}_2\text{H}_5$: Na, 2.85; found: 2.96, 2.75, 2.81.

The results agree with each other and with the theory better than we had expected.

Determinations of Halogens in the Impure Addition Compound.—In these analyses the quantity of sodium malonic ester used was so large that some of it remained undissolved in the solvent consisting of 1 part absolute alcohol to 12 of benzene (dried with sodium). The correction to be applied for the dissolved sodium malonic ester was determined by a parallel blank experiment in each case. In all other respects the procedure was the same as in the determinations of sodium. The halogen determinations were made by the method of Carius in a portion of the residue dried *in vacuo* to constant weight.

Residue, 0.3148, 0.3398, 0.3279. Correction, 0.1205, 0.1300, 0.1255. Subst., 0.1943, 0.2098, 0.2024; $\text{AgI} + \text{AgBr}$, 0.2191, 0.2368, 0.2248. Calc. for $\text{C}_6\text{BrI}_3(\text{NO}_2)_2\text{CHCO-NaOC}_2\text{H}_5\text{COOC}_2\text{H}_5$: I + Br, 57.08; found: 58.20, 58.34, 57.34.

The agreement here, although not so good as with the sodium, is as close as could be expected, when it is remembered that the correction may be seriously interfered with by the moisture and carbon dioxide of the air converting sodium malonic ester into the soluble free ester.

Fractionation of the Addition Compound.—To determine whether the red product was a compound or a mixture, and to obtain it, if possible, free from impurities, specimens of it were next divided into fractions according to solubility. Our first experiments aimed at preparing only 3 fractions. 3.86 g. of malonic ester and 15.1 g. of bromotriiododinitrobenzene (these are not far from molecular proportions) with 0.55 g. of sodium were allowed to react in a mixture of alcohol and benzene for at least 3 days, after which 175 cc. of the solution were evaporated in a Hempel *vacuum* desiccator charged with potassium hydroxide until its volume had been reduced to 10 cc. At this point sufficient solid had been deposited to render the liquid thick, and it was filtered. To secure the filtration of this viscous mass without decomposition by the carbon dioxide, or water in the air, the last part of the evaporation was carried on in a small Erlenmeyer flask, the neck of which fitted the platinum Gooch crucible to be used for the filtration. The hardened filter paper was carefully

fitted to the crucible, and the filtrate was received in a small test tube within the suction flask, which should not be too large. When the substance was ready for filtration, the Erlenmeyer flask was removed from the desiccator, stoppered, and fitted with a thin rubber hose on its neck; the stopper was then replaced by the inverted Gooch crucible with its suction flask, the adjustments being made as rapidly as possible. The suction was started, the apparatus inverted, and the filtration begun. It was found that even a good water pump did not give pressure enough to filter this viscous mass, so a powerful cylinder pump was used, but even with this the filtration lasted several hours. Fortunately, the dark red amorphous solid was not viscous enough to clog the filter. If the process had succeeded, the solid was completely soluble in a very small quantity of absolute alcohol. In some cases, however, it left a slight white residue of bromotriiododinitrobenzene. Specimens of these least soluble fractions from different preparations are numbered I and II in the analyses.

During the filtration the low pressure caused the evaporation of part of the filtrate, so that a second filtration gave a solid like the first, except that it showed a somewhat deeper red color. Specimens of such intermediate fractions are numbered III, IV, V in the analyses. When we tried to secure a third fraction in this way, very little solid was deposited, but we obtained a deep red liquid, which showed no sign of solidification on standing *in vacuo*, or by cooling with a freezing mixture. It was odorless, and mixed easily with benzene or alcohol. Analyses of such most soluble fractions are numbered VI and VII.

	I.	II.	III.	IV.	V.	VI.	VII.

A similar experiment with sodium malonic methyl ester gave a least soluble (VIII) and an intermediate fraction (IX).

VIII. Subst., 0.2265, IX, 0.2532 AgI + AgBr, 0.2735, 0.2908. Calc. for $C_6BeI_3(NO_2)_2CHCONaOCH_2COOCH_3$: I + Br, 59.19; found: VIII, 62.33; IX, 59.30.

The intermediate fractions, III, IV, V, and IX, agree sufficiently well with the percentage required by the formula. The less soluble fractions, I, II, VIII, seem to contain a slight impurity of bromotriiododinitrobenzene; the more soluble, VI and VII, one of sodium malonic ester.

A more elaborate fractionation on a larger scale was next undertaken with the object of breaking up the intermediate portion into smaller fractions, the analyses of which would settle the question, whether it was a homogeneous compound, and also, when this work was started, we had not given up the hope of obtaining the red compound in crystals.

A large amount of the red substance was made from equal molecules of the two reagents in a mixture of alcohol and benzene, and after standing 25 days, during which time no solid separated, was evaporated in a Hempel desiccator over potassium hydroxide, and fractionated systematically from absolute alcohol. 29 different fractions were separated—no light task even with the quicker evaporation in the Hempel desiccator, and in this way a large amount of material of intermediate solubility was obtained, which, judging from the results of the previous experiments, should consist of the pure addition compound. This presumably pure material was then divided into 4 fractions, X, XI, XII and XIII, of which the least soluble was X, the most soluble XIII. To show that the impurities had been removed in the preparation of the material for X to XIII, analyses are added of the most impure fractions rejected in making it, the least soluble being XIV, the most soluble XV. XIV and similar very impure least soluble fractions were pale red, and, when treated with absolute alcohol, left a white residue of unchanged bromotriiododinitrobenzene. All the other fractions were dark red and completely soluble in alcohol.

Calc. for $C_6BrI_3(NO_2)_2CHCONaOC_2H_5COOC_2H_5$: I + Br, 57.08.						

It seems to us that the inference to be drawn from the agreement between the analysis of the least soluble fraction X and the most soluble XIII is that the material, from which they were obtained, was a definite compound in a state of purity.

Properties of the Addition Compound, $C_6BrI_3(NO_2)_2CH(CONaOC_2H_5)(COOC_2H_5)$.—It is usually obtained as a very dark red amorphous solid, but on one occasion we think it appeared in clusters of needles so dark red as to look black. The solid can be kept as much as a year, if protected from the air, and its solution showed no sign of alteration after standing in a sealed tube for nearly 2 years. Water or an acid decomposes it, the product, in the latter case, being bromodiiiododinitrobenzene and iodomalonic ester (or if there is an excess of sodium malonic ester, ethanetetracarboxylic ester). Heat also decomposes the solution, forming a precipitate of sodium iodide. It is very soluble with a blood-red color in all the common organic solvents except ligroin, which precipitates a red oil from its solution in benzene and alcohol. 10 cc. of absolute alcohol dissolve more than 10 g. of the addition compound, and it seems to be equally soluble in benzene. To give an idea of its remarkable solubility we may say that 15 cc. of a mixture of absolute alcohol with some benzene held in solution 19.5 g. of it, and even when cooled

to -20° deposited no solid except a little benzene. On evaporating further the red solid appeared before the volume had been reduced to 10 cc. No salts containing other metals could be obtained from the addition compound.

CAMBRIDGE, MASS.

AZULENE, A BLUE HYDROCARBON. II.

By ALFRED E. SHERNDAL.

Received March 24, 1915.

Since the publication of the preliminary notice of the isolation of the remarkable new hydrocarbon which occurs in so many of the essential oils,¹ the following further work has been carried out, and is described below:

- (1) The preparation of a picrate, and its analysis.
- (2) The preparation of artificial blue oils from various oils of the sesquiterpene type.
- (3) The isolation and identification, by means of the picrate, of azulene from the blue sections of the oils of cubebs, camphor, and from the artificial blue gurjun oil.
- (4) The complete reduction of azulene to a colorless dihydrosesquiterpene.

The picrate is readily formed by combining the alcoholic solutions of its constituents, and crystallizes out almost immediately in the form of jet black, shiny needles, melting without decomposition at about 120° , and containing one mol of picric acid to one mol of azulene. This ready formation of a picrate is strong evidence that the hydrocarbon possesses an aromatic structure, since only this class of hydrocarbons has been found to yield additive compounds with picric acid, etc.² No true picrates of the hydroaromatic hydrocarbons have been prepared, the so-called picrates of pinene and thymene,³ being in reality picric acid esters, from which the original hydrocarbons cannot be regenerated. They also differ from the picrates of the aromatic hydrocarbons in conditions of formation, stability, etc. The picrate of azulene, on the other hand, resembles the true additive compounds of picric acid with the aromatic hydrocarbons in ease of formation, decomposition by water or dilute alkalis with regeneration of the original hydrocarbon, melting point, etc. It provides an excellent means of establishing the identity of the blue substances isolated from various oils, and of effecting a final and complete purification of the blue hydrocarbon.

³ Lextrait, *Compt. rend.*, 102, 555 (1886); Semmler, "*Die aetherischen Öle*," II, 253.

The method of preparation was as follows: To a solution of 1.0 g. picric acid in 20 cc. 95% alcohol, was added 1.0 g. azulene dissolved in 5 cc. alcohol. In a few minutes the mixture set to a mass of crystals which dissolved again when warmed on the water bath, and on cooling separated out in short, shiny, black needles. These were filtered off on the pump, and dried *in vacuo* over sulfuric acid. Yield, 0.73 g.; m. p. 118°. The picrate dissolves readily in alcohol, acetone and ether with a green color; in benzene and ethyl acetate with a blue color. The green color of the solutions is probably due to partial decomposition in the moist solvents. For the same reason, if dilute alcohol is used in the preparation, a substance with a lower m. p. is obtained, more or less contaminated by oil. Carbon tetrachloride and benzine dissolve out the azulene and leave the picric acid undissolved. To determine the amount of picric acid in the compound, it was decomposed by warm water containing a measured amount of barium hydrate, made up to definite volume, filtered, and the excess of barium hydrate determined by titrating an aliquot portion of the filtrate with standard hydrochloric acid, using phenolphthalein as indicator.

0.445 g. picrate, decomposed by warm water containing 17.6 cc. 0.1 *N* Ba(OH)₂, made up to 100 cc., filtered, and 50 cc. of the filtrate titrated with 0.1 *N* HCl. Required, 3.5 cc.

Found: 54.3% picric acid. Calc. for 1 mol picric acid: 53.5%; for 2 mol: 69.8%; for 1/2 mol: 36.6%.

The picrate accordingly contains one mol picric acid to one of the hydrocarbon.

The method of isolating azulene which was described in the first paper gives at least an approximation of the amount contained in the blue oil. As already shown, an intensely blue fraction which was examined, yielded about 0.28% azulene. Following the same procedure with a dark bluish green fraction of oil of cubebs, the amount of azulene which could be isolated amounted to only 0.03%. This shows strikingly enough how oils containing only a trace of the substance, might be intensely colored and still show the characteristics of a homogeneous substance. To give an idea of the color intensity of azulene, 0.064 g. of the pure hydrocarbon was dissolved in a liter of benzine, and an ammoniacal solution of copper sulfate made up to match it in depth of color. The latter solution contained 0.24 g. CuSO₄ to the liter and matched the azulene solution almost exactly both in depth and shade of the color, showing only a slightly less purple nuance.

The azulene was extracted from the oil of cubebs as follows: 250 g. of the oil were dissolved in 200 cc. of benzine, shaken out thoroughly in a separating funnel with 25 cc. of about 63% H₂SO₄, allowed to settle during a half hour, and the acid solution then drawn off. This was then

diluted with water, and extracted with benzine. The same operation was repeated three times, and the final extraction of the diluted acid made with ether. On evaporation of the ether, a residue of 0.073 g. was left, *i. e.*, 0.03% of the cubebs oil taken. This residue was mixed with a solution of 0.07 g. picric acid in 2 cc. absolute alcohol. The black crystalline mass which soon separated was recrystallized from a little alcohol, yielding then the characteristic black, shiny needles of azulene picrate, *m. p.* 122°.

The production of blue oils from products which do not originally show any blue color, has already been referred to. Wallach,¹ found that the hydrocarbon obtained by dehydrating guaïol with zinc chloride or phosphorus pentoxide, showed a strong blue color, and ascribed the color to the presence of a small amount of some substance containing oxygen. Gadamer,² in a similar manner, obtained a blue product by dehydrating atractylol, and noted also, that guaïene, by the absorption of oxygen, took on a blue color. α -Gurjunene, when heated under pressure with air or oxygen, yields a blue oil.³ All these colorations are undoubtedly due to the presence of small amounts of azulene, formed from the hydrocarbons by an oxidative process. Another reaction which produces azulene, was suggested in the previous paper, namely the action of sulfuric acid in acetic anhydride. By means of this reaction, blue oils were prepared from the oils of amyris, guaïac-wood, and gurjun, and from the latter azulene was isolated and identified by means of the picrate. The sesquiterpene fraction of oil of eucalyptus also gave a greenish blue oil, while from oil of cedar-wood and caryophyllene of clove oil the distillates showed no trace of blue or green color. The method of procedure was as follows:

10 cc. of gurjun oil were mixed with an equal volume of acetic anhydride and 2 cc. of strong sulfuric acid was added gradually, keeping the flask cool by ice water. A violent reaction took place; the mixture took on an intense purple color which changed to a dark blue, and sulfur dioxide was given off. After standing for some time, steam was passed through the acid mixture, and a distillate of 4 cc. of a dark blue oil was thus obtained. By extracting the azulene from this oil in the usual way, *i. e.*, by dissolving in benzine and extracting with 63% sulfuric acid, a yield of about 0.04% of the gurjun oil taken was obtained. The product gave a picrate which crystallized in coarse, black needles with blunt ends, melting at 122°. The blue oils from guaïac, amyris, and heavy eucalyptus sesquiterpene were made in the same way.

This is far from being a smooth reaction, which is not surprising con-

¹ *Ann.*, 279, 379 (1894).

² *Arch. Pharm.*, 241, 33 (1903).

³ *Ber.*, 47, 2252 (1914).

sidering the reagents used, but it shows, as do the other methods of producing blue oils, the nature of the reaction which results in the formation of azulene, namely, a splitting off of hydrogen by oxidative action, which results in the formation of new double bonds. In the terpene series we have the same reaction, that is, the oxidative removal of two hydrogen atoms from the compound $C_{10}H_{16}$, resulting in the formation of cymol, $C_{10}H_{14}$. This also is not a quantitative reaction, the yield of cymol being as a rule very low. But by such means the terpenes are converted into an aromatic molecule, which is structurally closely related to them. Now, all indications point to the conclusion that azulene also is an aromatic hydrocarbon. Its empirical formula, isomeric with the naphthalene homolog $C_{10}H_8$, C_8H_{10} , its picrate, its high specific gravity, its behavior towards sulfuric acid, are all evidence of aromatic structure. Once this is clear, the striking analogy between the conversion of the terpenes $C_{10}H_{16}$ on the one hand, to the benzene homolog cymol, and on the other hand the conversion of the sesquiterpene $C_{15}H_{24}$ to the aromatic molecule $C_{15}H_{18}$, isomeric with a naphthalene homolog, becomes immediately apparent. The similarity of the reactions by which these conversions are affected adds still more to the analogy. Compare, for instance, the formation of cymol from camphor, with the production of the blue oil from guaiol, both by the action of P_2O_5 ; the formation of cymol from turpentine by heating under pressure with CO_2 , with the formation of a blue oil by heating gurjunene under pressure with air or oxygen; the production of cymol from various terpenes by the action of sulfuric acid, with the formation of azulene by the action of sulfuric acid and acetic anhydride on various sesquiterpenes. The assumption is certainly not far-fetched that an analogous oxidative process takes place in all these cases, which although not smooth, yet from both classes of hydroaromatic compounds, tends to produce aromatic molecules of which the cyclic terpenes and sesquiterpenes, respectively, can be said to be hydro-derivatives. That the nucleus of the azulene molecule is not very different from that of the sesquiterpene from which it is produced, is indicated by the experiment described below, in which its reduction to a colorless dihydrosesquiterpene is effected.

If we could write formulae to illustrate the structure of the various types of sesquiterpenes, it would doubtless help to give an insight into the structure of azulene. The proposed formulae for the sesquiterpenes are, however, based upon such meager experimental evidence, that they cannot be accepted as in the slightest degree conclusive. Some experimental evidence of their close relation to the terpenes and isoprene, was given by Semmler,¹ who succeeded in identifying terpinene in the degradation products formed by heating the gurjunene sesquiterpenes under

¹ *Ber.*, 47, 2232 (1914).

pressure. In general they are assumed to be hydro-naphthalene derivatives. Semmler,¹ in reviewing the possible condensations of three isoprene molecules, brings into consideration, on the basis of unpublished experimental data, the formula

as the type of most of the sesquiterpenes, and states that this type can, under certain conditions, be readily converted into a naphthalene derivative. To another smaller class of sesquiterpenes he ascribes the type formula:

from which no naphthalene derivatives have as yet been obtained. It is evident that in these main types, pinene camphene, or tanacetone rings can take the place of ethylene bonds. The sesquiterpenes also probably include open chain and monocyclic compounds with a corresponding number of double bonds. The number of ethylene bonds, and consequently the ring structure, mono-, bi-, or tricyclic, is determined by the molecular refraction, and in recent times the elegant method of reduction by hydrogen in the presence of finely divided platinum or palladium, has provided an additional means for determining the state of unsaturation, the monocyclic sesquiterpenes being thereby reduced to the saturated molecule $C_{15}H_{30}$, the bicyclic to $C_{15}H_{28}$, the tricyclic to $C_{15}H_{26}$. By this method it was demonstrated that azulene is tricyclic, that is, it contains four double bonds. It was reduced quantitatively to the saturated molecule $C_{15}H_{26}$, which then showed the characteristics of a tricyclic dihydro-sesquiterpene. The reduction was carried out as follows:

¹ Ber., 36, 1038 (1903).

50 cc. of 50% alcohol and 0.2 g. of colloidal palladium were placed in a shaking flask connected with a gas buret, the whole apparatus filled with hydrogen at ordinary pressure, and shaken by a mechanical arrangement till no more hydrogen was absorbed. With a current of hydrogen running through the flask, 2.552 g. of azulene were introduced, the apparatus closed, and the shaking continued until the absorption of hydrogen ceased. The reduction required about twelve hours' shaking, the rate of absorption being uniform throughout and stopping suddenly. At 0° , 760 mm. about 1200 cc. hydrogen were absorbed. Calc. for H_8 : 1146 cc. When the reduction was complete, as shown by the sudden break in the absorption of hydrogen, the mixture was distilled in a current of steam and the oil collected in a narrow graduated tube. In this way were obtained about 2.5 cc. of oil with only a very faint green tint and the following constants:

Sp. gr. at 25° , 0.8935; n_{D20} 1.490, O. R. ≈ 0 .

The oil was insoluble in 63% sulfuric acid, gave an intense coloration with acetic anhydride containing a trace of sulfuric acid, and also with bromine in acetic acid solution.

Comparing these constants with those of other tricyclic dihydro-sesquiterpenes, it will be seen that the sp. gr. is considerably lower, indicating a differing structure. The color reaction also shows that we have to do with a peculiar structure.

The work of Deussen and Philipp,¹ Semmler and Spornitz,² Semmler and Jakubowicz,³ on the sesquiterpenes of gurjun oil, gives interesting data for comparison with the dihydro-sesquiterpene from azulene. Deussen and Philipp found that oil of gurjun consists of two sesquiterpenes. Semmler and Jakubowicz then showed that these were both tricyclic, the crude oil, on reduction by hydrogen and platinum, absorbing only two hydrogen atoms and yielding a dihydro product with sp. gr. at 20° 0.909; n_D 1.49; b. p. 115–117 at 7 mm. They succeeded further in separating the crude oil with the following characters: sp. gr. 0.922; O. R. -55° ; n_D 1.507, into the two tricyclic sesquiterpenes:

β -Gurjunene; sp. gr., 0.9348; O. R. $+74.5^{\circ}$; n_D 1.50275. α -Gurjunene, sp. gr., 0.918; O. R. -95° .

The β -gurjunene, which forms about 33% of the oil, resembles cedrene closely, but is not chemically identical. It does not give the color reactions characteristic of crude gurjun oil, and yields no blue oil on heating under pressure. Its reduction product by hydrogen and platinum has the characters:

Sp. gr., 0.9258; n_D 1.49775; b. p., 120° at 8 mm.

¹ *Ann.*, 374, 105 (1910).

² *Ber.*, 47, 1029 (1914).

³ *Ibid.*, 47, 1141 (1914).

α -Gurjunene gives the color reactions of the crude oil, and on heating under pressure with air or oxygen yields a blue oil.

From these data the approximate constants of the dihydro- α -gurjunene can be derived: Sp. gr. at 20° 0.900; n_D 1.492, which agree with those of the dihydro derivative from azulene. Summing up the characteristics of α -gurjunene, we find: (1) it gives the color reactions characteristic of crude gurjun oil; (2) it yields azulene on heating under pressure with oxygen; (3) it is reduced to a tricyclic dihydro-sesquiterpene with constants and chemical behavior such as color reactions, similar to those of the reduction product from azulene. All these properties differ from those of other tricyclic sesquiterpenes such as β -gurjunene and cedrene. It is possible that other sesquiterpene types may be inverted by the reagents used, and so show some of the same properties.

It seems quite probable, however, that the α -gurjunene is the type which produces azulene, and that the dihydro-sesquiterpene formed by the complete reduction of azulene is identical with dihydro- α -gurjunene, although further experiments are necessary to demonstrate any such identity.

In the present state of our knowledge of the structure of the sesquiterpenes and the experimental data on azulene, an attempt to ascribe a structural formula to the latter is necessarily purely speculative. Certain bases for a discussion of the possibilities are, however, not lacking, for instance:

- (1) It is closely related to the sesquiterpenes in structure, as shown by the mode of formation and its reduction product.
- (2) It is tricyclic and consequently contains four ethylene bonds.
- (3) It possesses an aromatic nucleus, indicated by the ready formation of a picrate.
- (4) It contains no hydroaromatic conjugate double bonds, since it is not reducible by sodium in alcohol.
- (5) It has a peculiar arrangement of the double bonds which accounts for its intense color, such color intensity being exhibited by no hitherto discovered hydrocarbon.

If we take, for the time being, the type formulae suggested by Semmler, and consider the possibilities of oxidizing to a tricyclic, tetra- or pentocyclic molecule $C_{15}H_{18}$, which could be reconciled with the above requirements, we arrive at structures such as the following:

Whether or not the azulene molecule has some such structure, can only be determined by further study, perhaps from its oxidation products. Its formation from the sesquiterpenes can aid but little in this direction, so long as their structure is so little known, but a synthesis from substances of known structure does not seem impossible. In this connection the formation of the blue oil by the dry distillation of calcium adipate, (Hentschel and Wislicenus),¹ is interesting. Such a synthesis would seem to give the greatest promise in indicating the structure of this remarkable substance, and would at the same time give additional evidence as to the structure of the sesquiterpenes to which it is related.

Two obvious typographical errors crept into the first article on azulene, in connection with the molecular weight determination (p. 169). This determination was made by Dr. Farnau of New York University, and the values found agreed well with those calculated for $C_{15}H_{18}$, 198.

THE CONSTITUTION OF THE SO-CALLED DITHIOURIMIDO-ACETYLACETONE.

BY WILLIAM J. HALE.

Received April 8, 1915.

The principal product resulting from the condensation of urea and acetylacetone has been called by Evans² acetylacetone-urea. The constitution of this substance, a 2-ketopyrimidine, has been thoroughly investigated by de Haan and others.³ At the same time de Haan recognized in the reaction product the presence of two new distinct substances. One of these new compounds was found to be a 2-ketopyrimidine-urea and identical in all respects with the second product which Evans had obtained by the use of a slightly acid condensing medium, and to which he had assigned the structure corresponding to a diurimido-acetylacetone. In all cases it is to be assumed that, during these condensations, one molecule of acetylacetone and one molecule of urea proceed directly to the formation of a pyrimidine ring, and that afterwards another molecule of urea condenses with this pyrimidine ring to form either a simple ureide derivative or a second ring leading to a compound of the diureino type.

According to Evans, the principal product in the condensation of thio-urea and acetylacetone is a 2-thiopyrimidine [II] (acetylacetone-thio-urea). By use of a small amount of acid he further secured the product corresponding to his diurimido-acetylacetone, namely, dithiourimido-

¹ *Ann.*, 275, 312 (1893).

³ *Rec. trav. chim.*, 27, 162 (1908); *THIS JOURNAL*, 36, 104 (1914).

acetylacetone (I). This 2-thiopyrimidine has lately¹ been shown to be possible of existence in a tautomeric form (III) but to a much less extent than that of the 2-ketopyrimidine. The dithiourimido product, however, received but little attention by Evans and has been known only in the form of a salt. It seemed more than likely that the products obtained from urea and acetylacetone might find their counterparts in the condensation mixtures from thiourea and this same ketone; consequently, a study of this condensation was undertaken to establish the exact constitution of Evans' dithiourimido-acetylacetone and at the same time to search for a third product of the diureino type (VI). The outlines of these condensations are given first as described by Evans in (I) and (II), and later as here to be interpreted in the light of previous work, especially that of de Haan² upon acetylacetone and the analogous substance urea.

¹ THIS JOURNAL, 37, 594 (1915).

² Loc. cit.

The distinctive property of acetylacetone-thiourea in failing to release its sulfur atom, even by prolonged action of such desulfurizing agents as mercuric oxide and basic lead acetate, distinguishes this type of sulfur directly bound to the ring as markedly different from that form usually present in a side chain and so readily split off by these same agents; on the other hand, this property stamps it as closely similar to sulfur held within the ring itself. This inactivity of the sulfur atom is due to the presence of the strongly negative nitrogen atoms at either side of the carbon which holds it. When one of these nitrogen atoms carries an alkyl substituent¹ this property is lost and the sulfur can be completely removed. The action of chloroacetic acid,² however, is sufficient to remove this sulfur even in the firmly bound condition previously described. Prolonged boiling of an aqueous solution of acetylacetone-thiourea and chloroacetic acid yielded acetylacetone urea.³

The product prepared by Evans and called dithiourimido-acetylacetone (I) was obtained, as a hydrochloride, when just a few drops of conc. hydrochloric acid were added to an absolute alcoholic solution of the reacting components. The free base is most readily prepared by gently warming a concentrated aqueous solution of thiourea (2 mol) and acetylacetone (1 mol) at the temperature of the steam bath. This product is of a light yellow color and when converted into a hydrochloride by the action of hydrochloric acid affords a salt which corresponds exactly to the hydrochloride obtained by Evans, melting at 219°. The method employed by Evans leads to the formation of both this product just mentioned and the hydrochloride of acetylacetone-thiourea, hence it is not to be recommended. The free base prepared directly and in comparatively pure state is always yellow, but when allowed to form by a slow condensation, without the aid of heat and in the dark, possesses a much lighter yellow color. There is, however, no other point of difference between the products.

This so-called dithiourimido-acetylacetone readily gave up a part of its sulfur to mercuric oxide. In order to remove all of the sulfur the prolonged action of chloroacetic acid in aqueous solution was employed. From the reaction product was obtained a good yield of 2-ketopyrimidine-urea (VII) melting at 197° and in every respect identical with the product formerly known as diurimido-acetylacetone. Desulfurization must have proceeded as here shown.

The structure, therefore, is clearly indicated by this transformation into the well-known 2-ketopyrimidine-urea. In order to check this point there remained only to condense one molecule of thiourea with acetyl-

¹ Hale and Williams, *THIS JOURNAL*, 37, 599 (1915).

² Wheeler and Liddle, *Am. Chem. J.*, 40, 549 (1908).

³ Hale and Williams, *THIS JOURNAL*, 37, 598 (1915).

acetone-thiourea and obtain the original product. This condensation proceeded well when these two substances were brought together in concentrated aqueous solution without the presence of condensing agent. The light yellow precipitate formed was identical in all respects with the so-called dithiourimido-acetylacetone, or 2-thiopyrimidine-thiourea, melting at 192° . There can be, therefore, no doubt as to the structure of the compound—that of a monothioureide of the base acetylacetone-thiourea. In the presence of strong acids in alcoholic solution, Evans obtained the more or less insoluble salts of acetylacetone-thiourea. When, however, acids are absent the aqueous, as well as alcoholic, solution of these reacting components favors the formation of the less soluble thiopyrimidine-thioureide. In the absence of alcohol, water and other condensing media, thiourea and acetylacetone yield both the thiopyrimidine and the thiopyrimidine-thioureide, but chiefly the latter, owing to its greater insolubility in acetylacetone itself.

Since the structure of dithiourimido-acetylacetone found its counterpart in the structure of 2-ketopyrimidine-urea, there seemed a possibility that a third product might be expected to accord with a 2,4-dithioureino-pentane, Formula VI. The analogous keto derivative was found to be present in very small quantities in the reaction product obtained by heating urea and acetylacetone upon a water bath. It remained always as the portion insoluble in alcohol. de Haan obtained small portions of this substance, decomposing at 290° , when urea and acetylacetone were allowed to condense in aqueous solution. Thiourea and acetylacetone were heated together under many conditions of temperature and pressure and scarcely a trace of a portion insoluble in alcohol could be procured. Several months' standing of absolute alcoholic solutions of thiourea and acetylacetone did yield a product practically insoluble in alcohol. This substance decomposed at 265° and refused to release its sulfur to mercuric oxide or basic lead acetate. Prolonged action of chloroacetic acid removed all of the sulfur and converted it into the 2,4-diureinopentane (VIII) of de Haan, decomposing at 290° .

The third possibility, therefore, in the condensation of thiourea and acetylacetone is fulfilled and a two-ring compound produced. The

great difficulty in producing any appreciable amount of this dithioureine would seem to rest upon the increased difficulty for the 2-thiopyrimidine-thiourea (IV) to undergo further transformation to yield another imino nitrogen (V), a necessary step preliminary to the second ring formation (V) to (VI). As previously reported¹ the stable form of 2-thiopyrimidine itself is undoubtedly quinoid in structure, and this transformation of the ring to produce a second imino form would be attended with greater and greater difficulty.

Experimental Part.

When concentrated sulfuric acid is added to an alcoholic solution of acetylacetone and thiourea, crystals of acetylacetone-thiourea hydro-sulfate soon make their appearance. The constitution and properties of the free base, liberated by the action of barium carbonate upon this salt, have previously been described.¹ On the other hand, when only a very small quantity of acid is used as the condensing agent in this reaction there results, according to Evans, a salt of dithiourimido-acetylacetone. This latter will now be described as a thiopyrimidine-thioureide.

6-Thioureido-4,6-dimethyl-2-thio-1,2,5,6-tetrahydropyrimidine (IV).—The condensation of thiourea and acetylacetone, upon the addition of a few drops of concentrated hydrochloric acid to the absolute alcoholic solution, resulted in the slow formation of a hydrochloride melting at 219°. Three days were required for the completion of the reaction as described by Evans. Under these conditions, however, a variable amount of acetylacetone-thiourea hydrochloride is always formed and naturally constitutes a part of the crystalline product. Many crystallizations are necessary to remove the last traces of this latter salt. As the free base from the former salt was not isolated by Evans, it seemed advisable to attempt its preparation by a condensation in the absence of acids. Accordingly thiourea and acetylacetone were brought together in an alcoholic as well as in an aqueous solution and in each case, after a few days, small, yellow crystals of the free base appeared. The slight solubility of thiourea in absolute alcohol materially lessened the quantity of condensation product formed, but with water as the medium a relatively large yield was obtained. Dur-

¹ *Loc. cit.*

ing this condensation in aqueous solution a considerable portion of colorless crystals of thiourea separate, but with the gradual increase in amount of thioureide precipitated a further solution of thiourea and subsequent condensation proceeds. After several weeks' standing in the dark an excellent yield of light lemon-yellow monoclinic prisms was removed. Gently warming the reaction mixture to effect complete solution from time to time, secures a more rapid conversion of thiourea into the final product; consequently, the following procedure was adopted as giving the best results.

Three grams (2 mol) of thiourea were dissolved by warming in 5 cc. of water and 2.5 g. (excess of 1 mol) of acetylacetone added. The test tube containing the mixture was then sealed and placed in a steam bath (98°) from 10 to 12 hours. Upon cooling the reaction mixture, 3.3 g. of yellow condensation product separated and from the mother liquor an additional 0.6 g. was collected, bringing the percentage of yield to 91% of the theoretical. The color of this product was of a more decided yellow than that possessed by the free base resulting through a slow condensation in the dark. Repeated crystallizations under varying conditions failed to reduce materially this yellow color of the product, whereas with the light lemon-yellow colored product, repeated crystallizations rendered it almost, but never quite, colorless. These two products are, however, identical in crystalline form and in all other respects. The melting point of this thiopyrimidine-thioureide is 192°. 4,6-Dimethyl-2-thiopyrimidine-thiourea is fairly soluble in water or alcohol, crystallizing from either, but better from the latter, in monoclinic prisms. It is only slightly soluble in acetone and practically insoluble in chloroform, ethyl acetate, benzene, ether or ligroin.

An aqueous solution of this substance readily blackens mercuric oxide or basic lead acetate—a point distinguishing it at once from acetylacetone-thiourea, and indicating the presence of a free thioureide group.¹

The formation of this thiopyrimidine-thiourea presupposes the intermediate formation of a thiopyrimidine in the reaction mixture and the subsequent condensation of this product and a second molecule of thiourea. The thiopyrimidine that must be formed, *i. e.*, acetylacetone-thiourea, is very soluble in chloroform and hence may readily be removed from mixtures of these substances when present. Under the conditions of the reactions here given the final crystalline products, by extraction with chloroform, failed to show the presence of any acetylacetone-thiourea. The presence therefore of water alone (and alcohol as well) as condensing medium, may be looked upon as facilitating the production of this thiopyrimidine-thiourea at the expense of the thiopyrimidine in process of formation.

¹ *Loc. cit.*

When a solution of 1 part of thiourea in 10 parts of acetylacetone alone is heated to boiling under a reflux condenser for 5 or 6 hours and then allowed to stand several days, these same yellow crystals of the thiopyrimidine-thiourea make their appearance. With less decomposition the same end is accomplished by warming the two ingredients in a sealed test-tube for 24 hours at about 98° (steam bath). The yellow prisms begin to separate during the heating, and upon cooling they are precipitated in an excellent state of purity. Washing with cold water removed no trace of thiourea. One gram of thiourea and 10 g. of acetylacetone yielded thus 1 g. of the thiourea crystals. When the red mother-liquor was evaporated to dryness upon a steam bath and the residue digested with chloroform, about 0.6 g. of the intermediate acetylacetone-thiourea was dissolved out. The portion insoluble in the chloroform (0.2 g.) consisted of the thiourea alone and increased its production in this case to 1.2 g. We may conclude, therefore, that the absence of water in the condensing medium makes possible the formation of both products: acetylacetone-thiourea and thiopyrimidine-thiourea, and that the favored formation of the latter, even in the presence of so large an excess of acetylacetone, is undoubtedly due to its slight solubility in this medium.

Preparation of 2-Thiopyrimidinethiourea from Acetylacetone-thiourea.

—When conc. aqueous solution of thiourea (1 mol) and acetylacetone (1 mol) are brought together at room temperature, prisms of thiopyrimidine-thiourea soon separate. These crystals when purified melt at 192° and are identical with the product obtained by condensing 2 molecules of thiourea and 1 molecule of acetylacetone in aqueous solution. The possibility of a molecular type of compound between these two component parts was at once dismissed. Many crystallizations from various solvents as well as many extractions with chloroform (in order to withdraw the readily soluble acetylacetone-thiourea portion) proved futile. The product is without water of crystallization.

0.1346 g. subst. gave 0.1912 g. CO_2 and 0.0686 g. H_2O .

Calc. for $\text{C}_7\text{H}_{12}\text{N}_4\text{S}_2$: C, 38.85%; H, 5.59%. Found: C, 38.75%; H, 5.70%.

In order to identify the hydrochloride obtained by Evans according to his mode of condensation, a portion of thiopyrimidine-thiourea was dissolved in water and treated with a little concentrated hydrochloric acid. The hydrochloride thus prepared crystallized from alcohol in irregular yellow prisms melting at 219° , checking exactly the observations reported by Evans. An analysis also accorded with the same result. There can be no doubt, therefore, as to the identity of the two products as hydrochlorides and hence, also, as free bases.

0.2220 g. HCl salt gave 0.1252 g. AgCl.

Calc. for $\text{C}_7\text{H}_{12}\text{N}_4\text{S}_2 \cdot \text{HCl}$: HCl, 14.42%. Found: HCl, 14.35% (Evans, 14.06%).

Replacement of Sulfur by Oxygen.—When 1 g. of thiopyrimidine-thiourea is boiled with 1.5 g. of chloroacetic acid in 15 cc. of water for five hours under reflux condenser, the sulfur atom of the thioureide side chain, as well as that directly united to the pyrimidine nucleus, is replaced by oxygen. The reaction mixture, evaporated to dryness, was extracted with absolute alcohol and the residue almost neutralized with potassium hydroxide solution, when it was again evaporated to dryness over the steam bath and the final residue extracted with benzene. Colorless crystals melting at 197° were obtained upon removal of the benzene. This substance proved to be identical with the 2-ketopyrimidine-urea (VII) of de Haan. Mixtures of the two showed this constant melting point and their solubilities also exactly accorded. de Haan¹ proved that urea and acetylacetone-urea condensed in alcoholic solution to produce this product melting at 197° and thus further proof of the constitution of the analogous thiopyrimidine-thiourea is established.

2,4-Dithioureinopentane (VI).—In repeating the work of earlier investigators de Haan showed that when urea and acetylacetone were heated together a very small quantity of a substance insoluble in alcohol could be obtained. The formula he assigned to this product is that of a 2,4-diureinopentane (VIII) and resulted upon the further intramolecular condensation of 2-ketopyrimidine-urea. In working upon thiourea and acetylacetone alone, no appreciable amount of a similar substance could be prepared. This type of compound, however, was isolated in three or four instances where thiourea and acetylacetone in absolute alcoholic solution had been allowed to stand in stoppered tubes over the summer months, more or less exposed to the sunlight. The dark yellow crystalline mass was powdered and extracted with boiling absolute alcohol. The alcohol removed the thiopyrimidine-thiourea, but left undissolved a colorless crystalline product insoluble in practically all reagents. It is only slightly soluble in acetone or water, but of course soluble in acids. It may be crystallized from acetylacetone in which it is fairly soluble. The decomposition point is about 265° .

0.1142 g. subst. gave 27.3 cc. N_2 (25.5° and 746.6 mm. over H_2O).
Calc. for $C_7H_{12}N_4S_2$: N_2 , 25.91%. Found: 26.08%.

As this substance does not blacken mercuric oxide, we may consider that its two sulfur atoms are in two separate positions similar to that one already indicated for 2-thiopyrimidine. By the action of chloroacetic acid, however, the compound is freed of all sulfur. The aqueous chloroacetic acid solution, after five hours' boiling with this product, was evaporated to dryness, extracted with absolute alcohol and the residue treated with moist silver oxide and again evaporated. Extraction of the final

¹ *Rec. trav. chim.*, 27, 175 (1908).

product with water gave a colorless substance, identical with that compound decomposing at 290° and obtained by de Haan as stated above.

It is exceedingly difficult to procure any appreciable quantity of this dithioureinopentane. The greater ease by which the diureinopentane may be procured is, in one respect at least due to the practical insolubility of this latter product in acetylacetone.

For the kind assistance of Mr. Frank C. Vibrans upon the analytical data in this paper the author desires to express his indebtedness.

INOSITE AND PINITE AND SOME OF THEIR DERIVATIVES.

BY EDWARD G. GRIFFIN AND J. M. NELSON.

Received April 12, 1915.

Inosite and its derivatives possess considerable interest. The sugar itself is interesting, due to its wide occurrence in nature and possible important physiological functions, and also due to its close relationship in chemical constitution to the hexoses and some hydroaromatic compounds. The synthesis of the derivatives of inosite, when compared to the synthesis of the analogous derivatives of a substance like glucose, affords a comparison of the effect on the properties of a hexose in which the carbons are arranged in the form of a closed ring instead of an open chain. The derivatives might also prove valuable in the study and synthesis of many complex substances like phytin and some of the tannins, which yield, on decomposition, inosite or closely related products like phloroglucin and quinic acid, $C_6H_7(OH)_4COOH$.

Derivatives of inosite mentioned in literature prior to this investigation are: the hexacetate, hexabenzoate,¹ hexa- and trinitrates,² monobromopentacetate, two isomeric dibromotetraacetates, and mono- and dibromohydrins.³ While this work was in progress, Müller published a second article describing a triacetate, three isomeric chlorohydrin-pentacetates, a chlorohydrintriacetate, a chlorohydrin, two new isomeric inosites, which he called iso and ψ ; and an iso-inosite hexacetate and tetrabenzoate.⁴

By the action of acetyl bromide on inosite the following products were obtained: Bromopentacetylcyclohexanpentol, $C_6H_5Br(OCOCH_3)_5$;⁵ two

¹ Maquenne, *Compt. rend.*, **104**, 297 (1887).

² Vohl, *Ann.*, **101**, 55 (1857).

³ Müller, *J. Chem. Soc.*, **91**, 1780 (1907).

⁴ *J. Chem. Soc.*, **101**, 2383 (1912).

⁵ The names ascribed to the esters and derivatives of inosite mentioned in literature are sometimes not satisfactory, and for that reason the Geneva system of nomenclature has been adopted.

isomeric dibromotetracetylcyclohexantetrols, $C_6H_6Br_2(OCOCH_3)_4$, called α and β for distinction in name; dibromocyclohexantetrol, $C_6H_6Br_2(OH)_4$; dibromodiacetylcyclohexantetrol, $C_6H_6Br_2(OH)_2(OCOCH_3)_2$; dibromotriacetylcyclohexantetrol, $C_6H_6Br_2(OH)(OCOCH_3)_3$; and tribromotriacetylcyclohexantriol, $C_6H_6Br_3(OCOCH_3)_3$. The first four products mentioned were identical with those obtained by Müller by glacial acetic acid, hydrogen bromide and hexacetylcyclohexanhexol, although the melting points of three of them were different.

Acetyl chloride gave products, none of which appeared to be identical with those obtained by Müller. They are: chloropentacetylcyclohexanpentol, $C_6H_6Cl(OCOCH_3)_5$; α - and β -dichlorotetracetylcyclohexantetrol, $C_6H_6Cl_2(OCOCH_3)_4$; and dichlorocyclohexantetrol, $C_6H_6Cl_2(OH)_4$. Another substance, probably dichlorodiacetylcyclohexantetrol, $C_6H_6Cl_2(OH)_2(OCOCH_3)_2$, was also obtained.

Many additional organic acyl derivatives were also prepared. Besides hexacetylcyclohexanhexol and hexabenzoylcyclohexanhexol, two isomeric hexacetylcyclohexanhexols which have been distinguished in name by the prefixes, α and β ; pentabenzoylcyclohexanhexol, $C_6H_6(OH)(OCOC_6H_5)_5$; tetrabenzoylcyclohexanhexol, $C_6H_6(OH)_2(OCOC_6H_5)_4$; hexanisylcyclohexanhexol, $C_6H_6(OCOC_6H_4OCH_3)_5$; pentanisylcyclohexanhexol, $C_6H_6(OH)(OCOC_6H_4OCH_3)_5$; hexacinnamoylcyclohexanhexol, $C_6H_6(OCOC_2H_2C_6H_5)_5$; two isomeric pentacinnamoylcyclohexanhexols, α and β , $C_6H_6(OH)(OCOC_2H_2C_6H_5)_5$; hexa-*m*-nitrobenzoylcyclohexanhexol, $C_6H_6(OCOC_6H_4NO_2)_5$; and penta-*m*-nitrobenzoylcyclohexanhexol, $C_6H_6(OH)(OCOC_6H_4NO_2)_5$, were obtained.

Up to the time of this investigation, no alkyl derivatives of inosite had been synthesized. By alkylation of inosite and subsequent purification by means of the intermediate alkyl acetyl derivatives, the following were obtained: monomethylcyclohexanhexol, $C_6H_6OCH_3(OH)_5$; a syrup, probably dimethylcyclohexanhexol, $C_6H_6(OCH_3)_2(OH)_4$; diethylcyclohexanhexol, $C_6H_6(OC_2H_5)_2(OH)_4$; and a syrup, probably monoethylcyclohexanhexol, $C_6H_6OC_2H_5(OH)_5$. Others were obtained as syrups, but so far not sufficiently pure to definitely decide on their true composition. The alkyl acetyl derivatives obtained were, pentacetylmethylcyclohexanhexol, $C_6H_6OCH_3(OCOCH_3)_5$; tetracetyldimethylcyclohexanhexol, $C_6H_6(OCH_3)_2(OCOCH_3)_4$; pentacetylethylcyclohexanhexol, $C_6H_6OC_2H_5(OCOCH_3)_5$; tetracetyldiethylcyclohexanhexol, $C_6H_6(OC_2H_5)_2(OCOCH_3)_4$; and triacetyldimethylcyclohexanhexol, $C_6H_6(OCH_3)_2(OH)(OCOCH_3)_3$.

From pinite itself the following acyl derivatives were also prepared: pentacetylmethylcyclohexanhexol, $C_6H_6OCH_3(OCOCH_3)_5$; pentabenzoylmethylcyclohexanhexol, $C_6H_6OCH_3(OCOC_6H_5)_5$; pentanisylmethylcyclo-

hexanhexol, $C_6H_5OCH_2(OCOC_6H_4OCH_2)_5$; and pentacinnamoylmethylcyclohexanhexol, $C_6H_5OCH_2(OCOC_2H_2C_6H_5)_5$.

Nitration and alkylation yielded syrups, which could not be crystallized and so far have not been identified.

In treating pinite with acetyl bromide, as was done in the case of inosite, no halide esters of pinite were obtained but, instead, halide esters of inosite. This shows that the methoxy groups were attacked by the acetyl bromide as well. The following inosite esters were obtained: α - and β -dibromotetracetylcyclohexantetrol and dibromocyclohexantetrol.

The object in the beginning of this investigation was the synthesis of inosite or compounds closely related to it. However, all the attempts proved unsuccessful, and their descriptions are only indicated briefly as follows:

1. Aldolization between the carbonyl and primary alcohol groups in glucose.

2. Removal of hydrogen bromide from bromotetracetyl glucose.

Attempts were also made to repeat the work of Rosenstiehl,¹ in which he claimed to have obtained sugars by treating benzene hexachloride with silver acetate, but no reaction was found to take place.

Neither was it possible to repeat the work of Carius,² who prepared a cyclic sugar, phenose, $C_6H_{12}O_6$, by the hydrolysis of benzene trichlorohydrin, $C_6H_5(\text{Cl OH})_3$.

Having failed to obtain any information as to the stereo-configuration of inosite by tying up the end carbon atoms of an open chain hexose molecule, the opposite was undertaken. It was hoped to pass from inosite to a hexose by opening the ring as follows:

¹ *Compt. rend.*, **54**, 178 (1862).

² *Ann.*, **136**, 323 (1866).

and thus the stereo-configuration might be established by noticing the particular hexose formed.

As yet, the identity of the products obtained has not been ascertained and will be further investigated.

Experimental Part.

Although the synthesis of inosite in this laboratory has thus far been unsuccessful, "steep water,"¹ a by-product obtained in the manufacture of corn products, has been found to offer a source for inosite in sufficient quantities for the study and preparation of several of its derivatives.

Procedure: In a vat containing 42 liters of "steep water," (sp. gr. 1.246) were poured 125 liters of boiling water containing 20 kg. of barium hydroxide. The precipitate was separated by means of a filter press and washed till the filtrate was colorless. The press cake obtained was transferred to a vat and stirred with 40 liters of water containing 12 kg. of commercial sulfuric acid. The dark red mixture was pumped through a filter press and washed with water till the filtrate totaled 100 liters. The solution was then evaporated to 12 liters, giving a heavy reddish black liquid (sp. gr. 1.484, b. p. 125°), containing approximately 33% sulfuric acid. This liquid was divided into eight portions of 1500 cc. each. A portion was placed in a tall meal jar and heated in a steam digester under a pressure of 5 atmos. at 150° for 4 hours. The resulting black liquid was diluted with water, filtered from the carbonaceous material and thoroughly washed. The red solution was diluted to 9 liters, three equal portions of which were placed in large jars. To each were added 5 liters of a hot aqueous solution, containing 1300 g. of barium hydroxide, and the resulting curdy, grayish precipitate vigorously stirred. The precipitate was filtered through large fluted filter papers with parchmented tips, and washed by boiling with water. The combined pale yellow filtrates were evaporated to 400 cc., yielding a dark, reddish green fluorescent liquid. While still hot, 1200 cc. of glacial acetic acid were added, which caused the inosite to separate on cooling. To complete the crystallization, the mixture was placed in the ice box over night. It was filtered by suction and washed with glacial acetic acid, which dissolved out the coloring matter, and finally with alcohol. A beautiful, white, crystalline product of practically pure inosite remained. Yield, 46 g.

The use of glacial acetic acid in precipitating the above solution was found to be very advantageous, since it removes the gums and coloring matter, which alcohol does not do. For the further purification of inosite, the following method was found to work satisfactorily: Fifty grams of crude inosite were dissolved in 200 cc. of water, a few drops of sulfuric

¹ The steep water was kindly furnished by the Corn Products Refining Company. Its use as a source for the preparation of inosite was suggested by Dr. A. R. Rose, recently of the New York Agricultural Experiment Station.

acid added to remove any barium, the solution was concentrated to 75 cc. and alcohol added to turbidity. When cold, 200 cc. of alcohol and 50 cc. of ether were added and the mixture placed in the ice box over night. The inosite separated nearly quantitatively in little, feathery crystals, melting at 225°.

Each of remaining seven portions were treated in the same manner. Some additional inosite was obtained from the acetic acid and alcoholic mother liquors, giving a total yield of 368 g.

Inosite, containing two molecules of water, crystallizes from water or dilute acetic acid in colorless rhombic prisms, melting at 225°, and charring slightly above this temperature. It is optically inactive and unfermentable.

Action of Acetyl Bromide on Inosite.

The fact that glucose and acetyl bromide yield bromotetracetyl glucose suggested that halide esters of inosite might be obtained in a similar manner. Accordingly, inosite was treated with acetyl bromide but only hexacetylcyclohexanhexol was obtained. It proved, however, to be an excellent method for the preparation of hexacetylcyclohexanhexol, giving better yields in a shorter time than by any of the methods heretofore used.

Acetylation of Inosite by means of Acetyl Bromide.—Three grams of dry inosite and 18 g. of acetyl bromide were gently heated together in a flask connected with a ground-in glass condenser. In ten minutes, a clear, red solution resulted which was slowly poured into water, whereupon a semicrystalline mass separated. The mass was filtered off and recrystallized from hot alcohol as a scaly crystalline product. Yield, 7 g. No lower acetylated derivatives were obtained from the mother liquors.

Since inosite is not easily decomposed by concentrated acids under pressure, the reaction was also carried out in a sealed tube. Under these conditions, however, no hexacetylcyclohexanhexol was obtained, but, instead, several bromo esters of inosite.

In a large glass tube, immersed in a freezing mixture in order to retard the reaction until the tube was sealed, 25 g. of inosite (dried at 110°) and 100 g. of acetyl bromide were placed. The sealed tube was heated for 6 hours at 120°. Care was taken in opening the tube to prevent loss of the contents due to frothing. The dark red syrup together with the glass tube, which was broken in pieces to regain the adhering syrup, was transferred to a flask and the mass evaporated in a vacuum on a water bath. The residue was taken up with a little absolute alcohol and again evaporated and finally crystallized from a large amount of alcohol. The crystals were dried on a porous plate and gave a yield of 18 g. and were designated (A). On evaporating the filtrate to half its volume by means of a current of air, a precipitate of smaller crystals gradually separated. These were filtered off and amounted to 12 g. (B). The dark red filtrate was further concentrated by a current of air to the point at which an oil began to form. Five grams of a crystalline precipitate (C) were obtained. The filtrate now measured about 75 cc. and on standing over night separated into two layers. The upper, a light red solution having a strong odor of ethyl acetate yielded 2 g. of a fine crystalline product (D). The lower layer was a black oil. This was combined with the filtrate from (D), alcohol and animal charcoal were added, and the mixture boiled for 6 hours. A pale yellow solution (E) was obtained, which did not crystallize. It was placed in the ice box over calcium chloride for a few days.

The various portions were mixtures and were best separated by fractional crystallization from alcohol. As there was no well-defined line of separation, the crystallization was carefully watched, and each kind of crystals filtered off as they formed. Two recrystallizations usually resulted in a constant melting point being obtained.

(A) consisted of bromopentacetylcyclohexanpentol and α -dibromotetracetylcyclohexantetrol. (B) was a mixture of α - and β -dibromotetracetylcyclohexantetrols and a small amount of dibromotriacetylcyclohexantetrol. From (C) was obtained dibromotetracetylcyclohexantetrol and dibromodiacetylcyclohexantetrol. (D) consisted of only dibromodiacetylcyclohexantetrol. (E) yielded a small amount of tribromotriacetylcyclohexantriol, as a fine, white powder. The mother liquors from (E) after standing in the ice box for several weeks changed to an opaque mass. It was freed from adhering syrup by crushing on a porous plate. This crude product, which amounted to 15 g., was boiled with benzene, which dissolved the coloring material and any tribromotriacetylcyclohexantriol, and was finally obtained as a white powder which proved to be dibromocyclohexantetrol.

Bromopentacetylcyclohexanpentol, crystallizes from boiling alcohol in fine, indistinct crystals, melting sharply at 240° . It is soluble in chloroform, ether, acetone and benzene, and is insoluble in water, ligroin or methyl alcohol. It is optically inactive.

Calc. for $C_6H_8Br(OCOCH_3)_5$: Br, 17.66%; C, 42.38%; H, 4.64%. Found: Br, 17.72%; C, 42.23%; H, 4.69%.

α -Dibromotetracetylcyclohexantetrol, differs from its isomer in its crystalline form and is less soluble. It separates as scaly crystals from alcohol and as long, flat, colorless prisms from benzene. It melts at 225° to a colorless liquid. It is optically inactive.

Calc. for $C_6H_8Br_2(OCOCH_3)_4$: Br, 33.75%; C, 35.44%; H, 3.78%. Found: Br, 33.83; C, 35.35; H, 3.83.

β -Dibromotetracetylcyclohexantetrol, crystallizes best from alcohol, forming large, brilliant, rhombic prisms, melting at 130° to a clear, colorless liquid which forms a crystalline foliated solid on cooling. It is soluble in benzene, chloroform, ether, glacial acetic acid, and ethyl acetate, and insoluble in water. It is optically inactive.

Calc. for $C_6H_8Br_2(OCOCH_3)_4$: Br, 33.75%; C, 35.44%; H, 3.78%. Found: Br, 33.71; C, 35.29; H, 3.72.

Dibromotriacetylcyclohexantetrol, crystallizes from alcohol in small, slender prisms, m. p. 124° . On acetylation, it yields β -dibromotetracetylcyclohexantetrol.

Calc. for $C_6H_8Br_2(OH)(OCOCH_3)_3$: Br, 37.04%. Found: 37.20.

Dibromodiacetylcyclohexantetrol, crystallizes from alcohol in clusters of soft, white needles, melting at 214° with decomposition. It is soluble

in alcohol, acetone and ethyl acetate, less soluble in ether or glacial acetic acid and insoluble in water, chloroform, and benzene. It is optically inactive.

Calc. for $C_6H_8Br_2(OH)_2(OCOCH_3)_2$: Br, 41.02%; C, 30.77%; H, 3.59%; Acetyl, 30.26%. Found: Br, 40.78 and 40.83; C, 30.59 and 30.88; H, 3.42 and 3.65; Ac,¹ 30.28 and 30.33.

On acetylation, dibromodiacetylcyclohexantetrol yields β -dibromotetracetylcyclohexantetrol.

Tribromotriacetylcyclohexantriol, crystallizes from benzene in microscopic plates, melting at 180° . It is soluble in alcohol, chloroform, benzene, acetone and glacial acetic acid and insoluble in water and in ligroin. It is optically inactive.

Calc. for $C_6H_5Br_3(OCOCH_3)_3$: Br, 48.48%; C, 29.09%; H, 3.33%. Found: Br, 48.36 and 48.29; C, 29.13 and 28.87; H, 3.49 and 3.12.

Dibromocyclohexantetrol, crystallizes from water in massive colorless prisms, melting at 216° with decomposition. It separates from hot ethyl acetate in small, shining prisms, and from alcohol in tufted crystals. It is soluble in benzene, chloroform, ether and amyl acetate. It is optically inactive.

Calc. for $C_6H_8Br_2(OH)_4$: Br, 59.29%; C, 23.53%; H, 3.27%. Found: Br, 59.29; C, 23.28; H, 3.35.

On acetylation, dibromocyclohexantetrol yields β -dibromotetracetylcyclohexantetrol.

It was found that four of the products prepared from acetyl bromide and inosite were identical with those obtained by Müller.² Since his method of procedure yielded a smaller number of esters, and since he mentions melting points for some of these compounds which are different from those observed in this laboratory, this part of his work was repeated.

Six grams of anhydrous hexacetylcyclohexanhexol and 20 g. of glacial acetic acid, saturated at 0° with hydrogen bromide, were heated in a sealed tube for 8 hours at 100° , and 8 hours at 150° . No pressure was noticed in opening the tube. The contents were divided into two portions. The products of one portion were separated according to the method of Müller, and the other, by the scheme adopted for acetyl bromide and inosite. Half the contents of the tube were emptied into water and the products which separated gradually solidified as a crystalline mass. This was extracted with cold alcohol which dissolved part of it. The insoluble residue was filtered off and the filtrate added to the water soluble portion. This mixture was evaporated in a vacuum to a thick syrup, water added, and boiled till solution took place. The clear liquid was concentrated and after standing in the ice box a few days a white powder separated. This was dried on porous plates and recrystallized from alcohol and finally from water, yielding large colorless prisms of dibromocyclohexantetrol, m. p. 216° .

¹ Correction made for halogen which was also saponified by the action of the sodium hydroxide.

² *J. Chem. Soc.*, 91, 1780 (1907).

The insoluble residue was a mixture of products which, by repeated crystallization from alcohol, were obtained pure. The small, indistinct crystals separating first were bromopentacetylcyclohexanpentol, m. p. 240° . These were followed by scaly crystals of α -dibromotetracetylcyclohexantetrol, m. p. 225° (Müller, m. p. 235°) and then massive rhombic prisms of β -dibromotetracetylcyclohexantetrol, m. p. 130° . (Müller, m. p. 140° .) From the alcoholic mother liquors two kinds of crystals were obtained. They were mechanically separated and each recrystallized from alcohol; one, massive prisms of β -dibromotetracetylcyclohexantetrol, m. p. 130° , and the other, soft, white needles of dibromodiacetylcyclohexantetrol, m. p. 214° . The latter substance is similar in properties to one observed by Müller, but not isolated by him. Müller, by hydrolysis of the mother liquors resulting from the separation of the above-mentioned products, obtained bromocyclohexanpentol. Neither by means of Müller's method, nor with acetyl bromide could any product like this be obtained.

The second half of the reaction mixture was treated as in the scheme for the separation of the products formed by the action of acetyl bromide and inosite, *i. e.*, direct evaporation in a vacuum and fractional crystallization from alcohol. Bromopentacetylcyclohexanpentol, m. p. 240° , separated first; followed by α -dibromotetracetylcyclohexantetrol, m. p. 225° , and then β -dibromotetracetylcyclohexantetrol, m. p. 130° , and finally dibromodiacetylcyclohexantetrol, m. p. 214° . The dark red mother liquors after long standing over calcium chloride yielded dibromocyclohexantetrol, m. p. 216° . (Müller, m. p. 210° .) The presence of tribromotriacetylcyclohexantriol or bromocyclohexanpentol was not observed.

This latter scheme of separating the products gave better yields than Müller's method.

Heating inosite with acetyl bromide in a sealed tube above 120° for a longer period than 6 hours had some effect on the amount of the products formed. When the reaction was carried out at 150° for 8 hours, none of the bromopentacetylcyclohexanpentol, but more of the tribromotriacetylcyclohexantriol was obtained. The formation of a tetra-halide ester of inosite at even higher temperatures was not successful since carbonization took place above 160° .

Besides the synthesis of these halogen esters of inosite some of their properties were studied to ascertain their behavior towards certain reagents. It was found that they were not affected by anhydrous aluminium chloride and dry benzene, nor by metallic sodium and ethyl bromide in ether, and only slightly affected by silver carbonate after long boiling in absolute methyl alcohol. Phenyl magnesium bromide in ether gave as final products, dark-colored resinous substances which were not identified, due to lack of material. It was hoped that by means of liquid ammonia, a halo-

gen in dibromotetracetylcyclohexantetrol might be replaced by an amino group. The products of the reaction showed that saponification of the acetyl groups had taken place, since only dibromocyclohexantetrol was obtained. However, the reaction was not given a fair trial, since large amounts of impurities such as water, iron, pyridine, etc., were subsequently found to be present in the liquid ammonia.

Five grams of β -dibromotetracetylcyclohexantetrol were mixed with liquid ammonia in a thermos bottle. After standing 12 hours, the contents were emptied into a flask to evaporate off the ammonia. The resulting dark-colored residue was extracted first with cold alcohol and then with water. The water solution yielded 1 g. of dibromocyclohexantetrol, while from the alcohol solution, after boiling with animal charcoal, was obtained 2 g. of unchanged β -dibromotetracetylcyclohexantetrol.

Action of Acetyl Chloride on Inosite.

When H. Müller,¹ heated hexacetylcyclohexanhexol with glacial acetic acid saturated with hydrogen chloride he obtained several monochloro esters of inosite, together with two new isomeric inosites, which he called iso and ψ .

By using acetyl chloride none of the above products seemed to be formed, but, as was to be expected, chloro esters of inosite were obtained similar in properties to those resulting from the action of acetyl bromide. Furthermore, these chloro esters of inosite appear to be isomorphous with the analogous bromo esters, since the latter served in inoculating the solutions from which the former were crystallized.

Twenty grams of inosite (dried at 110°) and 80 g. of acetyl chloride were heated in a sealed tube at 140° for 6 hours. Care was taken in opening the tube to prevent loss of the contents, due to frothing. The syrup obtained was emptied into a flask together with the pieces of the crushed glass tube. Absolute alcohol was added and the mixture evaporated in a vacuum on a water bath. The dark brown syrupy residue was dissolved in 500 cc. of hot alcohol and filtered hot. After cooling, the crystalline product (A) which separated was filtered and the filtrate evaporated to half its volume, with a current of air. A second crystalline product (B) resulted and the filtrate evaporated as before until an oil began to form, giving a white precipitate (C). The reddish black solution was heated with animal charcoal yielding a pale yellow solution which did not crystallize. Instead, a syrup slowly separated which dissolved on heating, but formed again on cooling. The mixture was evaporated to a syrup (D) in a vacuum and dried over calcium chloride. This syrup weighed 32 g. or 80% of the total yield obtained.

(A), (B), and (C) were mixtures and were separated by fractional crystallization from alcohol. (A) gave chloropentacetylcyclohexantetrol and α -dichlorotetracetylcyclohexantetrol while (B) yielded α - and β -dichlorotetracetylcyclohexantetrols. From (C), by mechanical separation, β -dichlorotetracetylcyclohexantetrol and a minute amount of white needles melting at 107° were obtained. The latter substance is probably dichlorodiacetylcyclohexantetrol, since its properties are similar to those of dibromodiacetylcyclohexantetrol. Furthermore, like the latter sub-

¹ *J. Chem. Soc.*, 101, 2383 (1912).

stance, it gave on acetylation the corresponding β -dichlorotetracetyl derivative. The syrup (D) was dichlorotriacetylcyclohexantetrol, which on hydrolysis with HCl gave dichlorocyclohexantetrol.

Chloropentacetylcyclohexantetrol crystallizes from hot alcohol in fine, indistinct crystals melting at 250° . It is soluble in benzene, chloroform and ether, and insoluble in water. It is optically inactive.

Calc. for $C_6H_6Cl_2(OCOCH_3)_5$: Cl, 8.70%; C, 47.00%; H, 5.14%. Found: Cl, 8.65; C, 46.87; H, 5.09.

α -Dichlorotetracetylcyclohexantetrol differs from its isomer in its crystalline form and is less soluble. It crystallizes from alcohol in shining scales, melting at 186° to a colorless liquid, which forms a crystalline mass on cooling. It is soluble in alcohol, chloroform, ethyl acetate, glacial acetic acid, benzene, ether and acetone, and insoluble in water and in ligroin. It is optically inactive.

Calc. for $C_6H_6Cl_2(OCOCH_3)_4$: Cl, 18.44%; C, 43.68%; H, 4.67%. Found: Cl, 18.37 and 18.25; C, 43.68; H, 4.75.

β -Dichlorotetracetylcyclohexantetrol crystallizes from alcohol in large, brilliant, rhombic prisms melting sharply at 118° . It is optically inactive.

Calc. for $C_6H_6Cl_2(OCOCH_3)_4$: Cl, 18.44%; C, 43.68%; H, 4.67%. Found: Cl, 18.42 and 18.50; C, 43.51; H, 4.60.

Dichlorotriacetylcyclohexantetrol distills at $216-217^{\circ}$ at 2.3 mm. It is a colorless, brittle gum, soluble in alcohol, glacial acetic acid, ethyl acetate and hot water. For analysis, small portions were dried to a constant weight at 80° in a vacuum over sulfuric acid. It is optically inactive.

Calc. for $C_6H_6Cl_2(OH)(OCOCH_3)_3$: Cl, 20.70%; C, 41.91%; H, 4.67%; Acetyl, 50.00%. Found: Cl, 20.73 and 20.78; C, 41.75; H, 4.14; Ac, 50.13 and 50.05.

On acetylation with acetic anhydride β -dichlorotetracetylcyclohexantetrol, was formed. Dichlorotriacetylcyclohexantetrol in an alcoholic solution was hydrolyzed for 12 hours with hydrochloric acid. The chlorides were removed with silver carbonate, and the solution boiled with bone black, filtered and evaporated to a syrupy consistency. On inoculating with a crystal of dibromocyclohexantetrol and vigorously agitating the mixture, a crystalline mass of dichlorocyclohexantetrol separated. This was filtered, washed with ethyl acetate and recrystallized from alcohol. On acetylation, it gave β -dichlorotetracetylcyclohexantetrol.

Dichlorocyclohexantetrol crystallizes from alcohol in small, colorless prisms, melting at 221° . It is soluble in water and in alcohol; less soluble in ethyl acetate and insoluble in chloroform, ether and benzene.

Calc. for $C_6H_6Cl_2(OH)_4$: Cl, 32.72%; C, 33.18%; H, 4.61%. Found: Cl, 32.62; C, 33.30; H, 4.77.

Maquenne¹ prepared hexacetyl and hexabenzoylcyclohexanhexol by

¹ *Compt. rend.*, 104, 297 (1887).

means of the acid chlorides. This suggested that other acyl derivatives of inosite might be obtained by employing other acid chlorides.

The method adopted was to mix powdered anhydrous inosite with quinoline in slight excess of that necessary to react with the calculated amount of acid chloride. The mixture was heated at 120° till solution was complete, usually half an hour. The resulting syrupy mass was dissolved in 100 cc. of chloroform and washed two or three times with dilute sulfuric acid. The pale yellow solution was concentrated to about 25 cc. and warm alcohol added to the point of precipitation. The products separated on cooling and were usually purified by fractional crystallization.

Hexa-, penta-, and tetra-acyl derivatives of inosite were thus obtained. The hexacyl derivatives were less soluble and the melting points lower than the corresponding pentacyl derivatives.

Benzoylation of Inosite.—Maquenne¹ by direct heating of inosite with benzoyl chloride and zinc chloride obtained hexabenzoylcyclohexanhexol and chlorotribenzoylcyclohexanpentol. By using quinoline, no chloro esters were obtained, but instead lower benzoyl derivatives of inosite.

Two grams of inosite, 10 g. of quinoline and 10 g. of benzoyl chloride were heated in a flask for half an hour at 120° . The orange red syrup obtained was dissolved in 100 cc. of chloroform and washed two or three times with 10% sulfuric acid, and then once with water. The light yellow solution was evaporated to 25 cc. and 100 cc. of alcohol added. A white crystalline precipitate of pentabenzoylcyclohexanhexol separated. The filtrate was concentrated to 50 cc. After standing in the ice box for 12 hours, 4 g. of hexabenzoylcyclohexanhexol were obtained in the form of crystals. When the alcoholic mother liquors were poured into water, a small amount of an amorphous product separated and proved to be the tetrabenzoyl derivative. They were obtained pure by recrystallization from other solvents.

Hexabenzoylcyclohexanhexol crystallizes from hot alcohol in microscopic crystals, m. p. 258° . It is soluble in benzene, glacial acetic acid and chloroform, slightly soluble in alcohol or ether, and insoluble in water.

Calc. for $C_6H_6(OCOC_6H_5)_6$: C, 71.64%; H, 4.34%. Found: C, 71.41; H, 4.42.

Pentabenzoylcyclohexanhexol crystallizes from benzene in large transparent prisms, m. p. 269° . It is soluble in chloroform, acetone, ethyl acetate, glacial acetic acid, and in benzene, insoluble in water, ligroin and in ether.

Calc. for $C_6H_6(OH)(OCOC_6H_5)_5$: C, 70.29%; H, 4.57%. Found: C, 70.39 and 70.29; H, 4.68 and 4.71.

Tetrabenzoylcyclohexanhexol separates from a mixture of chloroform and alcohol as a white amorphous powder, m. p. 231° .

Calc. for $C_6H_6(OH)_2(OCOC_6H_5)_4$: C, 68.46%; H, 4.69%. Found: C, 68.41; H, 4.55.

Anisylation of Inosite.—Two grams of dry inosite, 20 g. of quinoline and 11.5 g. of anisyl chloride were mixed in a flask and heated for half an hour at 120° . The resulting pale brown syrup was dissolved in 100 cc. of chloroform and washed twice with 10% sulfuric acid, and once with water. The yellow solution was concentrated to 25 cc. and 50 cc. of hot alcohol added. On cooling, a mixture of hexa- and pentanisyl-

¹ *Loc. cit.*

cyclohexanhexol separated, and was dried on a porous plate. This crude product amounted to 7 g. It was dissolved in a hot mixture of equal volumes of chloroform and alcohol, which gave on cooling hexanisylcyclohexanhexol. From the mother liquors pentanisylcyclohexanhexol was obtained.

The hexanisyl derivative crystallizes from a mixture of equal volumes of chloroform and alcohol in fine, white prisms, melting at 225° . It is soluble in chloroform, difficultly soluble in acetone or in ethyl acetate, and insoluble in alcohol, ether, benzene or in water. It is optically inactive.

Calc. for $C_6H_6(OCOC_6H_4OCH_3)_6$: C, 65.86%; H, 4.88%. Found: C, 65.81 and 66.09; H, 5.15 and 4.94.

The pentanisyl derivative crystallizes from a mixture of chloroform and alcohol in microscopic needles, melting at 251° . It is soluble in chloroform, less so in acetone, and insoluble in alcohol, water or in ether.

Calc. for $C_6H_6(OH)(OCOC_5H_4OCH_3)_5$: C, 64.94%; H, 4.94%. Found: C, 64.80 and 64.93; H, 4.80 and 5.01.

Cinnamoylation of Inosite.—Two grams of anhydrous inosite, 20 g. of quinoline, and 12 g. of cinnamoyl chloride (prepared by distilling a solution of cinnamic acid and phosphorus trichloride in a vacuum of 21 mm. at 145°), were mixed in a flask and heated for half an hour at 120° . The resulting orange-red syrup was dissolved in 100 cc. of chloroform and washed three times with 10% sulfuric acid and once with water. The pale yellow chloroform solution was concentrated to 25 cc. and hot alcohol was added till a turbidity formed. On cooling an amorphous product separated. 200 cc. of alcohol were added and the mixture set away in the ice box for 12 hours. The resulting mixture was filtered. The residue was dried on a porous plate giving 6 g. of a white powder. It consisted of two substances, hexa- and α -pentacinnamoylcyclohexanhexol, which were separated by fractional crystallization from a mixture of equal volumes of chloroform and alcohol. A third product, β -pentacinnamoylcyclohexanhexol, was obtained from the mother liquors in the form of an amorphous product contaminated with a syrup. It was purified by pressing out on porous plates and crystallizing from hot alcohol.

The hexacinnamoyl compound crystallizes from a mixture of chloroform and alcohol in clusters of fine needles, m. p. 199° . It is soluble in chloroform or in acetone, and insoluble in water, ether, alcohol, or in benzene.

Calc. for $C_6H_6(OCOC_2H_3C_6H_5)_6$: C, 75.20%; H, 5.00%. Found: C, 75.19 and 75.20; H, 5.32 and 5.31.

The α -pentacinnamoyl derivative crystallizes from chloroform and alcohol in microscopic prisms, m. p. 271° . It is soluble in chloroform or in acetone, and insoluble in water, ether, alcohol, or in benzene. It is optically inactive.

Calc. for $C_6H_6(OH)(OCOC_2H_3C_6H_5)_5$: C, 73.73%; H, 5.06%. Found: C, 73.58 and 73.50; H, 5.18 and 5.06.

The β -pentacinnamoyl derivative is a white, amorphous powder, m. p. 125° . It is soluble in chloroform, benzene or in alcohol, and insoluble in methyl alcohol, ether or in water.

Calculated for $C_6H_6(OH)(OCOC_2H_5C_6H_5)_2$: C, 73.73%; H, 5.06%. Found: C, 73.58; H, 5.16.

***m* Nitrobenzoylation of Inosite.**—Two grams of anhydrous inosite, 18 g. of quinoline and 14 g. of metanitrobenzoyl chloride were dissolved by heating at 120° for half hour. The resulting pale brown solution was taken up in 100 cc. of chloroform and washed two or three times with dilute sulfuric acid and once with water. The solution was concentrated to 40 cc. and 10 cc. of hot alcohol added. On cooling, a red syrup separated which changed to a crystalline mass on standing in the ice box over night. The mass was dried on porous plates, pulverized, and the color removed by boiling with alcohol. Eight grams of hexa-*m*-nitrobenzoylcyclohexanhexol were obtained in the form of an insoluble, white powder. The mother liquors gave a small amount of penta-*m*-nitrobenzoylcyclohexanhexol.

The penta-*m*-nitrobenzoyl derivative separates as a white powder from amyl alcohol, m. p. 226° . It is soluble in chloroform or in acetone, and insoluble in water, alcohol, ligroin, or in ether.

Calc. for $C_6H_6(OH)(OCOC_2H_4NO_2)_2$: C, 53.19%; H, 2.92%. Found: C, 53.00; H, 2.75.

The hexa-*m*-nitrobenzoyl compound crystallizes from ethyl acetate in fine, shining needles, m. p. 217° . It is soluble in chloroform or in acetone; slightly soluble in ethyl acetate or in benzene; and insoluble in water, ether, or in alcohol.

Calc. for $C_6H_4(OCOC_2H_4NO_2)_2$: C, 53.63%; H, 2.80%. Found: C, 53.81 and 53.75; H, 3.02 and 2.77.

Action of Chlorocarbonic Acid Ester on Inosite.—Carbonates of inosite are probably formed by heating inosite with chlorocarbonic acid ester and quinoline, and are insoluble in anhydrous solvents. The product obtained is a hygroscopic syrup soluble in alcohol but at the same time inosite is formed. This may be due to alcoholysis having taken place. Acetylation of the syrup yields a mixture of two isomeric hexacetylcyclohexanhexols, which were named α and β , and which are both different from the hexacetylcyclohexanhexol, obtained by direct acetylation of inosite.

Two grams of finely pulverized anhydrous inosite were thoroughly mixed with 10 g. of quinoline. Eight grams of chlorocarbonic acid ethyl ester were slowly added, keeping the mixture cold. After the frothing had ceased, the mixture was warmed until complete solution had taken place. The resulting dark-colored syrup was extracted with hot chloroform to remove the coloring material. After decanting off the chloroform, a white, hygroscopic syrup remained which was kept in a desiccator over sulfuric acid. The syrup was dissolved in acetic anhydride containing two drops of sulfuric acid, and the solution poured into water, from which an oil separated which gradually solidified. The white, amorphous mass thus obtained was washed with water and dissolved in hot alcohol. On cooling, a crystalline mass consisting of two acetylated products separated. By fractional crystallization from alcohol the α -hexacetylcyclohexanhexol was obtained, followed by the β -hexacetylcyclohexanhexol.

To determine the acetyl number a weighed amount (0.15–0.20 g.) was dissolved in 35 cc. of methyl alcohol in a flask connected with a ground-in reflux condenser, surmounted by a bent tube filled with soda lime. Thirty cubic centimeters of 0.1 *N*

sodium hydroxide were added and the solution warmed on the water bath for 2 hours—5 hours for substances containing halogen—and titrated with 0.1 *N* hydrochloric acid, using phenolphthalein as an indicator.

α -Hexacetylcyclohexanhexol crystallizes from alcohol in small, flat prisms melting sharply at 212°. It is soluble in chloroform, benzene and in glacial acetic acid; less soluble in ether and in methyl alcohol, and insoluble in water. It is optically inactive. On hydrolysis with methyl alcohol and sodium hydroxide it yielded inosite.

Calc. for $C_6H_6(OCOCH_3)_6$: C, 50.00%; H, 5.55%; Ac, 81.94%. Found: C, 50.06 and 50.01; H, 5.56 and 5.72; Ac, 81.73 and 81.80.

β -Hexacetylcyclohexanhexol crystallizes from alcohol in microscopic prisms melting at 200°. It is soluble in ether, benzene, chloroform and in glacial acetic acid, and insoluble in water or in ligroin. It is optically inactive. On hydrolysis with methyl alcohol and sodium hydroxide it yielded inosite.

Calc. for $C_6H_6(OCOCH_3)_6$: C, 50.00%; H, 5.55%; Ac, 81.94%. Found: C 50.03 and 50.15; H, 5.68 and 5.79; Ac, 82.17 and 81.90.

On one occasion, α -hexacetylcyclohexanhexol changed over to β -hexacetylcyclohexanhexol. This interesting transformation could not be repeated although several attempts were made.

In order to study the relation of hexacetylcyclohexanhexol to α - and β -hexacetylcyclohexanhexols, it was warmed with quinoline and chloro-carbonic acid ester but no change took place. Also, it remained unchanged when treated with acetic anhydride saturated with hydrogen chloride.

It is stated by Fick¹ that a pentacetate, m. p. 216°, and a tetracetate have been obtained on short heating of inosite with acetic anhydride. In repeating the work, hexacetylcyclohexanhexol, m. p. 126°, was the only crystalline body obtained. The mother liquors gave a syrup, probably lower acetyl derivatives.

Lower acetyl derivatives of inosite in the form of syrups and the hexacetyl derivatives, m. p. 212°, were obtained by Maquenne,² on heating inosite with acetyl chloride. The work was repeated by the same method used for the formation of acyl derivatives in the presence of quinoline as mentioned above. A poor yield of hexacetylcyclohexanhexol, in addition to a small amount of a hygroscopic syrup, was obtained. This syrup is probably a lower acetylated derivative, since it is soluble in chloroform and in alcohol, and insoluble in water. Being unimportant, it was not investigated.

Hexacetylcyclohexanhexol crystallizes from toluene in monoclinic prisms, melting sharply at 216°, to a clear, colorless liquid, which solidifies on cooling. It sublimes at 200° and boils in a vacuum (2.5 mm.)

¹ *Chem. Zentr.*, 1887, 452.

² *Bull. soc. chim.*, 48, 58 (1887).

at 234°. Saponification with liquid ammonia or with boiling alcoholic barium hydroxide gives inosite.

Calc. for $C_6H_6(OCOCH_3)_6$: C, 50.00%; H, 5.55%. Found: C, 50.04; H, 5.64.

Action of Liquid Ammonia on Hexacetylcyclohexanhexol.—The replacement of the acetyl groups with amino groups by means of liquid ammonia was undertaken. Only saponification of the acetyl groups took place with the production of inosite.

In a thermos bottle containing 50 cc. of liquid ammonia, 5 g. of the dry finely powdered compound were slowly added with stirring. After standing for 12 hours, the contents of the thermos bottle were emptied into a short-necked flask, the ammonia evaporating in about two hours. A brown residue resulted, which was extracted with alcohol. The alcohol solution gave a small amount of unchanged substance, but no intermediate acetylated derivatives could be obtained. The residue was dissolved in water, boiled with animal charcoal, and filtered. The filtrate was evaporated to 5 cc. and 30 cc. of alcohol added. The crystalline precipitate which formed was recrystallized from hot 80% alcohol, yielding 2 g. of inosite, m. p. 225°.

Alkylation of Inosite.

The occurrence of methyl ethers of inosite in nature suggested the alkylation of inosite. Of the many reagents employed for the alkylation of hydroxyl groups, dialkyl sulfate and a hot, 25% solution of sodium hydroxide was the only one which proved successful in the alkylation of inosite. The alkyl inosites obtained were of course optically inactive, and therefore it is impossible to say whether they are identical with the natural ethers which are active.

Unchanged inosite was obtained from heating inosite with diazomethane; a 15% alcohol solution of potassium hydroxide and methyl iodide; silver oxide, methyl alcohol, and methyl iodide, and also in a sealed tube; absolute methyl alcohol and hydrogen chloride in a sealed tube; and dimethyl sulfate with quinoline, and with pyridine.

Methylation of Inosite.—Ten grams of inosite were dissolved in 130 cc. of a 25% sodium hydroxide solution, heated to boiling, and 50 g. of dimethyl sulfate slowly added. The mixture was boiled for 24 hours, neutralized with a few drops of sulfuric acid and diluted with water. It was boiled with an excess of barium hydroxide, cooled, filtered, and the excess of barium hydroxide removed with carbon dioxide. The resulting pale yellow solution was acidified with acetic acid and boiled.

Any unchanged inosite was separated as the lead salt, $2C_6H_{11}O_4.5PbO$, by making the solution ammoniacal and then adding 50 cc. of a saturated solution of basic lead acetate, followed by 50 cc. of methyl alcohol. The addition of the alcohol causes the gelatinous mass to settle as a fine, white precipitate which is more easily filtered. The lead salts were decomposed with hydrogen sulfide and the resulting solution evaporated to 10 cc. Upon the addition of alcohol, 3 g. of inosite were obtained.

The lead salts in the original filtrate were precipitated with hydrogen sulfide. After boiling off the hydrogen sulfide the filtrate was concentrated on the water bath to a syrupy consistency. The syrupy mass was dried at 100° in a vacuum over sulfuric acid. The resulting hard, hygroscopic product was pulverized, emptied into 100 cc. of acetic anhydride, containing a few drops of sulfuric acid, and the mixture heated for an hour. After cooling, the mixture was filtered. The dark red solution was evap-

orated to a syrup, dissolved in alcohol and evaporated a second time. The syrupy residue was extracted with chloroform, filtered, and the chloroform distilled off. The dark-colored syrup thus obtained was dissolved in alcohol, boiled with animal charcoal, and filtered. The solution was evaporated to a pale yellow syrup, extracted with ether, and decanted from the tetracetyldimethylcyclohexanhexol which remained undissolved. From the ethereal solution, silky needles of pentacetylmethylcyclohexanhexol slowly separated. The mother liquors gave a yellow syrup, triacetyldimethylcyclohexanhexol, which was equal to 70-80% of the total yield obtained. Monomethylcyclohexanhexol was prepared by heating 2 g. of pentacetylmethylcyclohexanhexol with an aqueous solution containing 4 g. barium hydroxide. A slight excess of sulfuric acid was added and the mixture filtered. The filtrate was concentrated to a syrupy consistency and absolute alcohol added with stirring. A small amount of monomethylcyclohexanhexol separated as a white, amorphous mass. The alcoholic filtrate yielded a syrupy, optically inactive and which has not been identified.

Monomethylcyclohexanhexol crystallizes from hot alcohol in microscopic prisms, melting at 204° . It is soluble in water, less soluble in alcohol and insoluble in ether.

Calc. for $C_6H_9OCH_2(OH)_5$: C, 43.30%; H, 7.22%. Found: C, 43.42; H, 7.38.

Pentacetylmethylcyclohexanhexol, crystallizes from ether in long, white needles, melting at 141° . It is soluble in alcohol, benzene, glacial acetic acid, chloroform, and ethyl acetate. The crystals when exposed to the air for some time take up one and one-half molecules of water, and then melt at 96° . In a vacuum over sulfuric acid they lose this water and melt at 141° . It is optically inactive.

Calc. for $C_6H_9OCH_2(OCOCH_3)_5 + 1\frac{1}{2}H_2O$: $H_2O = 6.26\%$; 0.6789 g. subs. lost 0.0422 g. of water = 6.22%.

Calc. for $C_6H_9OCH_2(OCOCH_3)_5$: C, 50.49%; H, 5.94%; Ac, 73.02%. Found: C, 50.52 and 50.47; H, 6.10 and 6.01; Ac, 73.01 and 72.88.

Tetracetyldimethylcyclohexanhexol, crystallizes from alcohol in small prisms, which melt at 223° and sublime unchanged above 300° . It is soluble in benzene, chloroform, alcohol, ethyl acetate and acetone, difficultly soluble in ether, and insoluble in water and in ligroin.

Calculated for $C_6H_8(OCH_3)_2(OCOCH_3)_4$: C, 51.06%; H, 6.38%; Ac, 62.77%. Found: C, 51.05 and 50.93; H, 6.38 and 6.31; Ac, 62.45 and 62.52.

On hydrolysis with an alcoholic solution of barium hydroxide, a syrup soluble in water was obtained which is probably a dimethylcyclohexanhexol.

Triacetyldimethylcyclohexanhexol is a syrup which could not be crystallized. It distils at $212-213^{\circ}$, and 2.5 mm. pressure. It is soluble in alcohol, acetone, ethyl acetate and glacial acetic acid; slightly soluble in hot water. Portions for analysis were dried to constant weight in a vacuum over sulfuric acid at 100° .

Calculated for $C_6H_8(OCH_3)_2OH(OCOCH_3)_3$: C, 50.30%; H, 6.56%; Ac, 53.00%. Found: C, 50.48 and 50.34; H, 6.59 and 6.64; Ac, 52.85 and 52.73.

On hydrolysis with barium hydroxide solution, an unidentified syrup was obtained which will be further investigated.

Ethylation of Inosite.—Thirty-five grams of diethyl sulfate were slowly dropped into a boiling solution of 10 g. of inosite and 70 cc. of 25% sodium hydroxide. The boiling was continued for 48 hours and the sodium sulfate which separated was filtered off. The yellow solution was concentrated to a thick paste on the water bath and then dried in a vacuum over sulfuric acid at 100°. The resulting hygroscopic mass was pulverized and emptied into a flask containing 50 cc. of acetic anhydride and 2 drops of sulfuric acid. The mixture was heated for an hour, cooled and filtered. The filtrate was evaporated to a syrup, dissolved in alcohol and again evaporated. The syrupy mass was extracted with chloroform and the chloroform distilled off. The dark-colored syrup thus obtained was dissolved in alcohol, boiled with animal charcoal and filtered. The resulting pale yellow solution was evaporated to a syrup and dissolved in boiling ether. On cooling, small prisms of tetracetyldiethylcyclohexanhexol separated. As the ether gradually evaporated, soft, white needles of pentacetyldiethylcyclohexanhexol crystallized. The mother liquors gave a syrup equal to 70–80% of the total yield. This pale yellow syrup on hydrolysis yielded another syrup which has not been identified.

Pentacetyldiethylcyclohexanhexol crystallizes from ether in long, white needles melting at 128°. It is soluble in chloroform, alcohol, glacial acetic acid, acetone and in benzene. It is optically inactive.

Calc. for $C_6H_6(OC_2H_5)_2(OCOCH_3)_3$: C, 51.67%; H, 6.22%; Ac, 70.58%. Found: C, 51.54 and 51.60; H, 6.19 and 6.04; Ac, 70.41 and 70.46.

Tetracetyldiethylcyclohexanhexol crystallizes from alcohol in small prisms melting at 212°, and subliming unchanged above 300°. It is soluble in benzene, chloroform, acetone, and in ethyl acetate, slightly soluble in ether, and insoluble in ligroin or in water. It is optically inactive.

Calc. for $C_6H_6(OC_2H_5)_2(OCOCH_3)_2$: C, 53.46%; H, 6.94%; Ac, 58.42%. Found: C, 53.48 and 53.46; H, 7.01 and 6.93; Ac, 58.31 and 58.65.

An alcoholic solution of tetracetyldiethylcyclohexanhexol was heated with a slight excess of barium hydroxide, sulfuric acid added, and the solution concentrated to a thick syrup. Absolute alcohol was added and on agitating the mixture, diethylcyclohexanhexol was separated.

Diethylcyclohexanhexol crystallizes from hot alcohol in small, shining prisms, which melt at 212°. It is soluble in water and insoluble in ether or in benzene.

Calculated for $C_6H_6(OC_2H_5)_2(OH)_2$: C, 50.67%; H, 8.69%. Found: C, 50.78; H, 8.67.

Derivatives of Pinite.

Preparation of Pinite.—Pinite is obtained from the roots of the "Pinus Lambertina," a species of Californian pine tree, in the form of a dark-colored granular substance with an aromatic odor, mixed with resinous material and pine needles. It was purified in the following manner:

One hundred grams of the crude pinite were dissolved in 250 cc. of water and the volatile resins distilled with steam. The solution was evaporated to a syrupy consistency, dissolved in warm alcohol and filtered. The dark-red filtrate was transferred to a bowl and set away in the ice box. Crystals,

which adhered tenaciously to the sides of the bowl, separated. They were pulverized, dried on porous plates and recrystallized from hot alcohol. After remaining in the ice box for several weeks, another crop of crystals was obtained from the black mother liquors. A total yield of 71 g. of pinite was obtained. It gave the Scherer test.

Pinite, monomethylcyclohexanhexol, $C_6H_6OCH_3(OH)_6$, crystallizes from methyl alcohol in small, white prisms, which melt sharply at 186° . It sublimes unchanged above 200° giving fine, colorless needles. It crystallizes from water with difficulty. It is insoluble in absolute alcohol or in ether. The optical rotation was determined by dissolving 0.6950 g. of the anhydrous substance in 100 cc. of water, from which the air had been expelled. This gave $[\alpha]_D^{25} = +65.3^\circ$. This rotation approaches nearest $[\alpha]_D^{22} = +65.5^\circ$, the value determined by Maquenne.¹ Other investigators give² $[\alpha]_D^{20} = +65.0^\circ$; and³ $[\alpha]_D^{20} = +65.7^\circ$.

Previous to this investigation, no crystalline acyl derivatives of pinite had been prepared. The acetyl and benzoyl derivatives were obtained by direct heating with the acid chloride, while the anisyl and cinnamoyl ethers required the presence of quinoline.

Acetylation of Pinite.—Maquenne⁴ obtained, on heating pinite with acetic anhydride and zinc chloride, a white, amorphous mass which he called pinite acetate. The work was repeated, and the amorphous mass obtained, which however could not be crystallized. A crystalline pentacetyl derivative of pinite was finally prepared by employing acetyl bromide.

Three grams of pulverized pinite (dried at 110°) and 15 g. of acetyl bromide were placed in a round-bottomed flask connected with a long ground-in glass tube, and gently warmed for half an hour. Hydrogen bromide was given off as the pinite slowly dissolved. The reddish yellow solution was emptied into cold water and settled as an oil, which gradually turned to a white syrup. The syrup was dissolved in alcohol and hot water added till a turbidity formed. On cooling, a fine, white precipitate separated and was filtered. It was recrystallized from 80% methyl alcohol, giving 5 g. of pentacetylmethylcyclohexanhexol.

Pentacetylmethylcyclohexanhexol crystallizes from 80% alcohol in clusters of fine prisms, melting at 98° to a clear liquid. It is insoluble in water, but readily soluble in alcohol, methyl alcohol, glacial acetic acid, benzene, ether, chloroform, acetone and ethyl acetate, $[\alpha]_D^{20} = -9.67^\circ$.

Calc. for $C_6H_6OCH_3(OCOCH_3)_5$: C, 50.49%; H, 5.94%; Ac, 73.02%. Found: C, 50.50 and 50.41; H, 5.81 and 6.09; Ac, 73.30 and 73.11.

On hydrolysis with 50% methyl alcohol solution of barium hydroxide, pinite, m. p. 186° , was obtained.

⁴ *Loc. cit.*

Benzoylation of Pinite.—Three grams of pulverized anhydrous pinite and 11 g. of benzoyl chloride were placed in a round-bottomed flask connected with a long ground-in glass tube, and heated to boiling for fifteen minutes. To the resulting pale brown solution water was added giving a gummy product. This mixture was heated for an hour, after which a hard, white mass separated out. The water was decanted off and the mass dissolved in boiling absolute alcohol and water added till a precipitate formed. On cooling, a gummy, white mass separated which was filtered off and dried on porous plates. The resulting hard mass was pulverized, dissolved in boiling 80% methyl alcohol and yielded, on cooling, 7 g. of a white, amorphous precipitate of pentabenzoylmethylcyclohexanhexol.

Pentabenzoylmethylcyclohexanhexol separates as a white, amorphous powder, m. p. 97° . It is soluble in alcohol, methyl alcohol, benzene, ether, chloroform, and in glacial acetic acid, and insoluble in water and in ligroin. $[\alpha]_D^{20} = +32.3^{\circ}$.

Calculated for $C_{26}H_{30}OCH_2(OCOC_6H_5)_5$: C, 70.59%; H, 4.76%. Found: C, 70.50 and 70.44; H, 4.76 and 4.73.

A methyl alcoholic solution of this compound was boiled for twenty-four hours with barium hydroxide. An excess of sulfuric acid was then added and the filtrate evaporated to nearly a syrup. On the addition of alcohol a precipitate of pinite, m. p. 186° , resulted.

Anisylation of Pinite.—Three grams of pinite, 11 g. of quinoline, and 13 g. of anisylchloride were heated in a flask for half an hour at 120° . The resulting pale brown solution was dissolved in 100 cc. of chloroform and washed two or three times with a 10% solution of sulfuric acid and once with water. The pale yellow chloroform solution was evaporated to 25 cc. and 100 cc. of hot alcohol added. On cooling, 4 g. of long, white needles of pentanisylmethylcyclohexanhexol crystallized.

Pentanisylmethylcyclohexanhexol crystallizes from alcohol in long, white needles, m. p. 101° . It is soluble in alcohol, methyl alcohol, glacial acetic acid, chloroform, and in benzene. It is insoluble in water. $[\alpha]_D^{20} = \pm 0.0^{\circ}$.

Calc. for $C_{26}H_{30}OCH_2(OCOC_6H_4OCH_3)_5$: C, 65.29%; H, 5.09%. Found: C, 65.29 and 65.19; H, 4.93 and 5.06.

Cinnamoylation of Pinite.—Three grams of pinite, 12 g. of quinoline, and 12 g. of cinnamoyl chloride were heated together for half an hour at 120° . The dark orange-colored syrup was dissolved in 100 cc. of chloroform and washed three times with 10% sulfuric acid and once with water. The pale yellow chloroform solution was concentrated to 25 cc. and 100 cc. of alcohol added. On standing over night a yellow syrup settled, which was dissolved in the least amount of glacial acetic acid and then poured into 50% alcohol. Six grams of pentacinnamoylmethylcyclohexanhexol, in the form of a yellow, amorphous mass was obtained, which was purified by repeating the operation several times. A yield of 4.5 g. of the purified substance was finally obtained.

Pentacinnamoylmethylcyclohexanhexol slowly separates from hot absolute alcohol as a white, amorphous powder, m. p. 105° . It is soluble in benzene, chloroform, ethyl acetate, glacial acetic acid, and in acetone; slightly soluble in alcohol, and insoluble in water and in methyl alcohol. $[\alpha]_D^{20} = +41.2^{\circ}$.

Calc. for $C_6H_5OCH_2(OCOC_2H_5C_6H_5)_5$: C, 74.00%; H, 5.21%. Found: C, 74.13 and 74.06; H, 5.34 and 5.46.

Nitration of Pinite.—One gram of anhydrous pinite was dissolved in a mixture of 5 cc. of fuming nitric acid and 10 cc. of sulfuric acid. The colorless oil which separated was poured into water. The white syrup which gradually formed was purified by dissolving in alcohol and pouring into water. The syrup which separated was soluble in alcohol, methyl alcohol, ethyl and amyl acetates, acetone, ether, benzene, pyridine, chloroform, carbon disulfide and in glacial acetic acid, but did not crystallize. It was insoluble in ligroin and in water. It possessed a bitter taste, easily decomposed on heating, and exploded when struck with a hammer.

Action of Acetyl Bromide on Pinite.—By the action of acetyl bromide on pinite in a sealed tube, dibromo esters of inosite were obtained. This shows that the methoxy group was also effected by the acid bromide.

Five grams of pinite (dried at 110°) and 19 g. of acetyl bromide were placed in a sealed tube. After remaining 72 hours at room temperature, a dark red solution resulted. This was emptied into water and an oil separated which gradually solidified. The mass was filtered, dissolved in hot alcohol, and on cooling separated as a fine, crystalline substance. This proved to be a mixture, which was separated by fractional crystallization from alcohol. Scaly crystals of α -dibromotetracetylcyclohexantetrol and large prisms of β -dibromotetracetylcyclohexantetrol were obtained. The water solution obtained above was evaporated to 50 cc. and combined with the alcoholic mother liquors and the mixture boiled with animal charcoal for five hours. The resulting pale yellow solution was concentrated to 25 cc. and set away in the ice box over calcium chloride for several days. Colorless, prismatic crystals of dibromocyclohexantetrol, m. p. 216° , were obtained.

On analysis, α -dibromotetracetylcyclohexantetrol gave Br = 33.80%; calc. for $C_6H_4Br_2(OCOCH_3)_4$: 33.75%.

β -Bromotetracetyl glucose containing a trace of impurity readily decomposes. This was noticeable in the case of the halide esters of inosite but to a lesser extent.

TEMPERATURE COEFFICIENTS AND THE EFFECTS OF ACIDS, BASES AND SALTS IN REACTION VELOCITIES OF THE TRIPHENYLMETHANE DYES.

BY H. C. BIDDLE AND C. W. PORTER.

Received April 15, 1915.

1. Introduction.

The study of color changes among acid and basic derivatives of triphenylmethane has engaged the attention of many investigators.

As early as 1888 Nietzki¹ attributed a quinoid structure to the colored

¹ *Organische Farbstoffe*, 1888.

forms of triphenylmethane dyes. In 1892 Bernthsen¹ produced evidence that phenolphthalein derivatives have the lactone structure in their colorless forms and the quinoid arrangement in the colored modifications. K. H. Meyer and A. Hantzsch² have prepared double salts of quinoidal phenolphthalein with aluminum chloride and with stannic chloride. They studied the colors and absorption spectra of these components and in their opinion the colored form is invariably quinoidal. It is unnecessary to review the vast amount of work that has been done in establishing the nature of the dynamic isomerism of triphenylmethane derivatives. The fact that it consists of an establishment of equilibrium between benzoid and quinoid forms is generally recognized. The evidence upon which this conclusion is based has been critically examined by Stieglitz³ in his "Theory of Indicators;" and a summary of the early researches in this field is included in Ley's "Farbe und Konstitution bei Organischen Verbindungen."⁴ An interpretation of tautomeric change based on the movement of an electron from one part of the molecule to another⁵ has also been suggested, in connection with an oscillatory shift in constitution, as a possible explanation of color in the case of the triphenylmethane dyes.⁶

Several investigators have studied the velocity of changes among dyes of the triphenylmethane series and related bodies. Hantzsch⁷ and others employed the variation in electrical conductance as a measure of the speed. Sidgwick⁸ and his co-workers used a colorimetric method in determining the speed of change in diamino derivatives of triphenylcarbinol in the presence of acids and bases. Biddle⁹ employed a similar method in studying the conversion of triamino derivatives from the colorless into the colored forms under the influence of varying concentrations of hydrogen ion. He also noted the influence of neutral salts upon the reaction and made a preliminary study of this effect. This was followed by a study of the rate of fading of crystal violet in acid solution by Adams and Rosenstein.¹⁰

As pointed out by Biddle,¹¹ the effect of varying the concentration of hydrogen ion upon crystal violet and related bodies is two-fold. One effect is instantaneous producing in the colored form a change of tint.

The other is a time reaction leading to an alteration in the intensity of the color. It was further indicated that any equilibrium between benzoid and quinoid forms involves equilibria between the mono-, di-, and tri-basic ions of the colored and colorless forms. This idea has been elaborated by Adams and Rosenstein¹ who, following the suggestions of Rosenstiehl,² assume the formation of a series of intermediate benzoid ions of the type $(R_2N-C_6H_4)_2C$. Since, as indicated by E. and O. Fischer,³ the conversion of carbinol ion to quinoid ion may take place directly by loss of water, it is simpler to represent the equilibrium as existing solely between these two types. The forms between which equilibrium obtains in a solution of crystal violet we would, consequently, express as follows:⁴

Changes produced by varying the concentration of the H^+ ion produce instantaneous alteration in the ionic condition of the colored or colorless forms, as represented by the shifts in a vertical direction. In the quinoid forms, this is shown by an instantaneous change in tint. Simultaneously there begins an alteration in intensity of tint as quinoid or carbinol form shifts, ordinarily at a measurable speed, towards a condition of equilibrium. This is represented by the constitutional changes in the hori-

⁴ Since a rosaniline dye is capable of adding four mols of hydrogen chloride, an additional form would seem necessary, but this would be equivalent in type to the completely ionized carbinol and may consequently be omitted.

zontal direction, which take place with the loss or addition of a molecule of water.

The present investigation was undertaken: first to ascertain the influence of changes of temperature upon the velocity of the development of color and the rate of fading of the triphenylmethane dyes; secondly, to determine to a fuller extent the effect of varying the concentration of acid and base in producing these changes; and, thirdly, to extend the work of Biddle on the neutral salt effect.

2. General Method of Procedure.

The speed of the reaction was determined in every case by following the rate of fading or of the development of color in a Stammer colorimeter. A solution of crystal violet hydrochloride was prepared in 40% alcohol containing 1 g. of dye salt per liter. Fifty cubic centimeters of this solution were diluted to one liter in 40% alcohol for a stock solution. It contained, therefore, 5×10^{-5} g. of the dye per cubic centimeter. Two cubic centimeters of the stock solution were mixed with 10 cc. of potassium hydroxide solution in each fading experiment, so that the final concentration of the dye was 8.33×10^{-8} g. per cc. The standard color for comparison was made by diluting 10 cc. of the stock solution with 50 cc. of distilled water.

In the measurements of the rate of acquiring color, a stock solution of exactly the same concentration was prepared; but before diluting to the required volume 20 cc. of normal potassium hydroxide were added to convert the dye salt into the colorless carbinol. Two cubic centimeters of this solution were mixed with 10 cc. of acid in each color development experiment. The standard for color comparison was made by adding 10 cc. of the carbinol solution to 50 cc. of acid of known concentration and the mixture was allowed to stand in a thermostat at constant temperature two hours before using.

In order to determine the velocity constant with a fair degree of precision, an air thermostat was constructed in which the colorimeter and solutions could be held at any required temperature. The thermoregulator was sufficiently sensitive to insure a temperature constant within 0.2° . The apparatus consisted of an asbestos lined box provided with glass windows through which the thermometers, regulator, fan and colorimeter scale could be observed. Two arm holes were provided to allow the operator to mix the solutions and place them in tubes in the instrument without removing them from the air bath. When not in use the arm holes were covered with felt pads.

The source of heat was a bank of electric lights connected to the light circuit through a relay which was connected in turn with a mercury-toluene thermoregulator. The air in the apparatus was kept in rapid circulation by means of an electric fan. The standard color solutions

stood in flasks on shelves in the air bath two hours before using, this time being required to insure equilibrium in the reaction. A much shorter time would suffice to bring the solutions to the constant temperature of the air bath. The reaction mixture for comparison with the standard color was prepared as follows: Two cc. of the carbinol solution (or dye) were run from a long-stemmed buret into one arm of a branched tube, Fig. 1. Ten cc. of acid (or base) were then delivered from a buret into the other branch of the tube. The tube was stoppered and placed in the thermostat, care being exercised to avoid mixing the two solutions. From six to ten of these tubes were prepared for each concentration of acid or base used at each temperature, so that the results tabulated below are average results of six or more separate determinations in each case. The exact time of mixing the solutions in the branched tubes was determined by means of a stop watch provided with a mercury contact for the second hand and connected with a battery and an electric bell. One-minute intervals were thus announced by the ringing of the bell. The branched tube was vigorously shaken without removing it from the thermostat and its contents were transferred to a 50 mm. tube and inserted in the colorimeter. Readings were taken at two-, three-, or four-minute intervals, the bell relieving the operator of the necessity of simultaneously watching the clock and matching the colors.

Fig. 1.

The amount of carbinol changed in a given time is proportional to the length of column of standard solution required to match the color produced, and therefore the length of column may be substituted for the concentration of the colored form. The reaction is monomolecular with respect to the dye and the velocity constants were calculated from the equations $K_1 = 1/t \log a/a - x$ and $K_2 = 1/t_2 - t_1 \log a - x_1/a - x_2$. If x is the length in mm. of the column of standard color solution required at any time to match the color produced in a 50 mm. tube, then the value $(a - x)$ is obtained by subtracting from fifty the reading in millimeters on the colorimeter scale. In the fading experiments the colorimeter reading gives directly the value of $(a - x)$ since the reading approaches zero as the reaction approaches equilibrium.

3. Temperature Coefficient (Colorless to Colored).

The following tables give the velocity constants for crystal violet at four temperatures with varying concentrations of acid. The normality of the acid given in connection with each table refers to the free hydrochloric acid present in the solution after mixing the components and deducting the amount of acid neutralized by the excess of potassium hydroxide in the carbinol solution.¹

¹ A slight excess of base is necessary to hold the dye in the colorless form but the excess is easily estimated by titration. See Biddle, *THIS JOURNAL*, 36, 84 (1914).

Fig. 2.
 $K \times 10^2$.

These results are plotted in Fig. 2. The velocity constants multiplied by 100 are represented as abscissae and temperature as ordinates. The curves refer to crystal violet in various concentrations of hydrochloric acid as follows:

Curve I, 0.0234 *N* HCl; II, 0.0151 *N* HCl; III, 0.0068 *N* HCl; IV, 0.0051 *N* HCl; V, 0.0026 *N* HCl.

Within the range of these experiments the temperature coefficient appears to be independent of the concentration of the acid employed. A rise of five degrees increases the velocity 66%. We may, therefore, express the relationship between the velocities at temperatures t_1 and t_2 by the empirical formula

$$K_h = K_h(1.1066)^{t_2 - t_1}$$

or employing the more general formula proposed by Arrhenius,

$$\log \frac{K_h}{K_h} = A(t_2 - t_1),$$

the value of the constant A is found to be 0.044.

This equation enables us to calculate the error in the above results, due to the heat of solution of 2 cc. of 40% alcohol in 10 cc. of dilute acid. The rise in temperature varies slightly with the concentration of the acid and temperature of the components before mixing. The maximum eleva-

tion of temperature in the above experiments reached 0.6° . The rate of cooling was such that in every instance the temperature of the mixture in the color comparison tube was within 0.4° of the temperature of the air bath at the end of four minutes. The exact temperature of the air bath was attained in from twelve to fifteen minutes.

Rejecting the readings taken during the first four minutes and applying the above formula in the calculation of the error we find that the maximum deviation of temperature introduces variation in the third decimal place of the velocity constant. It is evident then that in the experiments that were completed within fifteen minutes the constants reported have no real significance beyond the third decimal place. In very rapid reactions the readings made within the first four minutes have been retained, but the results in these cases cannot be exact.

Table XX gives the ratios between the velocity constants (K_1) at different temperatures for various concentrations of hydrochloric acid. The ratio is quite constant for any five-degree interval, being apparently independent of the temperature and also independent of the concentration of the acid.

TABLE XX.

Concentration of acid.	$\frac{K_1^{30^{\circ}}}{K_1^{25^{\circ}}}$	$\frac{K_1^{35^{\circ}}}{K_1^{30^{\circ}}}$	$\frac{K_1^{40^{\circ}}}{K_1^{35^{\circ}}}$
0.0026 <i>N</i>	1.68	1.63	*
0.0051 <i>N</i>	1.68	1.73	1.67
0.0068 <i>N</i>	1.61	1.68	1.66
0.0151 <i>N</i>	1.58	1.67	1.68
0.0234 <i>N</i>	1.67	1.63	1.65

Average ratio, 1.66.

* With 0.0026 *N* acid at 40° the reaction ran to completion within two minutes.

4. Temperature Coefficient (Colored to Colorless).

In the fading reaction the temperature coefficient is smaller than in the reverse change. It is independent of the concentration of the base and has the same value for all temperatures between 25° and 40° as indicated in Tables XXI to XXXII.

In each case the concentration of the dye was 8.33×10^{-6} g. per cubic centimeter.

The ratio between the velocity constants at four temperatures with varying concentrations of potassium hydroxide are given in Table XXXIII.

TABLE XXXIII.

Concentration of base.	$\frac{K_1^{30^\circ}}{K_1^{25^\circ}}$	$\frac{K_1^{35^\circ}}{K_1^{30^\circ}}$	$\frac{K_1^{40^\circ}}{K_1^{35^\circ}}$
0.0033 <i>N</i>	1.40	1.44	1.44
0.0050 <i>N</i>	1.38	1.43	1.48
0.0083 <i>N</i>	1.38	1.42	1.43

Average ratio, 1.43.

Employing the formula $\log K_h/K_{h_1} = A(t_2 - t_1)$ we may calculate with fair precision the constant at any temperature if the constant at any other temperature is known. In this case $A = 0.03107$. Or we may employ the equation $K_h = K_{h_1}(1.074)^{t-t_1}$. The acceleration per five degrees is 43%. Since the temperature effect per degree is smaller than in the acid reactions the error due to the heat of solution of the alcohol is also smaller.

The velocity constants for the fading reactions are plotted as abscissae and the concentration of alkali as ordinates in Fig. 3.

Fig. 3.

The curves are isothermals showing the relation of velocity of fading, concentration of alkali and temperature. Curve I is at 25°; II, 30°; III, 35°; and IV, 40°.

5. Effect of OH Ion upon the Speed of the Reaction.

The rate of fading of triphenylmethane dyes, under the influence of an alkali, increases with increasing concentration of the alkali. In the case

of basic dyes the rate is exactly proportional to the concentration of the hydroxyl ions. In the case of acid dyes, such as phenolphthalein, the increase in the velocity of fading is slightly in excess of the increase in the concentration of the hydroxyl ions. The results obtained with phenolphthalein are given in Table XXXIV.

6. Effect of H⁺ Ion upon the Speed of the Reaction.

Under the direction of Professor Biddle a monamino triphenylmethane was synthesized by J. N. Lahiri¹ and the observation was made that the rate of development of color is an inverse function of the concentration of the hydrogen ions. The dye was, however, so faintly basic that the salt formed was largely hydrolyzed and the intensity of the color was insufficient for accurate measurement. The speeds of the corresponding reactions with diamino derivatives were determined by Sidgwick and Moore² and Sidgwick and Rivett³ who found the velocity of color development to be proportional to the two-thirds power of the acid concentration. With a triamino derivative Biddle⁴ found that, within a certain range, the speed of acquiring color is inversely proportional to the square of the hydrogen ion concentration.

Extending these researches over a wider range of acid concentration, the interesting fact is disclosed that each of these basic triphenylmethane derivatives acquires color at a rate varying with the concentration of the acid in such a way that the rate passes through a minimum at a certain definite acid concentration. The possibility of this effect was pointed out by Adams and Rosenstein in the case of crystal violet.⁵ The particular concentration corresponding to the minimum is different for the different dyes. That is to say, increasing the acid content of the reaction mixture, up to a certain limit, retards the speed of the reaction, but increasing the quantity of acid beyond that limit accelerates the change.

Thus for crystal violet the constants at 25° are as follows:

Normality of acid.....	0.0432	0.0234	0.0151	0.0068	0.0051	0.0026
K ₁	0.01170	0.00899	0.00969	0.01628	0.02482	0.10009

This is shown graphically in Fig. 4.

⁵ *Ibid.*, 36, 1452 (1914).

Fig. 4.

The minimum rate corresponds to a concentration of approximately 0.0234 *N* hydrochloric acid. In the case of malachite green the acid concentration corresponding to the minimum rate is approximately 0.007 *N*. This is indicated in Table XXXV.

It must be remembered, however, that these velocity constants are measures of the rates of approach to the colors of equilibrium mixtures in each of the given acid concentrations and not measures of the absolute velocities of reaction. The values are, therefore, not strictly comparable.¹ Table XXXV shows the effect of varying the acid concentration on malachite green carbinol.

7. The Neutral Salt Effect.

In many types of chemical change in which acids or bases are active catalysts the velocity constants are changed by the addition of small quantities of neutral salts. This phenomenon was investigated by Arrhenius² in connection with the rate of hydrolysis of cane sugar. He found

¹ See Biddle, *THIS JOURNAL*, 36, 90 (1914).

² *Z. physik. Chem.*, 31, 197 (1899).

that the speed of the reaction was increased to practically the same extent by equimolecular quantities of neutral salts if these salts were equally ionized. Salts having the smallest dissociation constants were least effective. He observed, moreover, that any particular salt produces a greater relative change in the presence of dilute acid than in more concentrated acid solutions. And Arrhenius attributed the salt effect to more than one cause, *e. g.*, the direct catalyzing influence of the salt molecules, and the formation of new electrolytes in the solution. Euler¹ made a similar explanation and suggested that the ionization of the solvent may be increased by the presence of salts and the catalytic influence of the salt is largely due to this effect. Acree,² on the other hand, believes "that catalysis by salts or other neutral substances is due not so much to a change in the dissociation constant of the water as to a number of other factors" which he enumerates as effects of the salt upon the viscosity of the solution, the solvation of the ions and undissociated molecules, the combination of the salt with the molecules undergoing transformation, and the influence of the salt upon the thermodynamic potentials of the reacting ions or molecules.

Stieglitz³ has expressed the opinion that the salt effect "is due to the fact that in salt solutions we are working with mixed solvents in which ionization, velocities, etc., cannot be expected to be the same as in a pure solvent."

In the results tabulated below are set forth the neutral salt effects upon reaction velocities which occur in transformations of dyes of the triphenylmethane series. Measurements have been made of the rates of change from the quinoid to the benzoid forms, and also the reverse changes, in the case of crystal violet and malachite green in the presence of varying quantities of neutral univalent salts. Qualitative observations have been made of the effects of univalent and bivalent salts under like conditions. Similar measurements have been carried out on the influence of neutral salts upon the fading of phenolphthalein in the presence of alkalis. The fading of the latter indicator, with and without neutral salts, has been a subject of study by Drs. E. Q. Adams and Merl Randall⁴ and the effect of neutral salts upon the ionization of the indicator was investigated by Rosenstein.⁵ Tables XXXVI to XLIX inc. refer to crystal violet.

Table XL shows the effect of sodium chloride. Each constant reported is the average of at least twenty readings. (Five readings at regular time intervals on each of at least four reaction mixtures.)

It is evident that the rate of developing color in crystal violet becomes slower as the concentration of the salt increases and a comparison of Table XL with the results given in Tables XXXVI to XXXIX reveals the fact that equimolecular quantities of KCl and NaCl are equally effective in retarding the change. The rate of development of color is likewise retarded by the presence of salts as indicated in Tables XLI to XLIX.

The rate of fading is approximately a linear function of the square root of the equivalent concentration of the salt as shown in Fig. 5.

The following tables, L and LI, show the salt effect on the rate of fading of phenolphthalein in different concentrations of alkali and salt. It will be observed that the salt effect is exactly opposite to that produced by salts in crystal violet. In other words, the rate of fading of phenolphthalein is accelerated by salts:

In this study, as indicated by the tables, we find that neutral salts in the presence of basic dyes behave like acids. That is to say, the addition of a quantity of a neutral salt to a solution of an acid dye, such as phenolphthalein, when fading under the influence of an alkali, produces

Fig. 5.

Square roots of salt concentrations are plotted as ordinates and rates of fading as abscissae. Curve I summarizes Tables XLII to XLVI (inc.); Curves II and III represent the values reported in Tables XLVIII and XLVII, respectively.

an acceleration equivalent to that effected by increasing the concentration of the alkali; while a similar addition of salt to a basic dye such as crystal violet or malachite green when shifting under the influence of either acid or base towards a state of equilibrium produces an effect equivalent to that resulting from the addition of an acid. This means that the speed of fading of a basic dye in the presence of an alkali will in all cases be diminished by the addition of a neutral salt. In the conversion of such a dye from the carbinol to the colored form in the presence of an acid, the salt effect will be determined by the concentration of the acid and may be accelerating, retarding, or indifferent. It will be recalled that for each carbinol base there is a particular concentration of acid at which the color is developed at a minimum rate. In acids of this particular concentration, neutral salts are without effect. In solutions of higher acid con-

centration, they are found to accelerate the development of color, and in less concentrated solutions with respect to the acid, they retard the rate of assumption of color.

Misses Alice Morse and Lulu E. Vance¹ found the catalyzing effect of such uniunivalent neutral salts as sodium chloride, potassium chloride, sodium nitrate, sodium bromide, sodium iodide and potassium nitrate, to be the same in equimolecular quantities within the limits of experimental error. The results recorded in Tables XLVIII to LVIII confirm this conclusion in the case of the salts studied. Unibivalent salts of bibivalent salts, however, give variable results. This, as previously shown,² is to be accounted for in these cases by the variation of hydrogen ion produced by partial hydrolysis. From an inspection of Tables XXXIV to XLI it will be noted, further, that the salt effect is greatest in solutions most dilute with respect to the acid. The effect, as will be seen, decreases with increasing concentration of the acid until the acid concentration producing the minimum rate is reached. Thereafter, the effect of the salt, though slight, increases with increasing concentration. In the fading experiments it will also be noted that the salt effect is greatest in solutions of greatest dilution with respect to the alkali.

Not only is the rate of change altered by neutral salts, the equilibrium is itself displaced, as was previously pointed out by Biddle.³ This is evident from the fact that in acid solutions, the colors produced vary with the amount of salt added, the direction of the variation being the same as that produced by increasing concentration of acid.

There is apparently no simple mathematical relation between the quantity of salt employed and the changes in velocity for the conversion of benzoïd to quinoid form in the presence of acids. In the conversion of colored to colorless form, in the presence of alkalies, however, a fairly regular decrease in rate is produced by increasing concentration of salt. The rate of fading is almost a linear function of the square root of the equivalent concentration of the salt (Fig. 5). In the presence of a concentration of base exceeding 0.02 *N*, however, there is considerable deviation from this rule. In such cases the graph obtained by plotting the speed against the square root of the sum of the concentrations of salt and alkali, more closely approximates a straight line.

Alcohol and acetone accelerate the rate of fading of crystal violet, brilliant green and other basic derivatives of triphenylmethane. They also accelerate the development of color. The effect is therefore just opposite to that produced by salts. The change in rate is relatively

¹ Unpublished Thesis carried out under the direction of H. C. Biddle, Univ. of California, 1914.

² Biddle, *THIS JOURNAL*, 36, 98 (1914).

³ *Ibid.*, 36, 86, 96 (1914).

greater as the concentration of the alcohol or acetone increases, in this respect also differing from the behavior of neutral salts. The addition of sugar reduces the rate of fading, but this is probably due to a diminution of the hydroxyl ions caused by combination of the base with the sugar molecules to form glucosates. It is possible practically to stop the progress of the fading reaction by the addition of sufficient sugar.

Summary.

1. The temperature coefficient for the conversion of a triphenylmethane carbinol into the quinoid form, in the presence of an acid, is independent of the concentration of the acid and between 25° and 40° independent also of the temperature. For crystal violet the increase in the velocity of the change is 66% for every five degrees. Changes of the same order of magnitude were observed in the case of diamino derivatives but comparatively few measurements were made with these dyes and the results have not been tabulated in this paper.

2. The temperature coefficient for the fading of a triphenylmethane dye in the presence of an alkali is independent of the concentration of the base and independent of the temperature (between $25-40^{\circ}$). For crystal violet the increase in velocity is 43% for five degrees.

3. For all concentrations of acid below 0.024 *N* the speed of the color development in crystal violet is an inverse function of the concentration of the hydrogen ions. For all concentrations of acid above this value the velocity is a direct function of the hydrogen ion concentration.

4. The rate of fading of a triphenylmethane dye is a direct function of the concentration of the hydroxyl ions and in the case of basic dyes, such as crystal violet, is exactly proportional to such concentration.

5. Neutral salts retard the rate of fading and also retard the rate of development of color in all the basic triphenylmethane dyes but accelerate the rate of fading of acidic dyes.

6. All uniunivalent neutral salts in equivalent concentrations are equally effective in modifying the catalytic influence of the acid or base. They behave like acids in their effect upon basic dyes and like bases in their influence upon acid dyes.

CONVERSION OF GALACTOSE PENTACETATE TO AN ISOMERIC FORM.

By C. S. HUDSON AND H. O. PARKER.¹

Received April 10, 1915.

Crystalline galactose pentacetate was prepared by Erwig and Koenigs²

¹ Contribution from the Carbohydrate Laboratory, Bureau of Chemistry, United States Department of Agriculture, and the Chemical Laboratory of Princeton University.

² *Ber.*, 22, 2207 (1889).

by the acetylation of galactose with acetic anhydride and sodium acetate. They found that the substance melts at 142° , and their analysis shows that its percentages of carbon, hydrogen and acetyl agree closely with the theoretical values for a galactose pentacetate. Fischer and Armstrong¹ found the specific rotation of the substance to be $+7.48^{\circ}$ in benzene solution. We have prepared a considerable quantity of this pentacetate by the indicated method, using the proportions 4 parts of sugar, one of anhydrous sodium acetate and 16 of acetic anhydride, have purified it without difficulty by recrystallization from alcohol, and have confirmed the quoted data on the melting point and the specific rotation in benzene. In chloroform solution (*chloroformum purificatum*, U. S. P.) we find dextro-rotation of the value $(\alpha) = +25^{\circ}$.

Erwig and Koenigs² mention that the boiling of this pentacetate with acetic anhydride and a little zinc chloride yields a sirupy product. We have investigated this change and find that there is produced a second galactose pentacetate which may be readily crystallized.

Fifty grams of the first pentacetate (m. p. 142°) were heated on the steam bath with 150 cc. of acetic anhydride containing 10 g. zinc chloride until the specific rotation changed from $+28^{\circ}$ to the constant value of $+105^{\circ}$, the reaction being complete within about fifteen minutes. The mixture was then poured into 500 cc. ice water, neutralized with sodium bicarbonate, and the solution extracted with chloroform, in which the acetates of the sugars are very soluble. The greater part of the chloroform was removed by distilling under reduced pressure, followed by evaporation in a strong air current. The residue was mixed with 95% alcohol to form a thick sirup and it was not difficult to bring about crystallization by scratching the wall of the glass container. The crystals were purified by several recrystallizations from alcohol until the specific rotation became constant.

The yield was about 70% of the weight of the first acetate. The substance, which we would designate for the present the second pentacetate of galactose,³ melts sharply at 95.5° .

On combustion, 0.2631 and 0.2746 g. subs. yielded 0.4727 and 0.4945 g. CO_2 and 0.1325 and 0.1385 g. H_2O .

Found: C = 48.99 and 49.10%; H = 5.52 and 5.60%. Theoretical, 49.23 and 5.64 for a hexose pentacetate.

The saponification of several half-gram samples of the substance by boiling 3 hours with 0.25 N sulfuric acid gave values ranging between 54.3 and 54.9% CH_3CO . Theory, 55.1. The saponification of the substance with alcoholic potash yielded crystalline galactose, which was identified by its specific rotation.

The specific rotations of the new pentacetate (m. p. 95.5°) in several solvents, all the rotations being in the right-hand direction, are recorded in the table.

¹ *Ber.*, 35, 838 (1902).

² *Loc. cit.*

³ In the following article a third crystalline pentacetate of galactose is described, and on account of its existence it appears preferable to avoid the designations α , β and γ until the relationship of these acetates to the α - and β -forms of galactose is established.—C. S. H.

Solvent.	Chloroform.			Benzene.		Methyl alcohol.	Glacial acetic acid.
Grams pentacetate per 100 cc. soln.	3.2500	3.3376	4.0084	1.6816	2.2412	3.9480	3.3732
$[\alpha]_D^{20}$	+106.7°	+106.9°	+106.1°	+94.8°	+92.3°	+113.6°	+114.0°

The second galactose pentacetate was crystallized also from the products of the acetylation of galactose with acetic anhydride and zinc chloride but the yield was so small that this method is not recommended.

Our thanks are expressed to Mr. A. S. Eastman, who has kindly verified some of the work.

WASHINGTON, D. C.

THE EXISTENCE OF A THIRD CRYSTALLINE PENTACETATE OF GALACTOSE.

By C. S. HUDSON.¹

Received April 10, 1915.

The acetylation of an aldose sugar with acetic anhydride and sodium acetate (the Liebermann method) has yielded the fully acetylated β -derivative in all cases in which a crystalline product was obtained. If one acetylates either the α - or β -form of glucose by this reaction, substantially the same product is obtained, namely, β -glucose pentacetate, mixed with a small proportion of sirupy acetylation products. It would seem probable in these cases that at least a small proportion of the isomeric alpha acetate is produced along with the larger amount of the beta derivative, and some months ago the writer undertook a careful search for the presence of the second pentacetate of galactose as a side product in the preparation of the first pentacetate² of this sugar by the Liebermann reaction. The acetates of galactose were chosen for the experiments because of the fact that the one which must be removed from the mixed products in order to permit the possible crystallization of the second pentacetate is a decidedly crystalline substance of low solubilities. On this plan, 400 g. of very pure galactose, prepared in the laboratory from lactose, were acetylated in the manner indicated and poured into cold water. About 275 g. of the first pentacetate of galactose (m. p. 142°) were obtained after one recrystallization from 95% alcohol of the crude crystalline product which did not dissolve in the water. The water was extracted with chloroform and this solution was mixed with the mother liquor from the crystallization of the first pentacetate and the chloroform allowed to evaporate slowly at room temperature. The sirupy residue crystallized somewhat in the course of several days, and these crystals proved to be more of the first pentacetate. The mother liquor from them later crystallized

¹ Contribution from the Carbohydrate Laboratory, Bureau of Chemistry, United States Department of Agriculture.

² See the preceding article in regard to the existence of these first and second pentacetates.

further, and after recrystallization from alcohol about 15 g. of a substance was obtained which melted at 96° . It was supposed that this was the product sought, namely, the second galactose pentacetate, which had been found to melt at $95-6^{\circ}$.¹ Later, an occasion arose to examine the specific rotation of this substance, which had not been done before because it was believed that its melting point characterized it sufficiently, and to my surprise it showed levorotation, $[\alpha]_D^{20} = -41^{\circ}$ in chloroform solution. The first pentacetate of galactose, melting at 142° , has $[\alpha]_D^{20} = +25$, the second, melting at $95-6^{\circ}$ shows $[\alpha]_D^{20} = +107$, both being of dextro-rotation. The levorotatory substance must therefore be considered a new acetate of galactose. At this stage Dr. J. M. Johnson undertook the further examination of these three acetates of galactose, an investigation which is now in progress, and I am much indebted to him for the following data which show that the new acetate is in reality a third pentacetate of galactose. From 175 g. of galactose he obtained by the method which has been described above, except with the improvement of neutralizing the aqueous solution with sodium bicarbonate before extracting it with chloroform, 163 g. of the first pentacetate of galactose (m. p. 142°), and sufficient of the new levorotatory acetate to yield 20 g. of it after several recrystallizations from alcohol to bring it to a constant rotation. This pure material showed $[\alpha]_D^{20} = -41.6^{\circ}$ in chloroform and melted at 98° . This temperature is thus quite distinct from that at which the second pentacetate melts, $95-96^{\circ}$, though of course the specific rotation of the latter, $+107^{\circ}$, fully distinguishes it from the new acetate. Saponification of the levorotatory acetate with alcoholic potash yielded crystalline galactose, which was recrystallized and identified by its initial and final specific rotations.

Acetyl determinations made by boiling half-gram samples with 100 cc. of 0.25 *N* H_2SO_4 during three hours, indicated 54.6 and 54.8% acetyl (CH_3CO). Theoretical value for a galactose pentacetate, 55.1. The value for a tetracetate is only 49.4%. Mol. wt. determinations in benzene solution by the freezing-point method gave values between 386 and 404. Theoretical for a galactose pentacetate, 390.

These data show that the substance is a third crystalline pentacetate of galactose. From a theoretical standpoint the existence of three such isomers is noteworthy because, while two of them may be assigned the usual stereomeric structures,

¹ See the preceding article by Hudson and Parker.

the existence of a third isomer must be accounted for on other grounds. It is possible of course that the third form may have the oxygen ring linkage on some other than the gamma carbon atom. This is the suggestion which Fischer¹ has recently made in connection with his discovery of a third modification of methyl glucoside which he obtained in the form of a distillable sirup. As mentioned, Dr. Johnson and myself are continuing the investigation of the isomerism of the three galactose pentacetates.

ON THE COMBINATION OF PROTEIN WITH HALOGEN ACIDS.†

BY J. H. LONG AND MARY HULL.

Received April 28, 1915.

Certain classes of combinations between protein bodies and halogen acids, and, in particular, hydrochloric acid, have been studied and frequently described. Before the full recognition of the fact that the proteins may act as basic bodies and hold these acids in salt forms, the distinction between such salts and substitution compounds was not clearly made. Hydriodic acid, for example, forms salts with egg albumin, but it forms also substitution products in which the iodine replaces hydrogen in nucleus groups. In this manner relatively large amounts of iodine may be added, but the products lose the properties of proteins.

In the production of these compounds and in the determination of the proportions in which proteins and halogen acids unite, a number of quite different processes have been employed. The results vary with the process and we are still without a satisfactory answer to some phases of the general question. Among the earliest papers describing definite combinations between proteins and acid those of Paal² may be referred to. Paal produced compounds which he considered as definite salts of peptones, containing from 10 to 15% of HCl. These were made by treatment of egg albumin with diluted acid and also by digestion of the protein by acid and pepsin. In these cases the salts were separated in comparatively pure form, but in most inquiries on the subject the aim has been to determine the ratio of combination between protein and halogen, rather than the isolation of the actual compounds. This has been done, usually, by finding the amount of acid held by a given weight of protein, when an excess is added and this excess measured by the aid of an appropriate indicator. In this manner, for example, Osborne⁴ showed, by use

¹ *Ber.*, 47, 1980 (1914).

² Presented at the New Orleans meeting of the American Chemical Society, April 2, 1915.

³ C. Paal, *Ber.*, 23, 1202 (1892); 27, 1827 (1894).

⁴ *THIS JOURNAL*, 21, 477 and 486 (1899).

of tropaeolin, that 1 g. of certain proteins will bind from 9 to 13 cc. of 0.1 N HCl. With the pure protein edestin, the mean amount was 12.7 cc. or 46.3 mg. This is 4.63% of the protein weight. Panormow¹ described definite molecular combinations of albumins with several acids which were obtained by mixing the proteins with dilute acids and precipitating by alcohol. The weights of hydrochloric and other acids combined in this manner appear from the analyses, however, to be rather low. In one case a hydrochloride contained HCl amounting to about 3.2% of the weight of the protein.

By aid of titrations with Guenzburg's reagent, Hoffa found that serum albumin will combine with about 6.3% of its weight of HCl, while the albumoses from egg albumin will combine with about 7.7%. These values become greatly increased as the proteins undergo digestion.²

Spiro and Pemsel³ followed a different method to determine the amount of acid which may be combined by proteins. This was based on the fact that the hydrochlorides or other combinations may be salted out as are the proteins themselves. By adding an excess of 0.2 N or 0.1 N acid to the protein solution, then a sufficient amount of ammonium sulfate solution for precipitation, the uncombined excess of acid may be titrated in the filtrate. Results are given for egg and serum albumins. For the former the amount of HCl combined was about 5% of the protein weight, and for the latter about 7% in the mean.

By following the general method of Cohnheim and Krieger, results were found by Erb⁴ which show a far greater maximum combining power of HCl than is indicated by the work of other observers. These results cannot be reconciled with the values obtained by Spiro and Pemsel, who did not observe any marked increase in the amount of HCl held when the weight mixed with the protein is increased. In the Erb experiments the amount of HCl held by 1 g. of serum albumin increases from 104 mg. to 204 mg. when the volume of 0.1 N acid used in solution is quadrupled. However, by use of a method identical in principle v. Rhorer⁵ reached the conclusion that the acid held by the protein does not vary as claimed by Erb. He showed, further, that the method followed by Erb could not be expected to yield accurate results. This conclusion seems justified by the facts.

We have sought to throw some light on the problem by working in a

⁵ *Arch. ges. Physiol.*, 90, 368 (1902). See also the discussion by Robertson, in *Ergebnisse der Physiologie*, 10, 216 (1910), where there is a very full citation of the literature.

very simple manner and by methods which at first sight might not be expected to give definite results. Our investigations grew out of some experiments intended to show the extent of combination between the acids and solid or coagulated proteins, and the behavior of these compounds on hydrolysis.¹ In our experiments we have added known volumes of diluted acids to known weights of proteins and have dried the mixtures at a low temperature or over sulfuric acid, followed by drying over solid alkali. It will be seen that reasonably constant results may be secured in this way which have some meaning.

While the titration of the excess of free acid standing over a mixture of acid and protein cannot give a correct measure of the acid which may be held, because of the ready dissociation of such compounds with liberation of acid, and because, also, of the behavior of available indicators in presence of unaltered protein, still the results in this way have some value for comparison. Some of the results reported by other workers, and referred to above, were thus secured, for example, those by Osborne cited.

We made mixtures of coagulated egg albumin with 25 cc. of 0.1 *N* HCl and 25 cc. of water and treated them as described below. The albumin used was in the form of dried, soluble, egg albumin which was weighed out in multiples of gram portions, dissolved and poured into a large excess of boiling distilled water containing a little dilute acetic acid. By pouring slowly and stirring constantly it is possible in this way to secure a very fine uniform coagulum. For each gram of weighed egg powder the protein in the coagulum amounts to 700 mg. Methyl orange was finally added to the mixed protein and acid, and the free acid determined. The difference between this and the acid added is calculated as acid held. The results are of course below the truth, somewhat. Some of these residual titrations were made at once and some after certain intervals. In some cases the acid solution and protein were mixed by stirring, without further agitation. In other experiments the mixtures were actively shaken in flasks and then allowed to stand, while, finally, in other experiments, the protein and acid were well rubbed together in a mortar. Table I gives the results secured.

The table discloses the fact that, even after long standing, the combination between acid and protein is incomplete if the mixture is simply stirred. Even after thorough shaking the same is true, but constant results come speedily when the mixture are well rubbed in the mortar. We secure practically the same end result from the solid protein, in this manner, that others have reported for protein solutions. The egg albumin combines with about 3% of its weight of HCl, when heat is not applied, and this represents a somewhat constant value for the combination as

¹ See paper in a recent number of *THIS JOURNAL*, by one of us, "On the Physiological Behavior of Combined Hydrochloric Acid," 37, 1333.

measured by indicators. For other proteins the results are not necessarily the same, of course.

TABLE I.

	Coag. from gm. egg.	Wt. of HCl held.			
		At once.	After 30 min.	After 60 min.	After 90 min.
Mixture made without shaking.....	1	0.0065	0.0112	0.0183	0.0189
	2	0.0102	0.0205	0.0284	0.0339

	3	0.0690	0.0700	0.0773	0.0740

By heating the proteins with dilute acid solutions on the water bath and evaporating slowly to dryness an increase in weight follows which corresponds to the addition of the acid and not to addition of acid plus water, which would be the case if hydrolysis had taken place. This is illustrated by the following experiments in which a constant weight of fibrin was mixed with increasing volumes of 0.2 *N* HCl, evaporated slowly to dryness, and weighed after heating to practically constant weight in the electric oven to 105°. The dry weight of the fibrin alone was 0.677 g. After weighing, the residue was mixed with carbonate and nitrate and fused. In the melt the HCl was determined by the Volhard method.

TABLE II.

7.....	2.5	18.3	0.696	0.019	0.0176

The determination of the chlorine is much more accurate than is that of the dry weight. It is somewhat difficult to bring the protein, with or without the acid, to a constant weight, but the results show a satisfactory degree of constancy. In Nos. 1, 2, 3 and 4 it is evident we have added a great excess of acid, and that the excess was expelled without adding water by hydrolysis. An amount of acid below that in No. 5 is insufficient to saturate the protein, under these conditions. The mean increase in weight for the first four mixtures is 0.0655, while the mean HCl addition in the same 0.0646. It is evident that we have no water addition here. In similar experiments made with egg albumin the mean increase in weight was 0.0680 and the mean HCl content 0.0704.

With this point established the greater number of experiments were concerned with the extent of the halogen acid addition, rather than with the gross weight increase. The experiments were made essentially in the same manner, using casein, fibrin and egg albumin.

Casein and HCl.

5.....	7.5	54.8	45.8	
6.....	5.0	36.5	32.9	
7.....	2.5	18.3	16.4	

As several experiments suggested that a high temperature might have the effect of causing the addition of too much acid, accompanied by some hydrolysis, the later tests were made by evaporating on a water bath, and slowly. Table IV shows the results secured by this condition of evaporation.

With the lower temperature the acid held is somewhat less and amounts to 9.04% of the weight of the casein. It is clear that no excess of acid is added in the cases where an excess of acid was mixed with the casein at the outset. The capacity for combination seems to be a constant in this respect, but apparently varies with the temperature. This result, which is confirmed by many others, seems to disprove completely the view of Erb, referred to above, that the amount of acid taken up by the protein increases with the amount added.

Fibrin and HCl.

The fibrin used for these tests was thoroughly washed until white, mixed with toluene and pressed out as dry as possible, after passing a number of times through the meat chopper. The mass so prepared holds enough toluene to keep some weeks unchanged, at a low temperature. It is not necessary to freeze it. The experiments were made as with the casein, by evaporating slowly on a water bath. Two independent sets of experiments, A and B, are given in Table V.

The results here for the larger acid concentrations are very regular and close to a mean value. They are somewhat higher than the corresponding results for the casein and show, as we found there, that no increase in the amount of HCl combined follows from increase in amount added to the fibrin.

TABLE V.
2.5 g. fibrin = 750 mg. protein, plus HCl.

No.	Cc. 0.2 N HCl	Mg. HCl.	A. Mg. HCl held.	B. Mg. HCl held.	Mean of first four.
1.....	20.0	146.0	71.1	70.1	70.8
2.....	15.0	109.5	70.0	70.3	
3.....	12.5	91.2	71.1	72.1	
4.....	10.0	73.0	71.1	70.3	
5.....	7.5	54.8	50.7	51.5	
6.....	5.0	36.5	31.9	32.8	
7.....	2.5	18.3	16.4	17.3	

Egg Albumin and HCl.

We have made at different times a large number of tests as to the rate of combination between the acid and this common protein. The egg used for the purpose was referred to above, when another experiment was described. It was part of a large lot of clear dried egg white of Chinese origin which was selected because of its solubility and low color, and which we have used as a standard preparation for a number of years. In these experiments a known amount was weighed and coagulated, as explained above, and small portions of the coagulum, to correspond to 750 mg. of anhydrous protein, taken for each test. Volumes of 0.2 N HCl were added as in the other tests and the mixtures evaporated slowly to dryness on the water bath. After this the residue was dried at 105° to a constant weight. As the coagulum holds a large amount of water the dry weights taken are not as accurately defined as with the casein or the fibrin.

Two sets of experiments are here given, A and B, Table VI.

TABLE VI.
1.07 g. egg = 750 mg. protein, plus HCl.

No.	Cc. 0.2 N HCl	Mg. HCl.	A. Mg. HCl held.	B. Mg. HCl held.	Mean of first four.
1.....	20.0	146.0	80.3	70.3	77.7
2.....	15.0	109.5	84.0	80.3	
3.....	12.5	91.2	81.8	83.6	
4.....	10.0	73.0	70.3	71.2	
5.....	7.5	54.8	51.5	52.9	
6.....	5.0	36.5	32.8	35.0	
7.....	2.5	18.3	17.3	16.0	

The values for the egg combination are not as uniform as were the others, but it is clear that no excess of HCl is held by the higher concentrations. Egg albumin seems to have a higher binding power than has fibrin or casein, the relations, calculated for the gram basis, being:

Casein, 90.4, or 9.04%; fibrin, 94.4, or 9.44%; egg albumin, 103.6, or 10.36%.

These values are much higher than are those found by means of indicators, and undoubtedly have as definite a meaning. Before going into any further discussion concerning them, the results given in corresponding experiments with hydrobromic acid and hydriodic acid will be given.

Hydrobromic Acid and Protein.

Portions of the three proteins were treated with 0.2 *N* HBr exactly in the manner given for HCl. The bromine was found after fusion of the dry residue.

TABLE VII.

750 mg. of anhydrous casein plus HBr.

10.....	2.5	40.5	40.4	

TABLE IX.

1.07 g. egg albumin powder = 750 mg. protein plus HBr.

No.	Cc. 0.2 <i>N</i> HBr.	Mg. HBr.	Mg. HBr held.	Mean of first three.
1.....	30.0	485.7	376.5	375.3
2.....	27.5	445.2	378.7	
3.....	25.0	404.8	370.7	
4.....	20.0	323.8	309.2	
5.....	15.0	242.8	224.7	
6.....	12.5	202.4	179.7	
7.....	10.0	161.9	147.8	
8.....	7.5	121.4	109.2	
9.....	5.0	80.9	76.5	
10.....	2.5	40.5	39.6	

The above results show that hydrobromic acid is taken up in large quantity by the three proteins and in amounts relatively much greater than is hydrochloric acid. For 1 g. of the proteins the acid combination is as follows:

Casein, 365 mg. or 36.5%; fibrin, 398 mg. or 38.9%; egg albumin, 500 mg. or 50%.

It is evident that the combination cannot be on the same basis as that of the hydrochloric acid, as the amounts combined are not in the proportion of 36.5 to 80.9. But the weights combined with 1 g. of protein stand in the same order for the two acids, as seen by these figures, the amount held by the casein being called 100.

HCl: Casein, 100
HBr: 100

Fibrin, 104.4
106.6

Egg albumin, 114.6
137.0

For the casein the HCl and HBr combined are in the proportion of 90.4 mg. to 365 mg. for the gram of protein, or nearly in the ratio of 5 to 9 molecules. For the HBr combination with fibrin the ratio is a little higher with reference to the HCl. For the egg albumin the HCl and HBr combinations stand to each approximately in the proportion of 5 to 11 molecules. These numbers probably have some significance, which will be taken up below.

Hydriodic Acid and Protein.

By the same general plan combinations between the three protein bodies and hydriodic acid were made. But a little study showed that the constancy in combining ratios found with the other acids is lacking here. When this acid is added to prepared proteins and the mixture evaporated the increase in weight is roughly in agreement with the iodine taken up, calculated as HI. But sometimes there is a discrepancy, and the total increase in weight may even be less than the added iodine. This can be the case only when something else is driven out of the protein molecule, that is, when a substitution, as well as an addition follows. This is seen from Tables X and XI. In the experiments made with egg and fibrin these results were secured.

TABLE X.

1.07 g. egg albumin powder equivalent to 750 mg. protein and 806 mg. dry residue plus HI.

No.	Cc. 0.2 N HI.	Mg. HI.	Dry residue.	Inc. weight.	Mg. HI held.
1.....	30.0	768	1400	594	588
2.....	25.0	640	1278	472	463
3.....	20.0	512	1185	379	381
4.....	15.0	384	1111	305	287
5.....	12.5	320	1082	276	245
6.....	10.0	256	1014	208	197
7.....	7.5	192	985	179	161
8.....	5.0	128	919	113	108
9.....	2.5	64	866	60	53

In four additional experiments with the largest amount of 0.5 N acid added, 30 cc., the weight increase and HI fixed were as follows:

Increase in weight.....	603	588	581	572	Mean,	586
HI held.....	589	561	568	583	Mean,	575

It is somewhat difficult to dry these mixtures to constant weight, and this may account for part of the irregularity. In the course of the evaporation and final drying they become dark, which suggests the liberation of iodine, but treatment with carbon disulfide or chloroform fails to bring anything into solution. The following results were secured by repeated experiments with smaller weights of iodine added to the constant weight of egg:

TABLE XI.

1.07 g. egg powder = 750 mg. protein plus HI.

		305	397

In the first of the above tests in which the 30 cc. of 0.2 N HI was added, the amount held by the protein is over 76% of the weight of the protein. This cannot be accurately titrated by normal alkali, as is the case with the hydrochloric acid combinations of the egg albumin and other proteins. In these combinations the titration results and the chlorine determinations with silver nitrate, after fusion, agree. It appears, therefore, that the HI combinations by heat are of an order different from those of the HCl compounds. But the combinations made without heat are apparently similar, as will be shown below.

It has been shown in a previous paper by one of us¹ that HI combines with casein under the same conditions and to yield compounds containing for 1 g. of anhydrous casein about 575 mg. of iodine, calculated as HI. This appeared to represent the maximum combining power. Like the other combinations, these possessed an ochre color, suggesting a product resembling the iodalbose of Weyl.² This product was prepared by add-

¹ THIS JOURNAL, 29, 1334 (1907).² Z. physiol. Chem., 68, 236 (1910).

ing egg albumin to concentrated hydriodic acid at water bath heat, and pouring the mixture into an excess of water. The other precipitate which formed was purified by solution in alkali and reprecipitation. The iodine is firmly fixed in the product, which seemed to be lacking in some of the characteristic protein reactions. In all our experiments the iodine was used only in the form of dilute HI solution and in absence of heat no other-red color was developed. The concentration of the dilute acid in evaporation possibly leads to the same or similar compounds.

Some later experiments on the combination between casein and hydriodic acid, carried out as were those for the other proteins, gave the following results. The amount of iodine held is much larger than in the earlier experiments, but whether by addition or substitution is not clear. The iodine is calculated as HI.

Most of the compounds of iodine and protein described in the literature are substitution products, and are obtained by the action of the halogen, as solid, tincture or in KI solution. The products contain from about 5 to 15% iodine, but show reactions deviating from those of proteins in some respects. Such compounds have been described by Hofmeister,¹ Blum,² Liebrecht,³ Hopkins and Pinkus,⁴ Kurajeff,⁵ Pauly and Gundermann⁶ and others and are not to be confounded with the salts secured by treatment with weak HI. Because of the easy decomposition of the latter, however, and its marked reducing properties, iodine is liberated to be carried into the molecule.

With the hope of throwing further light on the nature of the reaction, we have repeated a number of the above experiments in such a manner as to remove the excess of acids at a low temperature. This was accomplished by adding the 0.2 N acid to the solid protein as before, and allowing the mixtures to stand some weeks over sulfuric acid to remove

most of the water. The small evaporating dishes holding the residues were then placed in bell jars over powdered sodium hydroxide to absorb acid vapors. In this manner practically all of the acid was removed, and most of the water. The mixtures with HCl and HBr evaporated down without much color, but the HI mixtures became reddish brown, as before. A short, final drying in the air oven was necessary to bring to constant weight. Table XIV shows the final weights and the halogen content of the products.

Only the larger volumes of acid were added in these experiments.

			Mean,	71.3			Mean,	329			Mean,	413

These results are extremely interesting, as they show the extent of combination without the aid of heat. The final temperature of drying to constant weight in the electric oven was not over 75°, and this heat was not applied until all acid vapors had been absorbed in the desiccators. It will be seen that the results are very close to those secured by evaporating the acid and protein mixtures in the water bath and drying at 105°.

It is evident, therefore, that the proteins and acids unite in this manner in proportions which are apparently definite, but not in proportion to the molecular weights of the acids. The power of combination is possibly connected with the volatility of the acid, since we find that HI unites with the proteins in proportion greater than does HBr, and this, in turn, greater than HCl. Nothing is shown in the HI column of the last table which would suggest that the halogen acid addition is accompanied by the loss of water. That is, no hydrolysis appears to have taken place,

but the reaction follows as would that between glutaminic acid and hydrochloric acid, for example. In the complex protein molecules there are many of these amino groups available and the number of acid molecules which may be united to them apparently depends on the "strength" of the acid, as measured by its lower volatility.

Table XIV discloses the important fact that we have a constant combination for the hydriodic acid, when amounts above 15 cc. of the 0.2 *N* solution are used with 750 mg. of protein. For 1 g. of each protein about 553 mg. of HI goes into combination, and this evidently represents a maximum under the conditions. When heat is applied much more may be held in some form.

These halogen acid combinations, whether made by simple action of the acid on the solid protein or by this treatment followed by evaporation, undergo a rather marked degree of dissociation by contact with water. The dry hydrochloride of egg albumin gives up its acid and on this account the compound has been used to some extent as an aid to digestion. The rate of dissociation is, however, slow. Some information on this point is given in a recent publication from this laboratory in which the hydrogen concentration of HCl separated from egg albumin was measured by the gas chain method.¹ In the treatment of a given weight of a protein hydrochloride with successive equal volumes of water the acid strength of the dissociated portion gradually diminishes.

It has been shown above that the behavior of hydriodic acid with protein when evaporated is different from the behavior of the corresponding chlorine and bromine acids. But the combination as measured by indicator titration is of the same order, as shown by these results. Portions of the three substances corresponding to 750 mg. of dry protein were rubbed up in a mortar with 10 cc. of 0.2 *N* acid and washed into flasks with 10 cc. more. At the end of an hour the excess of "free" acid was found by 0.1 *N* alkali and methyl orange.

TABLE XV.—COMBINATION OF HCl, HBr AND HI WITH 750 MG. OF PROTEINS AS DESCRIBED.

	Cc. 0.2 <i>N</i> HCl	Cc. 0.2 <i>N</i> HBr	Cc. 0.2 <i>N</i> HI
Egg.....	3.4	3.0	3.8
Fibrin.....	3.5	3.7	4.5
Casein.....	2.2	2.1	1.5

In each case the fibrin seems to hold more acid and the casein less than the egg. We should expect the same volume of acid to be combined with the different proteins. The discrepancy is probably due to the lack in delicacy in the behavior of this indicator in presence of undigested protein, but the results are close enough to show that the combinations are of the same type.

¹ THIS JOURNAL, 37, 1333 (1915).

In place of titrating directly, similar mixtures were filtered and the residues on the filter washed with successive equal portions of water, 20 cc. in each case. These washings were titrated separately. It was found that the fibrin held the acids more tenaciously than the other proteins. In seven or eight washings about one-fifth of the hydrochloric acid could be removed from the egg, a tenth from the fibrin, and a fourth, or less, from the casein. The dissociation of the hydrobromic acid is of the same order.

The behavior of hydriodic acid is most interesting here in view of the large weight held after evaporation experiments. The figures of Table XVI show the amount of 0.2 *N* NaOH required to titrate the first filtrate and successive washings in experiments with egg and fibrin.

TABLE XVI.

	Egg.		Fibrin.	
	a.	b.	a.	b.
1st filtrate and washing.....	13.75 cc.	14.30	12.55	13.20
2nd filtrate and washing.....	1.90	2.25	1.55	1.90
3rd filtrate and washing.....	1.25	1.30	1.50	1.20
4th filtrate and washing.....	0.90	0.60	0.70	0.90
5th filtrate and washing.....	0.60	0.20	0.60	0.40
6th filtrate and washing.....	0.30	0.00	0.50	0.20
7th filtrate and washing.....	0.40	0.10
8th filtrate and washing.....	0.20	..
9th filtrate and washing.....	0.10	..
Total.....	18.70	18.65	18.10	17.90
Cc. 0.2 <i>N</i> HI held.....	1.30	1.35	1.90	2.10

It is seen that after the prolonged washings about two-thirds of the HI held by the egg is washed out and over half of that held by the fibrin, as measured by the direct titrations. While the procedure is lacking in quantitative accuracy it gives a good comparative result. It is evident that when heat is not applied the hydriodic acid is very loosely held. The type of salt produced in this way suffers extended dissociation by water.

Resume.

The experiments detailed above show that the amounts of the halogen acids which combine with casein, fibrin and egg albumin, as measured by the usual indicator titration, are low and not accurately proportional to the molecular weights of the acids. The discrepancies are probably due to the lack of delicacy of the indicator in presence of unchanged protein, on the one hand, and to the more or less complete dissociation of the protein-acid compound on the other. The latter is doubtless the more important factor, since it has been shown that a large fraction of the acid may be washed away from the protein.

When the proteins named are treated with the halogen acids of 0.2 *N* concentration, in excess, and the mixtures evaporated at a low temperature by standing over sulfuric acid some weeks, followed by similar treatment over solid alkali, and final drying to constant weight at 75°, very constant weights of acid are taken up and held by the protein. These weights of acid are not increased by the excess added, which points to the definite character of the reaction. The amounts are not proportional to the molecular weights of the acids, the combining proportion being relatively greater for HI than for HBr and greater for the latter than for HCl. But the compounds all appear to be salts of the protein molecule and contain many times as much acid as is suggested by the titration combinations. These dry salts undergo dissociation readily when mixed with water.

If the acid-protein mixtures are evaporated on the water bath, in place of being dried at a low temperature, the behavior of HCl and HBr remains essentially the same. No greater amounts of the acid are taken up by a gram of protein and we doubtless reach here a maximum in the combining power of the acid and protein. A salt of a type different from that formed in solution at a low temperature is secured. In the case of the HI, however, there is no such limit to the iodine held, and it is probable that we have here a substitution of the element in the nucleus of the protein molecule, as well as an addition of the acid. As much as 75% of the weight of the original protein may be so held and the combination has a brownish ochre color, with loss of protein reactions.

STUDIES ON THE CULTURE MEDIA EMPLOYED FOR THE BACTERIOLOGICAL EXAMINATION OF WATER.

1. THE SCHARDINGER-DUNHAM MEDIUM FOR TESTING FOR THE PRESENCE OF HYDROGEN SULFIDE FORMING BACTERIA.¹

By E. M. CHAMOT AND H. W. REDFIELD.

Received March 27, 1915.

Introduction.

Although an enormous amount of time and labor has been spent upon investigations of bacterial culture media with a view of shortening the time required for diagnostic results and producing media yielding more uniform and more constant results, a critical review of the literature fails to show, save in a few instances, that the media which have eventually been proposed have received truly systematic study and that the concentrations suggested are necessarily those which are best fitted for the purposes for which the media have been made.

¹ Papers read at the Rochester Meeting, American Chemical Society, September, 1913.

That slight variations in concentration in most of the media employed in the bacteriological examination of water may lead to relatively great differences in both quantitative and qualitative results has long been recognized and has been the basis of suggested so-called standard media, but the fact has apparently been ignored that in the selection of concentrations, those should be chosen, a slight variation from which will lead to the least possible variation in the diagnostic characters sought; will furnish dependable results in the shortest possible time; and yet will give practically identical results in the hands of different analysts and investigators.

Comparison of the data obtained by different water analysts shows such variations between wide limits, even making due allowances for the personal equation, that it is evident that our standard media need more study and possibly revision.

In the laboratories of the senior author considerable routine work is carried on in the periodic examination of waters and the control of purification plants. In this work he found that the media prepared at different times by himself and coworkers frequently failed to yield identical results.

Although it seemed probable that the only satisfactory solution of these problems lay in abandoning such variable materials as meat broth and peptone and adopting nutritive substances of definite composition—in other words, so-called “synthetic media”—an attempt was made to study the causes of the variation in results obtained in our work and thus to eventually find, if possible, a really satisfactory “synthetic” medium. With these ends in view, investigations of all the different culture media employed in water examinations were begun several years ago and will be continued until all the media have been studied.

The results obtained proved to be so interesting, curious, and at variance with what we expected that it seems worth while to present the facts in a series of articles, of which this is the first.

Part I. Historical.

In 1877 Gayon¹ published what appears to be the first recorded proof of the formation of hydrogen sulfide by bacteria acting upon albuminous material. Two years later, 1879, Miquel² succeeded in isolating from sewage, from contaminated waters and also from waters believed to be potable, an organism having the power of changing free and combined sulfur to hydrogen sulfide. Three years later Boehm³ obtained similar results with an organism isolated from well water. These results paved the way for a large amount of work upon the formation of hydrogen

² Miquel, *Bull. soc. chim.*, [2] 32, 127 (1879); *Ann. de l'Obser. Mont-Souris*, 1880.

³ Boehm, *Monats.*, 3, 224 (1882).

sulfide from organic and inorganic sulfur compounds by the action of bacteria, but no investigator appears to have seriously considered the possibility of making practical use of this property of certain bacterial species in the examination of water until in 1894, Schardinger¹ pointed out the advantages in sanitary water examinations of applying tests which would reveal the presence of hydrogen sulfide producing bacteria. Up to this time even search for the presence of members of the colon group of organisms was but seldom practiced in routine work, the procedure usually followed, namely, that of ascertaining merely the number of micro-organisms in a certain definite volume of the sample, Schardinger did not consider to be a reliable criterion of the quality of the water. In searching for methods which would yield more definite information as to the nature and probable source of the bacteria present in the water, he states that he was guided by the investigations of Nencki, in which it was shown that in the small intestine of healthy men, the bacterial processes are chiefly fermentative, but that in the large intestine they are chiefly putrefactive. Since in the great majority of polluted waters we have to deal with fecal contamination there are two groups of bacteria, those causing fermentations and those causing putrefaction, "concerning which one must inform himself in a suspected water."

The method suggested for testing for the presence of putrefactive bacteria consisted in adding 100 cc. of the sample of water to 10 cc. of a sterile solution containing 1 g. Witte peptone and 1 g. sodium chloride. After incubation for twenty-four hours at 37°, a strip of filter paper impregnated with lead carbonate was hung in the neck of the flask.

"If the investigated water was impure, there appeared in a marked degree (a) a pronounced fecal-like odor; (b) the turning of the lead carbonate paper yellow-brown to black, immediately or within a very short time, due to the formation of lead sulfide."

Much work upon "putrefactive" organisms followed, but Schardinger's work appears to have escaped the attention of water analysts until 1897, when Dunham² investigated the Schardinger method and like his predecessors he appears to have been guided by Nencki's work, for he states that

"All sewage which receives human feces contains the bacillus coli communis, or if it does not, has been subjected to germicidal agencies that would also kill pathogenic bacteria, derived from the cases of disease. It is fair to assume that ordinary sewage would also contain the common bacteria of putrefaction. We must therefore direct our attention to the means of demonstrating the presence or absence of those species in the water under examination."

For the detection of "putrefactive" bacteria Dunham made the following slight modification in the Schardinger medium: To about 90 cc. of water, 10 cc. of a 10% peptone, 5% salt solution, previously sterilized,

¹ Schardinger, *Cent. Bakt.*, 16, 853 (1894).

² Dunham, *THIS JOURNAL*, 19, 391 (1897).

were added. This gave a resulting solution containing 1% of peptone and 0.5% of sodium chloride. The mixture was made in a sterile Erlenmeyer flask, provided with a cotton plug. A strip of paper, impregnated with lead carbonate, was suspended over the mixture and the flask was then placed in the incubator at 37° for twenty-four hours. Under these conditions of temperature and nutrition, Dunham claimed that

"The colon bacillus and the bacteria of putrefaction readily multiply and the latter cause the production of hydrogen sulfide which discolors the lead paper."

Although a few water analysts have made use of the Schardinger-Dunham method in the examination of suspected waters, so far as the authors have been able to ascertain no further work has been published upon the subject of the significance of the presence of hydrogen sulfide producing bacteria in drinking waters nor of methods for their detection.

In the course of some ten or more years of experience with this modified method in the hands of the senior author upon many hundred waters, it was found to be of exceeding great value in forming a definite opinion, especially in waters of the class which would have been graded as "suspicious" were only the usual methods followed. The chief drawback was that the indications were not obtained in a short enough time. With badly contaminated waters strong tests for hydrogen sulfide could be obtained in from twenty-four to forty-eight hours, but with other waters from three to four days of incubation were necessary. Moreover, it appeared probable that the hydrogen sulfide rapidly formed was not due to the colon group but to some other class of bacteria, while the slowly evolved hydrogen sulfide might possibly be ascribed to colon group organisms rather than those classed by Dunham as putrefactive.

Part II. Experimental.

Upon studying the data collected, some abnormally short incubation periods were noted and some preliminary work showed that the medium could be sensitized in various ways, and, as the speed with which results can be obtained is a very vital point in the bacteriological examination of water, it was thought that the medium was worthy of a systematic study with a view of obtaining one which would yield positive results in the shortest time and with the greatest possible uniformity.

In the Schardinger medium we have three things which will influence the growth of the bacteria: (1) The concentration of the peptone; (2) that of the inorganic salt present (in this case sodium chloride), and (3) the nature of the reaction of the medium. We may therefore consider that we are dealing with a three-component system and in order to facilitate the investigation the triangular diagram may be resorted to.

The diagram was used in the manner originally proposed by Gibbs and not in the manner later proposed by Roozeboom, which latter is the way in which it is now used by most physical chemists.

By using the diagram according to the Gibbs method, which it will be recalled, gave very excellent results in the hands of Schreiner,¹ in the study of plant nutrients, the concentrations of the three factors, the peptone, inorganic salts, and reaction adjustor could be varied in a systematic manner between wide limits, so as to find the maximum and minimum limits beyond which it would be useless to go in subsequent work, where only one component would be varied at a time. In other words, fields could be found within which the production of hydrogen sulfide would be most rapid and most energetic, and further work confined to those fields.

The rulings of the triangular diagram used gave sixty-six points of intersection and hence in each case sixty-six different combinations of the three components; but in order to obtain combinations in which the salts were high when peptone was low and *vice versa*, and a similar relation of concentrations with respect to acidity recourse must be had to a series of diagrams in which first the order of concentration of one component was reversed, and then another. A series of eight diagrams covers all possible combinations.

It is of course obvious that in each one of the eight diagrams there are a number of points representing possible media which must necessarily be omitted in any given run, as, for example, all those containing no peptone. The actual number of culture media made up in each diagram will therefore never be sixty-six, but will be considerably less than this.

Peptone Used.—The peptone employed was that known as "Witte Peptone" obtained from Kahlbaum. The investigation having extended over a period of three collegiate years, three different lots of peptone were employed. In the case of each shipment, a 10 kilo package was carefully sampled and subjected to chemical and physical tests. The three lots were found to be remarkably uniform and substantially identical in character. But in order to eliminate any possible doubt, simultaneous runs were made on two samples at a time. Identical results were obtained with all three samples in every instance. In addition, it was found desirable to check the compositions by determinations of the acidity, the specific gravity, optical rotation and the coefficient of viscosity of different concentrations of the different samples of peptone at different temperatures. Substantially identical results were obtained.

The chemical analyses of the different samples included moisture, ash, nitrogen, sulfur and phosphates in the ash. The variations in the different samples were no greater than the differences in percentage found in different portions of the same sample.

As is well known, what we ordinarily call a peptone solution is not a solution at all, but is a colloidal suspension, and when peptone is boiled with water there is always formed a heavy sediment which may properly

¹ Schreiner, Bur. Soils, U. S. Dept. Agr., *Bull.* 70.

be considered to be that part of the peptone which is not fine enough to stay in suspension.

In order to ascertain whether this assumption is true and also in order to find out whether any effect would be produced upon hydrogen sulfide production if this sediment were filtered from the medium, the following tests were made:

1. Quantitative determinations were made of the amounts of sulfur, nitrogen, ash, and phosphates in the ash of the sediment and of the peptone. These various constituents were found to be identical within the limits of error of the methods.

2. In each of fifteen of the special culture flasks described below, was placed 10 cc. of unfiltered 30% peptone solution and 0.5 g. of sodium chloride. Another fifteen flasks were similarly prepared, except that filtered peptone solution was used in place of the unfiltered. All of the flasks were plugged and sterilized, and then each was inoculated with 90 cc. of artificial sewage and incubated under similar conditions.

The amounts of hydrogen sulfide produced in the filtered and the unfiltered media were practically identical. It therefore appeared that the precipitate was peptone and that it made no difference whether unfiltered or filtered media were employed. Nevertheless, since it is decidedly advantageous to start with a clear medium so as to detect the growth of bacteria by means of the turbidity and sediment produced in the medium, all peptone solutions were filtered before they were used.

The Witte peptone employed was found to contain 1.006% total sulfur by the Liebig-Koch method,¹ while the peptone in the culture media after filtration was found to contain 0.911% total sulfur, showing that in filtration there is substantially no loss of sulfur.

Koch and Carr² have shown that lipid sulfur compounds are soluble in alcohol, whereas protein sulfur compounds are not. Applying this extraction method to the peptone, two portions were obtained, one soluble in alcohol and one insoluble in this solvent. It was found that the soluble portion contained 0.80% of total sulfur, while the insoluble portion contained 1.08% total sulfur.³

Culture media made from alcohol-soluble peptone and from alcohol-insoluble peptone gave in neither case results as good as those made from the original peptone.

Aqueous solutions of peptone are distinctly acid to phenolphthalein, the amount or degree of acidity rapidly rises with the temperature; hence in adjusting media care must be observed that the media shall always be adjusted at the same temperature. Nor must it be forgotten that

¹ Redfield and Huckle, *THIS JOURNAL*, 38, 607 (1915).

³ Redfield and Huckle, *Ibid.*, 38, 612 (1915).

when placed in the incubator the medium becomes more acid than it was at room temperature. After considerable experimentation it was found most convenient to add the reaction adjustor after titrations made at 20°, this being so nearly room temperature as to be readily and quickly obtained. In all the work hereinafter described it will be understood that the stated reactions of the media refers to that at 20°. The acidity of a simple peptone solution or peptone solutions containing simple neutral salts is directly proportional to the concentration.

In the course of some preliminary investigations undertaken some years ago, it was found that the culture flasks employed for testing for the presence of hydrogen sulfide should have wide necks and thus expose a moderate surface of liquid to the air. A 100 cc. modified Pasteur flask was therefore made, having a neck 2 cm. in diameter and of such a size as to bring 100 cc. and 110 cc. levels in the neck of the flask, marks being made for these heights. The small tube of the ground cap was made 4 cm. long and 4 mm. in diameter. This tube serves to hold a cotton plug at its lower end and above the plug a strip of lead acetate paper.

These flasks having answered admirably in routine work were used throughout the present investigation.

After inoculation with a sample, a tin foil cap was placed over the upper end of the tube carrying the lead paper.

As the investigation progressed, evidence was obtained that a better type of flask could probably be devised and further work along this line is being conducted.

The Effect of Peptone Concentration upon Hydrogen Sulfide Formation.—Flasks of media were prepared with the compositions required by the triangular diagram reading clock-wise with concentrations varying between the following limits: 0 to 5% peptone; 0 to 5% acidity in terms of normal hydrochloric acid and 0 to 5% sodium chloride. These runs were made upon reversed diagrams as already described. These flasks were inoculated with equal amounts of sewage¹ and incubated at 38°, and observed at frequent intervals for the first appearance of the blackening of the strips of paper impregnated with lead acetate which had been placed in the tubular top of the caps of the flasks.

It was found in these four runs that the respective fields in which hydrogen sulfide was most quickly developed were as follows:

3.0 to 4.5% peptone;	0.0 to 1.5% NaCl;	0.0 to 2.0% N acid.
2.5 to 3.0	1.0 to 3.0	1.0 to 2.5
4.0 to 5.0	0.0 to 2.5	0.0 to 2.5
4.5 to 5.0	2.0 to 2.5	2.5 to 3.0.

¹ In most of the runs an artificial sewage was prepared by adding one loopful (0.02 g.) of fresh human feces to one liter of water, shaking thoroughly and pouring the turbid liquid through a sterile cloth. This water was found to contain 2000 to 5000 organisms growing on gelatin at 26°, 100 to 200 colonies on agar at 38°, of which from 20 to 40 were of the *B. coli* group.

From a careful study of all of the data obtained in the four runs, it was found that the very best conditions had been obtained within the following limits:

2.5 to 5.0% peptone; 0.5 to 1.5% NaCl; 0.5 to 1.5% *N* acid.

Consequently a run was now made, in which all of the possible combinations of 2.0%, 2.5%, 3.0%, 3.5% and 4.0% of peptone; 0.5%, 1.0% and 1.5% of NaCl; and 0.5%, 1.0% and 1.5% of normal acid were used, plotted on two component diagrams.

Four checks with 2.0%, 2.5%, 3.0% and 4.0% of peptone, with no added salt and with a reaction of 1.0% normal acid were also prepared.

It was found in the uninoculated media, that of the combinations prepared, the only ones which were clear, with very little sediment, were those containing 3.0% of peptone, 1.0% and 1.5% of NaCl, and with an acidity to phenolphthalein of 1.5% normal acid. It was, moreover, a general rule that the quantity of peptone and of sodium chloride did not seem to have much influence on the amount of turbidity in the solution, but that the reaction did have such an influence; the less the acidity, the greater the turbidity; but there were many exceptions.

Each flask was inoculated with 90 cc. of artificial sewage.

As regards the turbidity of the inoculated media before incubation, none were perfectly clear, with no sediment, but the best combinations were those in which the reaction was equivalent to 0.5% normal acid, and where NaOH had been used to adjust the reaction.

The inoculated flasks were incubated at 38° and frequently observed for evidences of hydrogen sulfide production.

As regards the rapidity of hydrogen sulfide production, it was found to be most rapid in those combinations containing 3.5 and 4.0% of peptone, the concentration of the sodium chloride and the reaction of the media apparently not making a great deal of difference, in the narrow limits used.

The largest amounts of hydrogen sulfide were produced in general in the flasks having from 3.0% to 4.0% of peptone; from 0.5% to 1.5% of NaCl; and with a reaction equivalent to from 1.0% to 1.5% normal acid. These were also the combinations in which the media became the most turbid after incubation and in which the largest amounts of grayish green sediment were produced. It was also noted that in most of these flasks, there were particles of dark green material floating on the surface which sank on tapping the flasks.

In order to obtain more reliable information as to which combinations were really best and produced hydrogen sulfide most rapidly, it was deemed advisable to make up in triplicate those combinations which had given the best results. While none of the combinations used were perfectly clear and free from sediment either before or after inoculation, they were

near enough so for all practical purposes, so far as judging how the growth and development of the bacteria had proceeded on incubation.

The results of all the combinations tried showed that when sodium chloride was the inorganic salt present, there was not much choice between 3.0%, 3.5% and 4.0% of peptone, all of which were much superior to 2.0% and 2.5% of peptone.

In order to throw light upon the question of the effect of the inorganic salt upon the peptone concentration, runs were made, similar in all respects to those recorded above but with the difference that sulfate, nitrate and phosphate of sodium were substituted for sodium chloride; and also in which the chloride, sulfate, nitrate and phosphate of potassium, of ammonium, of calcium and of magnesium were, respectively, substituted for sodium chloride and in which the reaction was adjusted in a variety of ways.

Without giving the details of the results of each run, suffice it to say that in all cases from 3.0% to 4.0% of peptone furnished the best concentrations for most rapid and most energetic production of hydrogen sulfide by the bacterial floras employed. The value of the inorganic salt in the medium will be discussed below.

In most standard culture media it is customary to add an extract of fresh lean beef as one of the components. It was therefore thought essential that the value of such an addition to the Schardinger medium be investigated. To this end fifty flasks were prepared in which varying volumes of meat broth were added. The meat broth used was prepared by digesting 2100 g. of finely chopped beef with 4200 cc. of water. The extract was filtered through cloth and the meat pressed in an iron press until substantially dry. The extract was then boiled, made neutral to phenolphthalein with sodium hydroxide and filtered through paper. The clear meat extract thus obtained contained 2.22% of total solids of which 0.69% was ash. The fifty flasks employed were divided in lots of ten of similar concentration, with respect to meat extract and peptone. Each set of ten was again subdivided, half receiving 0.5% of potassium chloride, the other half no potassium salt. The series after inoculation contained from 0 to 3% peptone and from 0 to 50 cc. meat extract. The 3% peptone contained no meat extract and the 50 cc. meat extract flasks no added peptone, between these two limits the media contained variable quantities of each nitrogenous component. In every case the volume of the media was 65 cc. and to this was added 35 cc. of sewage. At the end of eighteen hours all of the flasks containing meat broth had begun to show hydrogen sulfide, while those containing peptone, but no meat, had not yet developed a test. At the end of twenty-four hours the simple peptone media had begun to show hydrogen sulfide, but the media containing meat broth still showed more. The most powerful evolution

occurred in media containing 2.25 g. of peptone and 50 cc. of meat extract. In all the media in this run the presence of the potassium chloride led to more rapid production of hydrogen sulfide and in larger amounts.

Were conclusions to be based merely upon the time of the appearance of hydrogen sulfide as revealed by the lead acetate paper, it would appear that the medium was greatly improved by the addition of the meat extract. Subsequent investigations and a careful study of data showed that, just as with peptone alone, concentration played an important role. Extracts made with meat purchased at different times were found to be variable in composition and therefore could not be relied upon as yielding media of reliable uniformity and concentration with respect to the sulfur containing body or bodies. The media in all of the flasks containing beef extract remained yellow in color even after much hydrogen sulfide had been produced, and what little sediment was present was light yellow in color, while the 3.0% peptone, 0.5% potassium chloride media all turned turbid and green with dark green sediment and dark green floating cakes. This color reaction, joined to an intense fecal odor in the peptone media, constitutes a most valuable indication that the water being tested is seriously contaminated—indications which are usually lost when meat extract is present. It therefore appeared probable that the slight shortening of the period required for the first appearance of hydrogen sulfide was more than outweighed by the greater labor involved and by the loss of valuable diagnostic features.

Further study of the addition of meat broth was abandoned and a study of other possible sensitizing agencies was attempted.

The Influence of the Addition of Inorganic Salts.—Both Schardinger and Dunham recommended the addition of sodium chloride to their culture media. In fact, the addition of this salt to culture media has been quite uniformly practiced by bacteriologists. A careful search of the literature failed to disclose any data upon which a reliable opinion could be based as to the actual influence of this compound, nor evidence that the quantities employed were the best concentrations for the ends in view.

That some inorganic salts in the media were desirable, there was no question, for it had long before been found by one of us that media made up with water from the University water supply gave better results than when made from distilled waters so far as their applicability to the examination of at least the natural waters of the East Central United States. "Tap" water was therefore invariably employed in making up all media.

A study of the data yielded by the runs on the triangular diagrams already tried showed that the presence of sodium chloride was highly desirable.

The problem we next set ourselves was that of ascertaining whether sodium chloride was the best salt to use and the influence of varying con-

centrations of the different salts tried. A series of runs was made in which sodium sulfate, sodium nitrate, potassium chloride, magnesium chloride calcium chloride and ammonium chloride were, respectively, substituted for the sodium chloride.

Advantage was taken of the experience which had been gained in making the runs with sodium chloride, so that with a simple change in the arrangement of the diagram, it was possible to gain as much information from the use of one triangular diagram for each of these salts as had been obtained from running four separate diagrams with sodium chloride. The modified diagram read in a clock-wise direction in the following manner: 1.0 to 6.0% peptone; 5.0 to 0.0% *N* acid; 5.0 to 0.0% salt.

Starting with 1.0% peptone instead of 0.0% had the following advantages: It eliminated the 0.0% and 0.5% peptone solutions which were obviously worthless and it placed the 2.5%, 3.0% and 0.5% peptone solutions in that part of the diagram where the concentrations of salt and acidity had been found to be the best suited to good growth and hydrogen sulfide production.

In the previous runs the peptone had been weighed out for each concentration desired, but from this time on proportional amounts of 30% peptone solutions were used. This had the advantage of using the same identical solution of peptone for all of the inoculations and also of making the uninoculated media of larger volume, thereby better keeping all of the components in solution.

In all of these runs, the same check solutions were used in order to make them as nearly comparable as is possible whenever a fresh lot of sewage must be prepared for each run. These check solutions had the following compositions:

3.0% peptone	0.5% NaCl	1.5% <i>N</i> acid
3.5%	1.0%	1.5%
4.0%	1.5%	1.5%
3.0%	0.5%	1.02% (unadjusted)

After inoculation the results obtained with these checks were always similar in character.

The best results obtained with the other media containing the different inorganic salts were as follows:

Sodium chloride from 0.5 to 1.5%, more than 1.5% inhibiting; sodium sulfate from 0.5 to 1.5%, more than 1.5% inhibiting; potassium chloride from 0.5 to 3.0%, required more than 3% to inhibit; magnesium chloride from 0.5 to 1.0%, more than 2% inhibiting; calcium chloride from 0.5 to 2.0%, more than 2% inhibiting; ammonium chloride from 0.0 to 1.5%, more than 2% inhibiting.

The results of these runs seemed to indicate that potassium chloride was the best of the salts tried and that its addition to the media was decidedly advantageous. Nevertheless it was felt that more evidence was

essential before a reliable opinion could be formed and especially did it seem necessary to try as many different combinations as possible of basic and acid ions.

As the net results of some eight hundred runs already made the optimum conditions for the formation of hydrogen sulfide appeared to be in media having a peptone content of 3% and an acidity equivalent to from 1.0 to 1.5% normal acid. It was further found that, when this acidity was obtained from the unneutralized natural acidity of the peptone itself, the results appeared to be a little better than when obtained through the addition of an acid after neutralization with an alkali; in all such cases due allowance being of course made for the increased amount of inorganic salt thus introduced.

Although, as stated above, after a large amount of data had been collected, it was found that just as good and in most cases, better results were obtained when using an unadjusted 3% peptone medium, of which the reaction was always about 1.02% of normal acid; still in the early part of the work many experiments were tried to find the best reaction, and such bases as sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium oxide and magnesium oxide, and such acids as hydrochloric, sulfuric and nitric were used in adjusting the reaction to neutrality and also to various degrees of alkalinity and of acidity; in combination with various salts and also with no added inorganic salts.

As a result of the data collected in this connection in about five hundred inoculations, sodium hydroxide and potassium hydroxide proved to be the best alkalis to use, with little choice between them, due presumably to the very small amounts of basic elements which were introduced in adjusting the reactions. Hydrochloric acid proved to be the best of the acids. Nitric acid, as would naturally be expected, proved a positive detriment.

When peptone, potassium chloride, hydrochloric acid and potassium hydroxide were used in preparing the media, good results were obtained in some two hundred inoculations over a much wider field than with any other combination, as has already been noted; very good and quick results having been obtained with concentrations of acidity from 0.5% to 3.0%, inclusive, but the very best results were obtained when the acidity was from 1.0% to 1.5% with very little choice between these concentrations, the preference, if any, being for 1.5%. This preference, however, was so slight that it is outweighed by the greater simplicity of leaving the reaction unadjusted at about 1.02%, when 10 cc. of 30.0% peptone is used in 100 cc. of inoculated media.

The limits for the best concentrations of initial acidity for salts other than potassium chloride were found to be as follows, the titrations being made at 20°:

For NaCl,	from 0.0% to 2.0% <i>N</i> acid, best at 1.0%.
For Na ₂ SO ₄ ,	from 0.5% to 1.0% <i>N</i> acid, best at 0.5%.
For MgCl ₂ ,	from 0.5% to 1.5% <i>N</i> acid, best at 1.0%.
For CaCl ₂ ,	from 1.0% to 2.0% <i>N</i> acid, best at 1.5%.
For NH ₄ Cl,	from 1.0% to 1.5% <i>N</i> acid, best at 1.0%.
For K ₂ SO ₄ ,	from 0.5% to 2.0% <i>N</i> acid, best at 1.0%.

Having thus established the limits for acidity, runs were made in which the variable component was the inorganic salt. Concentrations of 0.5, 1.0 and 1.5% of the following salts were tried: NaCl, KCl, NH₄Cl, CaCl₂, MgCl₂, Na₂SO₄, K₂SO₄, (NH₄)₂SO₄, CaSO₄, MgSO₄, NaNO₃, KNO₃, NH₄NO₃, Ca(NO₃)₂, Mg(NO₃)₂. Two check flasks were also prepared containing no added salts.

The quickest and most abundant evolution of hydrogen sulfide was obtained in the media containing 0.5 and 1.0% KCl; 0.5 and 1.0% NaCl; 0.5% K₂SO₄; 0.5% CaSO₄; 1.0 and 1.5% MgSO₄. Again considerably the best results were obtained with KCl. The nitrates all showed a marked inhibiting action.

The five salts which were found to yield the best results were again tried, but in narrow limits of concentration, 0.25, 0.50, 0.75 and 1.0%. Again the best results were obtained with KCl in concentrations of 0.50 and 0.75%, with NaCl next in order. The areas upon the triangular diagram enclosing the best concentrations for these five salts are shown in Fig. 1.

Phosphates were not included in the tables on account of the fact that preliminary trials had already indicated that they were of little, if any, value and probably objectionable. It seemed nevertheless wise to study their effect separately. The following salts were tried, with the results indicated: H₂KPO₄ in concentrations in the finally inoculated media of from 0.0 to 1.5%. Peptone, 3%; acidity, 1.2%. All the solutions precipitated badly. When sterilized, those containing the highest proportions were practically turbid jellies before inoculation. None of the series developed hydrogen sulfide at the end of twenty-four hours and only a few at the end of seventy-two hours. Of the checks with KCl and NaCl the former gave the most rapid and abundant evolution of the gas.

The marked inhibiting effect of this salt is probably not necessarily due to the PO₄ ion, since the acidity from a 0.5% solution was found to be as high as 5.0% in terms of normal HCl. It is manifestly impossible to reduce this acidity to an equivalent of between 1 and 1.5% (the optimum acidity previously found), since the addition of an alkali would necessarily change the nature of the phosphate added. HNa₂PO₄, HK₂PO₄, HMgPO₄, HCaPO₄, H(NH₄)₂PO₄, HKNH₄PO₄, HNaNH₄PO₄, these salts were introduced into peptone solutions, unadjusted in amounts such that the inoculated media would contain 0.05, 0.15 and 0.25% of the basic element present in the salts. The added concentrations equivalent to the best

concentrations obtained with NaCl and KCl. These salts were thus calculated because it had been previously found that it was the potassium or sodium ions which appeared to be beneficial and that the acid ion, so far as Cl and SO_4 are concerned, had little effect. As checks, media containing KCl, K_2SO_4 and NaCl, respectively, were prepared with the K and Na ions present in the proportion 0.05, 0.15 and 0.25%. Other checks contained no added inorganic salt.

Fig. 1.

Upon sterilizing the phosphate containing media it was found that considerable hydrogen sulfide resulted from a chemical reaction between these salts and the peptone. The largest quantity of this chemically formed hydrogen sulfide appeared in media containing ammonium phosphate, and least in those containing magnesium phosphate.

None of the phosphate containing media gave as good results as the check flasks, while of these the media containing KCl prove to be superior to the others. Of the phosphated media those with HMgPO_4 were better than the others, then followed HNaKPO_4 , HK_2PO_4 , $\text{HNNH}_4\text{KPO}_4$, HNa_2PO_4 , HCaPO_4 , $\text{HNaNH}_4\text{PO}_4$, $\text{H}(\text{NH}_4)_2\text{PO}_4$.

The influence of tertiary (normal) phosphates was next investigated.

Media were prepared in which were introduced an amount of the basic ion equivalent to that found to have given the best results with KCl. In these runs the following salts were tried: $Mg_3(PO_4)_2$, $Ca_3(PO_4)_2$, NH_4MgPO_4 , Na_3PO_4 , K_3PO_4 , KNa_2PO_4 and NaK_2PO_4 . Check flasks with NaCl and KCl were inoculated and incubated at the same time.

In the media containing the phosphates only traces of hydrogen sulfide were formed, while all the checks developed large amounts.

In order that the influence of moderate amounts of phosphates should be studied in all its phases, media were next prepared in which in addition to the phosphates some received KCl, some NaCl and some K_2SO_4 . In these media only those containing HK_2PO_4 and KCl yielded appreciable traces of H_2S .

In all of the trials made with phosphates more than mere traces exerted a decidedly deleterious effect so far as the formation of hydrogen sulfide was concerned. As has already been stated part of this deleterious action is unquestionably due to too high an acidity. Although any addition of a compound which would reduce this acidity would necessarily change the character of the phosphates present and probably result in undesirable precipitates, it was decided to try the effect of the addition of a little finely divided $CaCO_3$. Moreover, it had been found that the final acidity to phenolphthalein was about 3.0% in those flasks of media in which much hydrogen sulfide was produced. This is doubtless due to the decomposition of the peptone into simpler amino, or other organic acids. The question naturally arose "Is it not possible that if some carbonate, which itself will not effect the reaction of the medium but which will tend to neutralize the acid products of bacterial activity, is introduced, that by so neutralizing these by-products it may materially aid the bacteria in producing hydrogen sulfide?" Calcium carbonate was first tried and was introduced to the amount of 0.5% in combination with the following:

0.25%	K	from KCl.	
0.25%	Na	from NaCl.	
0.25%	K	from K_2SO_4 .	
0.20%	K	from KCl and 0.05%	K from K_2HPO_4 .
0.15%	K	from KCl and 0.10%	K from K_2HPO_4 .
0.175%	K	from KCl and 0.075%	K from K_2PO_4 .
0.10%	K	from KCl and 0.15%	K from K_2PO_4 .
0.225%	K	from KCl and 0.025%	K from KH_2PO_4 .
0.20%	K	from KCl and 0.05%	Na from Na_2HPO_4 .
0.15%	K	from KCl and 0.10%	Na from Na_2HPO_4 .

There was a heavy sediment of insoluble calcium carbonate present throughout the run, which is an undesirable feature as it renders difficult, if not impossible, the formation of an opinion as to the character of the growth in the cultures.

As a result of the run, it was found that hydrogen sulfide was developed rapidly and in large amounts in just about as many flasks that contained no carbonate as was the case when the carbonate was present, leading to the conclusion that calcium carbonate has no beneficial influence on the production of hydrogen sulfide by bacteria.

Before abandoning the addition of carbonates it was deemed advisable to try a soluble carbonate and, as it was desired to use one which would least influence the reaction of the medium to phenolphthalein, sodium bicarbonate was chosen. The carbonate, in amount sufficient to give a concentration of 0.25% in the final inoculated medium, was used in combination with potassium chloride, sodium chloride and potassium sulfate, respectively, each of these salts being used in amounts to give 0.25% of the basic element present. As controls, flasks were prepared in triplicate containing 0.25% sodium bicarbonate without other salt; and with 0.25% of basic element furnished by potassium chloride, sodium chloride and by potassium sulfate without any sodium bicarbonate being present; and also three flasks containing no added salt.

As the result of the run, it was found that after sterilization and before inoculation, all of the flasks containing the added carbonate showed an undesirable, slight turbidity, and a marked deposit in the form of an adherent white film on the glass. This deposit, after thorough washing, was tested microchemically and proved to be calcium carbonate in the form of sphero-crystals of minute size. After the flasks had been inoculated and incubated, this film still persisted, being slightly augmented. A quantitative determination of the amount of calcium carbonate was made by titrating hot with 0.1 *N* hydrochloric acid, using ethyl orange as the indicator and it was found to be equivalent to 0.33%.

As far as the production of hydrogen sulfide was concerned, the results were very markedly against the use of sodium bicarbonate, as only one flask containing it showed even a trace of hydrogen sulfide produced. Moreover, when sodium bicarbonate was present, there was no greening of the solution or formation of dark green or grayish green sediment or cakes. The control flasks containing no sodium bicarbonate all produced hydrogen sulfide quickly and in large quantities, those containing potassium chloride giving the best results.

The reaction of those media not containing the carbonate when they showed a trace of hydrogen sulfide production, was about 0.70% normal acid on the average, using phenolphthalein as indicator, while the average reactions in the flasks which contained the sodium bicarbonate was 1.68% normal acid when showing a like amount of hydrogen sulfide. It may be concluded from these figures that it is erroneous to suppose that the presence of a carbonate would be beneficial by reason of the neutralizing effect which it would have upon the acid reacting substances

set free by the bacteria, thus removing from the field the by-products of bacterial life which it was thought might have an inhibiting influence on the development of the bacteria and the consequent production of hydrogen sulfide. Quite to the contrary, they proved that the bacteria must first neutralize this carbonate and then develop an acidity to phenolphthalein of 1.68% normal acid in the solution before they could begin breaking down the sulfur compounds of the peptone to yield hydrogen sulfide.

That hydrogen sulfide had not been produced and then held in solution as sodium sulfide, potassium sulfide, ferrous sulfide or calcium sulfide was demonstrated by the fact that no appreciable amounts of hydrogen sulfide could be detected upon acidifying a number of the cultures with hydrochloric acid.

During the course of the work, and more especially, while making titrations of some of the media after incubation, it was noted that there would be at times a very rapid evolution of hydrogen sulfide. This never occurred during the first twenty-four hours of incubation, and never, as far as observed, before the cultures had reached an acidity of 3.0%.

The evolution was so rapid at times that from one-quarter to one-third of the lead acetate papers in the tubes of the culture flasks would be blackened in the half hour, or so, that it took to titrate a group of fifteen or twenty cultures.

It was also noted that the same thing occurred in the incubator in short periods of time.

In order to try out the method with waters of a varying degree of pollution, an artificial sewage was prepared and plated on standard gelatin and on standard agar on lactose-litmus agar and also inoculated into fermentation tubes containing a 2.0% dextrose, 3.0% peptone, 0.5% potassium chloride medium.

After forty-eight hours of incubation, the gelatin plates showed 2800 colonies per cc. with 20 *B. coli communis* per cc., and the agar plates showed 200 colonies per cc. Of the fermentation tubes, those which had been inoculated with 1 cc. and with 0.1 cc. had one-half of the closed arms filled with gas, but those inoculated with 0.01 cc. and 0.001 cc. showed no signs of gas or growth.

For inoculating the media for the detection of hydrogen sulfide, dilutions of the sewage of 5 : 100, 10 : 100, 15 : 100, 20 : 100, 25 : 100, 30 : 100, 35 : 100, 40 : 100, 45 : 100, 50 : 100, 55 : 100, 60 : 100, 65 : 100, 70 : 100, 75 : 100, 80 : 100 and 85 : 100 were made with sterile tap water, and the flasks inoculated with these dilutions were incubated at from 37-38°.

There was, as would be expected, a gradual increase in the amounts of hydrogen sulfide produced and also in the rapidity with which it was produced as the concentration of the sewage was increased, but after eigh-

teen hours of incubation, the sewage which had been reduced to 85 : 100 had given an appreciable amount of hydrogen sulfide with a turning green of the medium and turbidity produced therein; and after thirty hours, much hydrogen sulfide had been produced with a dark green sediment and dark green floating cakes and an accumulation of gas at the top of the solution by even the 10 : 100 dilution; so it may be concluded that a positive test will be given in eighteen hours with a 90 cc. inoculation of a water which would show 2380 colonies per cc. on standard gelatin with 17 *B. coli* per cc.; 170 colonies on standard agar; and gas in dextrose, peptone, potassium chloride medium in fermentation tubes with a 1 cc. inoculation; while a positive test will be given in thirty hours with a water containing only about one-eighth of this amount of pollution, with a proportionate amount of time required by degrees of pollution between these extremes.

These figures are well within the limits of what will be found in sewage polluted waters and hence the method of detecting sewage pollution in a water by means of the hydrogen sulfide produced in the proposed medium by the putrefactive organisms, affords a very valuable method for augmenting and helping to interpret the data obtained by the chemical and bacteriological examinations of water samples.

In order to ascertain whether the feces of domestic animals contributed to contaminated waters bacteria which produce hydrogen sulfide, and in what relative amounts, the following experiments were made:

Into one liter of filtered water taken from the University service pipes there was introduced one loop full (0.02 g.) of the feces of the animal selected for study. Two series of culture flasks were prepared; in each case such that when ready for incubation a final volume of 100 cc. would be obtained containing 3% of Witte peptone, 0.5% potassium chloride, and would have an acidity a trifle over 1.0%. One series contained 90 cc. of culture media, the other 10 cc.; to the first series 10 cc. of the above described artificially contaminated water, and to the second 90 cc. were slowly added.

The results obtained can best be shown by Table I.

It will be seen that in every case hydrogen sulfide was eventually produced, but that in the case of the horses, cows, and sheep, the formation of this compound was slow, only traces being formed under thirty-six hours. Should further investigations substantiate these results their importance in the interpretation of the formation of much hydrogen sulfide in eighteen to twenty-four hours in the case of contaminated waters is not to be ignored.

It was thought essential that the investigation be extended to include a study of the action of pure cultures of the *B. coli* group. We had available thirty-four strains and substrains of organisms believed to be

B. coli which had been isolated from contaminated waters and sewage. These thirty-four strains were being employed in the study of carbohydrate media and were taken for use from a series of tubes of Harrison's esculin bile medium and from a series of fermentation tubes of Stokes' neutral red medium. This gave sixty-eight strains or substrains in all. These were inoculated in different bacterial dilutions into media whose final incubated concentrations were 3% peptone, 0.5% potassium chloride, acidity 1.02%. The results obtained were as follows:

- 18 hours, 1 culture had begun to develop hydrogen sulfide.
- 24 hours, 5 cultures had begun to develop hydrogen sulfide.
- 36 hours, 7 cultures developed H_2S , two of them moderate amounts.
- 48 hours, 9 cultures developed H_2S , two of them moderate amounts.
- 4 days, 26 cultures developed H_2S , four of them moderate amounts.
- 5 days, 43 cultures developed H_2S .
- 6 days, 47 cultures developed H_2S .
- 7 days, 49 cultures developed H_2S .
- 8 days, 52 cultures developed H_2S while 16 still showed none.

Although the authors do not consider that these results are conclusive, they do believe that taken in conjunction with the results of the runs made upon animal feces and those obtained from the examinations of contaminated waters, the production of large quantities of hydrogen sulfide in from eighteen to twenty-four hours is to be regarded as indicative of the presence of organisms other than *B. coli*¹ and there appears

¹ This is further substantiated by the work of Kendall, Day and Walker, THIS JOURNAL, 35, 1201 (1913), who find that the proteolytic activity of the *B. coli* group is relatively very low and slow.

to be good grounds for the use of the term "putrefactive bacteria" in water examinations as suggested by Schardinger and by Dunham.

Some evidence has also been obtained by the authors that in a mixed flora the formation of hydrogen sulfide is more rapid than from the isolated pure cultures.

If, therefore, tests for hydrogen sulfide production are to be made in water examinations the analyst must take into account the rate and the amount of this gas formed and the time of its first appearance.

In the course of the investigation a number of purely biochemic questions and problems arose upon which considerable time was spent such as, for example, the actual source of the hydrogen sulfide evolved, whether from firmly or loosely bound sulfur compounds, the actual quantity formed, the rate of formation, the influence of the presence of oxygen, etc. Some of these questions have already been alluded to, but although interesting, appear to have no direct bearing upon the sanitary significance of hydrogen sulfide production. The influence of oxygen, however, needs more than a passing word of comment. It is generally stated in most text-books of microbiology, that hydrogen sulfide is formed by a reducing reaction and therefore the most favorable conditions should be

those in which the growth of the organisms producing this reaction takes place in the presence of a minimum amount of oxygen. It is obvious that this has a direct bearing upon the testing for the presence of hydrogen sulfide forming bacteria in water and required investigations. The details of the work done need not be here discussed. In all the experiments made, quantitative analyses showed that more hydrogen sulfide was evolved and less sulfur remained in the peptone culture media if air was present than if it was absent when using a mixed sewage flora. The largest quantities of hydrogen sulfide were obtained when a slow current of sterile air was passed over the surface of the liquids in the culture flasks. Actually 100% more total sulfur was thus converted into hydrogen sulfide.

In routine testing, therefore, it is advantageous to use flasks with wide neck tubes of large diameter in order that a considerable surface shall be exposed to the air.

In the accompanying tables are given the results obtained with the tests for hydrogen sulfide production upon a number of different water samples. Although the data have been greatly abridged it is hoped that sufficient information has been given to enable the reader to properly grade the water samples. Since most natural waters usually exhibit a very marked seasonal change in their bacterial flora, the samples have been tabulated by months.

*From small plant using a patented "water sterilizer."

Summary of Results Obtained.

1. Irrespective of the inorganic salts present and of the acidity of the medium, a concentration of between 3 and 4% peptone in the final inoculated and incubated medium appears to be best for the most rapid and energetic production of hydrogen sulfide.

2. The addition of beef broth to simple peptone media slightly increases its sensitiveness, but not in proportion to the increased trouble and labor involved.

3. If sodium chloride is used, the quantity added must not be over 1.5%. Cultures to which this salt was added showed greater hydrogen sulfide production than those which contained none.

4. In 3% peptone media, the presence of from 0.5% to 1% of potassium chloride had a decidedly beneficial influence and led to quicker, better and far more uniform results than any other inorganic salt tried.

5. Positive results of hydrogen sulfide formation may be obtained in eighteen hours.

6. No hydrogen sulfide formation is obtainable in as long a period as seventy-two hours from natural waters which are truly "clean," while much is formed in from twelve to twenty-four hours with contaminated waters.

7. The feces of domestic animals contain bacteria which are capable of producing hydrogen sulfide from a simple peptone medium in as large amounts as is the case of the bacteria from human feces.

8. The large amounts of hydrogen sulfide *rapidly* produced by organisms of sewage appears to be not due primarily to members of the *B. coli* group.

9. This group of hydrogen sulfide producing bacteria do not actively ferment carbohydrates. Hence testing for their presence is a valuable aid supplementing tests for gas producers and is of especial value in polluted waters in which the *B. coli* group is absent.

10. Some evidence has been obtained which apparently indicates that hydrogen sulfide is more rapidly produced in waters containing a mixed bacterial flora than by the isolated pure cultures alone.

**ON THE ORIGIN OF THE HUMIN FORMED BY THE ACID
HYDROLYSIS OF PROTEINS.**

BY ROSS AIKEN GORTNER AND MORRIS J. BLISH.
Received April 10, 1915.

Introduction.

It is well known that, when proteins are subjected to hydrolysis by boiling acids, a blackening of the solution occurs, and that, when the boiling is continued for some time, black insoluble particles separate from solution. These compounds may be purified to a greater or a less degree by solution in alkali and reprecipitation by the addition of acid. They are, however, insoluble in all of the usual organic solvents and have never been obtained in crystalline form.

A very considerable amount of work has been done on these humins or "melanoidins" as Schmiedeberg¹ calls them. Schmiedeberg found that indol and skatol were formed in an alkali fusion and Samuley² by reduction obtained evidences of pyridine formation. Inasmuch as humin was not formed from proteins when the hydrolysis was carried out in the presence of stannous chloride, Samuley concludes that the formation of this dark-colored product is due to an oxidative process.

¹ *Arch. Exper. Path. u. Pharm.*, 39, 1-84 (1897).

² *Beitr. chem. Physiol. u. Path.*, 2, 355-88 (1902).

The question as to the nature of the mother substance from which these humins are formed is of the greatest importance. In a study of the nitrogen partition of proteins it often happens that several per cent. of the total nitrogen must be recorded as "humin nitrogen."¹ All of the other fractions obtained in the nitrogen partition can be correlated with known structures in the protein molecule, but the humin nitrogen has no known meaning other than that it varies in the different proteins.

The questions therefore remain: *Is the humin nitrogen derived from some known product of protein hydrolysis, or is it formed from some unknown constituent?* If it is formed from some known amino acid, can the reaction not be made quantitative and thus form a basis for the estimation of this amino acid?

In an attempt to answer the above questions we have performed a few experiments. We believe that we have answered the first question, and that we have secured some evidence which may help to answer the second question.

Osborne and Jones,² in a study of the hydrolysis products of proteins, state:

"There can be no doubt that this substance (humin) is a mixture of the secondary decomposition products formed from different constituents of the protein by the action of acids, for some of these, such as tryptophane, histidine, and carbohydrate, are known to yield colored products under such conditions. That the melanin originates chiefly from these substances is indicated by the fact that zein, which gives no reaction for tryptophane or carbohydrate and yields only a small amount of histidine, gives rise to the merest trace of humin when subjected to prolonged hydrolysis with acids."

Van Slyke³ later took up one phase of this problem in so far as tryptophane was concerned. He boiled 0.9 g. of tryptophane for 12 hours with 100 cc. of 20% hydrochloric acid and concentrated the solution *in vacuo*. He states:

"The solution was clear, free from insoluble matter, and but very slightly colored. . . . Tryptophane is responsible for none of the nitrogen estimated as ammonia, arginine, or melanin."

In view of Osborne's statement that zein yielded almost no humin and that tryptophane, was not present it seemed possible that Van Slyke might be in error as to his conclusions. It will be noted that he boiled the tryptophane alone, and not in the presence of other products of protein hydrolysis. It therefore seemed advisable to mix zein with definite amounts of tryptophane and to submit the mixture to acid hydrolysis and then secure the nitrogen partition on the hydrolyzed mixture.

¹ Owing to the similarity of this humin, both in color and solubility, to the naturally occurring melanins it is often referred to as "melanin" and its nitrogen as "melanin nitrogen." One of us (Gortner, 1912, *Science*, n. s. 36, 52-3) has already pointed out that other criteria of relationship should be secured before such a confusing terminology is adopted.

² *Am. J. Physiol.*, 26, 305-28 (1910).

³ *J. Biol. Chem.*, 10, 15-55 (1911).

Experimental.

The purity of the material was the first consideration. The zein employed in the following experiments was from a sample kindly given us by Professor Osborne. A Kjeldahl determination of nitrogen gave only 15.25%. This figure is lower than that given by Osborne,¹ 16.13%, but it is probable that our sample contained moisture, inasmuch as we did not deem it advisable to dry it with the aid of heat.

The tryptophane was prepared by the tryptic digestion of casein and subsequent separation by the method of Hopkins and Cole.² The product was repeatedly treated with bone-black and recrystallized from dilute alcohol. It was obtained in the form of almost colorless nacreous plates.

Nitrogen found, 14.06%; calc., 13.72%. Amino nitrogen (by van Slyke's apparatus): found, 6.81%; calc., 6.86%.

Histidine-di-hydrochloride was prepared from cattle blood.³

Amino nitrogen found, 6.07%; calc., 6.14%.

The dextrose was from a sample prepared by the U. S. Bureau of Standards and contained no nitrogen.

The method of analysis was as follows: to the protein + the added substances 50 cc. of hydrochloric acid, sp. gr. 1.115, was added, and the mixture was boiled under a reflux condenser for 48 hours. The acid was distilled off under diminished pressure and ammonia nitrogen determined according to Van Slyke⁴ by distilling with calcium hydroxide at 40–45° under a pressure of less than 30 mm.

The residue remaining in the distilling flask was filtered and the precipitate containing the humin washed with hot water to the absence of chlorides. A Kjeldahl nitrogen determination on the filter and its contents gave the humin nitrogen.

The filtrate from the humin was concentrated to about 100 cc., 10 cc. of concentrated hydrochloric acid and 7.5 g. of phosphotungstic acid were added and the mixture heated for a few minutes on a water bath and then allowed to stand in a cool place for 48 hours. The phosphotungstates of the bases were then filtered off and washed as described by Van Slyke.

The entire precipitate was used for a Kjeldahl nitrogen determination.

The results of the analyses may be found in the accompanying table.

When zein was hydrolyzed alone the solution did not become intensely black but when tryptophane had been added the black color developed sooner and was much more intense. Besides the black color there was a distinct reddish color in the hydrolysate from the zein + tryptophane, the filtrate from the humin, as well as from the phosphotungstate precipitate, being likewise darker in the case of added tryptophane.

In the ammonia determinations when tryptophane had been added in large amount there was an intense frothing toward the end of the distillation, after the alcohol had largely distilled off. In no other material have we obtained such a result.

¹ Osborne gives the nitrogen partition of zein as ammonia N 18.4%, human N 0.99%, basic N 3.0%, nonbasic N 77.5%. The amount of human nitrogen varied in Osborne's determinations from 0.31% to 1.48% in different determinations. See Osborne and Harris, *THIS JOURNAL*, 25, 323 (1903). Our higher percentage of ammonia nitrogen is probably due to a longer hydrolysis.

Discussion.

It will be seen from the table that Van Slyke's conclusion that tryptophane nitrogen is not transformed into humin nitrogen holds true only when tryptophane is boiled alone. When, however, tryptophane is added to a protein a very considerable portion of the tryptophane nitrogen passes into the humin fraction (approx. 0.0070 g. when tryptophane is added to 1 g. of zein). The remainder of the tryptophane nitrogen is distributed between the bases and the filtrate from the bases. In no case does added tryptophane cause an increase in the ammonia nitrogen.

From Experiments 2 and 3 it will be seen that the formation of humin from tryptophane had reached a maximum when 0.125 g. of tryptophane had been added, since no additional humin nitrogen was obtained when 0.25 g. of the amino acid was added. This observation shows, as does the fact that no humin is formed from the pure tryptophane, that the reaction involves not only tryptophane but also some other product of hydrolysis. We therefore boiled dextrose + tryptophane, zein + dextrose and zein + dextrose + tryptophane and found that when tryptophane was heated in the presence of a carbohydrate practically 90% of the tryptophane nitrogen remained in the humin fraction. It seems very possible that with a slightly longer hydrolysis, or with the altering of some of the conditions of hydrolysis that the reaction might have been made quantitative. It is, however, nearly enough quantitative for our present purpose, and we did not have sufficient material to work out the ideal conditions of the reaction.

It is well known that when carbohydrates are boiled with mineral acids a small amount of furfural is formed and it seems highly probable that the reaction involved in humin formation is a condensation of tryptophane with an aldehyde. Miss Homer¹ has prepared condensation products of tryptophane with various aldehydes and states:

"Indol derivatives by virtue of the —NH group in the nucleus will react with formaldehyde and trioxymethylene in the presence of a condensing agent to form substances of intense color and marked insolubility in ordinary solvents other than concentrated mineral acids."

When, however, the condensation takes place on the aliphatic —NH_2 group, colorless, crystalline compounds are formed.

From our experiments with zein + dextrose it appears certain that the humin nitrogen is not a result of an absorption phenomenon. The hydrolysate in this instance was jet-black and full of suspended flecks of solid humin formed by the decomposition of the carbohydrate, while the humin nitrogen was but slightly in excess of the experimental error, considering the relatively large amount of humin and lime to be washed free from nitrogen.

The fact that the hydrolysis of zein does give rise to some humin, and

¹ *Biochem. J.*, 7, 101-15 (1913).

that there is a slight increase in the humin nitrogen due to the addition of glucose may, however, be due to the presence of tryptophane in the zein molecule in such small quantity that it is difficult to detect with the color tests. For a long time gliadin was supposed to contain no lysine, but Van Slyke¹ found it to be present in this protein, and his findings were later confirmed by Osborne and Leavenworth.²

Osborne and Harris³ state:

"Whether any of the above proteins wholly lack tryptophane could not be determined, as we were able to get a very slight reaction with a relatively large quantity of zein by cautiously adding the sulfuric acid up to one-half the volume of the glyoxylic acid. The color thus produced was, at the most, very slight and transitory."

Mann⁴ in a discussion of the humin formed from carbohydrates states:

"If in addition to the carbohydrate, ammonia or other nitrogenous substances are in solution, then the humins combine with the ammonia and thereby become nitrogenous."

We do not believe that this reaction, if it takes place at all, can be any great factor in the formation of the humin nitrogen of protein hydrolysis, for our analyses show a variation in the amount of ammonia nitrogen which is certainly not much greater than the experimental error. Thus we have 0.0154 g. of ammonia *N* from 0.5 g. of zein hydrolyzed in the presence of 0.5 g. of dextrose, and 0.0316 g. of ammonia *N* from 1 g. zein when hydrolyzed alone, a difference of only 0.0008 gram *N* calculated on a 1 g. basis. Again there is a loss of only 0.0001 g. ammonia *N* when 1 g. of gliadin was hydrolyzed in the presence of 2 g. of dextrose. In this instance there is an increase in the humin nitrogen and it is of interest to note that this increase comes from the bases and the filtrate from the bases in the ratio of approximately 4:6, almost the identical ratio (38.7:61.3) which Van Slyke⁵ finds for the distribution of tryptophane between the bases and the filtrate from the bases.

Experiment 4 indicates that histidine has no part in the formation of humin nitrogen, since there was no increase in color over that produced when the zein was hydrolyzed alone, and there was no significant increase in the humin nitrogen, the histidine nitrogen being quantitatively recovered in the bases.

We believe, therefore, that we have shown that, in a large measure at least, the humin nitrogen represents a portion of the tryptophane nitrogen, and that if sufficient carbohydrate be present the humin nitrogen can be regarded as an almost quantitative determination of the tryptophane nitrogen. What reaction takes place when no carbohydrate is present

⁵ *Loc. cit.*

and humin nitrogen is formed, as in Experiments 2 and 3, we are unable to state. Various possibilities present themselves, such as the oxidation of tryptophane itself to indol aldehyde, which would in turn unite with more tryptophane to form a deeply colored, insoluble compound;¹ or possibly traces of some other amino acid may be oxidized to the corresponding aldehyde. Isham and Vail² have recently shown that ether is readily oxidized to aldehyde by atmospheric oxygen at 110°. A contamination of the protein with a small amount of ether, or of the aldehyde formed from the ether during extraction, would account for this humin formation, if tryptophane were present. We regret that lack of material prevented our trying further experiments in this direction.

Summary.

1. We have shown that in all probability the humin nitrogen of protein hydrolysis has its origin in the tryptophane nucleus.

2. When tryptophane is boiled with mineral acids in pure solution no humin is formed, but when tryptophane is added to a protein, or when carbohydrates are present, an abundance of humin is formed. This humin contains nitrogen which can belong to no amino acid other than tryptophane.

3. The reaction involved in humin formation is probably the condensation of an aldehyde with the —NH group of the tryptophane nucleus.

4. When an abundance of carbohydrate is present nearly 90% of the tryptophane nitrogen remains in the humin nitrogen fraction.

It is suggested that this property be utilized to determine the approximate quantity of tryptophane in proteins.

5. The addition of histidine causes no increase of humin nitrogen, the histidine being quantitatively recovered in the bases. Histidine, therefore, can be eliminated as a factor in the formation of humin nitrogen.

6. Adsorption of ammonia by non-nitrogenous humins formed from carbohydrates is not an important factor in the formation of humin nitrogen.

7. These findings allow us to assign a distinct value to humin nitrogen determinations.

ST. PAUL, MINN.

NOTE.

On Rapid Organic Combustions.—The use of cerium dioxide as contact substance for rapid organic combustions, in place of the more expensive platinum of Dennstedt, has recently been recommended.³ In trying out the method in this laboratory, it has been found that it is not entirely

¹ Homer, *Biochem. J.*, 7, 116 (1913).

² *THIS JOURNAL*, 37, 902 (1915).

³ Julius Bekk, *Ber.*, 46, 2574 (1913).

satisfactory in the hands of beginners. The reasons for this are two: first, part of the substance is carried through the tube unburned if the stream of oxygen is even a little too slow or, on the other hand, so rapid that the vapor of the substance mixed with oxygen is carried too quickly past the catalyst; second, after the asbestos impregnated with cerium dioxide has been used several times, it crumbles to a fine powder and a slight amount of this may be carried into the absorption apparatus if the stream of oxygen is very rapid.

These difficulties can be overcome by the following modification of the method: Instead of the large quantity of asbestos, impregnated with cerium dioxide, recommended by Bekk, a layer of cerium dioxide asbestos only 3 cm. long is placed in the center of a combustion tube of the usual length. Following this is a 20 cm. layer of cupric oxide in wire form, held in place by a cupric oxide gauze plug. The cupric oxide furnishes oxygen for the burning substance in case the supply of gaseous oxygen is insufficient, or if the vapor of the substance has been carried too fast over the catalyst, and prevents the dust of the cerium dioxide from being carried forward in the tube.

In the back end of the tube is the usual 10 cm. cupric oxide gauze spiral. This serves to break the stream of oxygen and does away with the necessity for the "double oxygen" apparatus of Dennstedt and the glass tube surrounding the boat recommended by Dennstedt and by Bekk.

The absorption apparatus described by Dennstedt in an early paper¹ has been found perfectly satisfactory. It consists of the usual calcium chloride U-tube and two 12 cm. U-tubes with ground glass stoppers.² The one next the calcium chloride tube is filled with soda-lime, the other contains solid potash with a 2.5 cm. upper layer of fused calcium chloride in each arm. The soda-lime tube can be used for two combustions; the potash tube almost indefinitely.

The procedure differs from that of the usual method in the following points: The combustion boat should be placed not more than 2 cm. from the cerium dioxide asbestos. This is important, as explosive mixtures of gases form if there is any considerable space in which the vapor of the substance and oxygen can mix before they come in contact with the catalyst. As soon as the front end of the tube is hot and the boat in place, a rapid stream of oxygen is turned on and the forward burners are lighted to within about 8 cm. of the boat. If the substance to be burned is very volatile, the stream of oxygen should be less rapid and the cerium dioxide asbestos more cautiously heated by first placing above it hot tiles from the forward

¹ "Entwicklung der Organischen Elementaranalyse." Sammlung chemischer und chemisch-technischer Vorträge, Ahrens, Stuttgart, 1899, p. 105.

² Leakage at the stoppers can be prevented by using the rubber lubricant recommended by Richards (Carnegie Institution of Washington, Publication No. 56, 16 (1906)).

end of the tube. As the vapor of the substance and oxygen come in contact with*the hot cerium dioxide, the latter glows brightly. The soda-lime tube becomes very hot from the absorption of carbon dioxide. When the glowing has ceased and the *soda-lime tube cools*, the combustion is ended.

The following results have been obtained:

Succinic Acid, 0.2028 g.		Salicylic Acid, 0.1975 g.	
	Time, 17 minutes.		Time, 11 minutes.
Calc. for $C_4H_6O_4$:	C, 40.66 H, 5.08	Calc. for $C_7H_6O_3$:	C, 60.85 H, 4.34
Found:	C, 40.57 H, 5.12	Found:	C, 60.66 H, 4.37
Benzoic Acid, 0.1749 g.		Naphthalene, 0.1888 g.	
	Time, 9 minutes.		Time, 13 minutes.
Calc. for $C_7H_6O_2$:	C, 68.85 H, 4.91	Calc. for $C_{10}H_8$:	C, 93.75 H, 6.25
Found:	C, 68.67 H, 5.10	Found:	C, 93.61 H, 6.31
Sugar, 0.2080 g.		Methyl Dibenzylidene Phenyl Glutarate, 0.1585 g.	
	Time, 18 minutes.		Time, 14 minutes.
Calc. for $C_{13}H_{20}O_{11}$:	C, 42.10 H, 6.43	Calc. for $C_{27}H_{30}O_4$:	C, 78.64 H, 5.82
Found:	C, 42.17 H, 6.44	Found:	C, 78.80 H, 6.05

Aside from the great saving of time, the method is satisfactory for beginners, in that it is free from some of the usual sources of difficulty; water does not draw back in the tube nor collect around the forward stopper because of the rapid stream of oxygen, and there is no danger of burning the stoppers, since it is not necessary to heat the tube near the ends.

A disadvantage is that the method cannot be used for the simultaneous determination of carbon, hydrogen and halogens as can the Bekk method where no cupric oxide is used. It is available however, for the analysis of compounds containing nitrogen if a longer empty space is left at the forward end of the tube for the boats of lead peroxide¹ and care is taken to keep that end of the tube fairly cool. The combustion should be run a little less rapidly than with carbon and hydrogen alone.

The following results have been obtained:

Acetamid, 0.1707 g.		Acetanilid, 0.1788 g.	
	Time, 28 minutes.		Time, 24 minutes.
Calc. for C_8H_9NO :	C, 40.67 H, 8.47	Calc. for C_8H_9NO :	C, 71.11 H, 6.66
Found:	C, 40.91 H, 8.42	Found:	C, 71.01 H, 6.70
Propyl Cyancinnamylideneacetate, 0.1591 g.			
	Time, 25 minutes.		
Calc. for $C_{18}H_{19}NO_3$:	C, 74.68 H, 6.22		
Found:	C, 74.46 H, 6.16

Pp. 74.

This series of six sets of tables is made up of data extracted from Volume 3 of the **Annual Tables of Physical Constants and Numerical Data** and is issued in this form in order that selected classes of data may be made available at a lower price and in a more convenient form. The books are issued by the University of Chicago press and are listed at the following prices: *a*, *b*, and *f*, 10 francs each; *c*, 2 fr. 50; *d* and *e*, 4 fr. each.

E. W. WASHBURN.

Handbuch der Mineralchemie. DOBLTER, *et al.* Bd. II. No. 7 (Bogen 11-20). Theodor Steinkopff, Dresden and Leipzig. Price, M. 6.50.

In scanning these pages the reader is struck by the great amount of space devoted to the *formulae* of mineral substances. The remarkable fruitfulness of this form of study in the organic field has inevitably affected the development of mineral chemistry. To disparage work of this character would serve only to define the interests of the critic, but at least we may say that the results have not been at all commensurate with those in organic chemistry and that speculation so far from the facts as much of this is cannot be expected to advance science materially. It seems to the reviewer that much of the matter on this subject and mineralchemie might be condensed to advantage.

There are several subjects in this issue of Mineralchemie of more than average interest, notably the nephélite group of mineral and the ultra-marines.

E. T. ALLEN.

been shown in every line, and particularly in the places where the literature is confused and most authors blunder more or less seriously. Part II (67 pp.) deals with the nonvalent group of elements. It gives a condensed, but lucid and very complete summary of all that is known about the inert gases. Judging from the initial volume, the whole book will be an indispensable work of reference that should be on the desk of every chemist.
